Preface

In issuing its forty-third annual volume of TRANSACTIONS, the American Institute of Electrical Engineers has published in chronological order the papers and discussions presented at the four conventions and two regional meetings held under its auspices during the year, 1924. The articles have all been printed in the JOURNAL either in full or in abridged form; they are published here in entirety with the discussions for each special group immediately following. Owing to lack of space several articles of importance but of somewhat transitory interest have been omitted. These will be found listed on page 1369. The reports of the Technical Committees at the Annual Convention are included; also the Board of Director's annual report for the fiscal year ending April 30, 1924, and lists of the several officers, committeemen, Section and Branch officers for the corresponding period, appear toward the end of the volume. The index contained herein is a greatly improved feature, the subjects being classified under general headings chosen with regard to the information contained in the papers. In many instances the subjects are also cross-referenced.

Superpower Transmission

Economies and Limitations of the Transmission System of Extraordinary Length

BY PERCY H. THOMAS
Fellow, A. I. E. E.
Consulting Engineer, New York, N. Y.

Review of the Subject.—*This paper is a study of the transmission of very large blocks of power for extraordinary distances and has for its purpose the bringing out of the major operating characteristics of such a system, the characteristics which it possesses which are different from those of shorter transmissions and the duties imposed upon generators, transformers, synchronous condensers, switches, etc., primarily as affecting their design. The paper defines a superpower transmission line as a line of great length in which the charging kilovolt-amperes per mile of length is of the same order of magnitude as the reactive kilovolt-amperes developed by the full-load line current passing through the reactance of the line and in which the resistance is small relative to the reactance.*

Such a line is adapted for economical transmission only for a fairly definite amount of load and any great increase or decrease below this point leads to poor economy or unstability. Since, however, the load appropriate to a given line depends upon the voltage, an appropriate line can be laid out for any reasonable amount of power to be transmitted.

In order to secure a definite set of conditions to serve as a specification for determining the performance of generators, transformers etc., all applying consistently to the same system, a typical hypothethical transmission has been assumed, namely, a delivery of 400,000 kw. over a distance of 500 miles over four circuits 220,000-volt at each end.

The characteristics of this line are worked out showing the efficiency, condenser capacity required, data on circuit breaker arrangements, protective relays connection to receiving network, provision for spare parts, switching of units and ratings of various apparatus.

It is shown that such a system is very sensitive to the receiving end voltage; when this voltage drops there will be a tendency for the generators to run away if the system is not properly laid out.

In addition a discussion is given of the effects of various prescribed values for the terminal voltage between 220,000 and 245,000 to show the effect of increasing the voltage 10 per cent, of maintaining the generating end 10 per cent higher than the receiving end and also of stabilizing the middle point with synchronous condensers.

The typical hypothetical case chosen shows one layout, it being recognized that other layouts may be chosen. This particular layout is operated without any high-tension switching of live lines. The layout is intended to relieve the duty on circuit breakers and as a matter of fact no breaker can be called upon to interrupt a short circuit of more than ¾ of a million kilovolt-amperes; this is a very favorable condition and is secured without materially limiting the equalization of the load. The layout connects with the assumed distribution net at a considerable number of points and no large portion of the total delivered power can be concentrated at any one point; this serves to secure a very intimate connection between the network and the transmission, and at the same time prevents any one breakdown, however, complete, from materially disturbing the major portion of the transmission system.

INTRODUCTORY

THE art of electric power transmission is just entering upon another stage of development, and this a most important one. The period characterized by the general adoption of the 100,000-volt line has been most fruitful. The coming period with lines of voltages in the neighborhood of 225,000 volts and of very great length will be marked by important changes from the old apparatus and the old practise. Considering electrical problems, the 100,000-volt line, to the usual designer, is a problem in drop, to keep the voltage at the substation within reasonable range of the generator voltage with varying load, to secure a good efficiency, and to watch the charging current to see that the light load conditions do not cause an unduly high potential or overload a generator. There is also the problem of insulation, but this is constituted largely of selecting a good make of insulator and watching the manufacturer, also the maintenance of the insulators in good condition during operation.

For the superline of the coming period, the problem of the designer is much more complex. The matter of power factor instead of being merely one of the underlying factors in drop calculations, becomes the all-important feature of the line, serving as the only feasible means of controlling voltage and efficiency. It must be completely under control of the operator. Instead of establishing the voltage at one end of the line as a means of controlling the voltage at the other end, the voltage in the superline must be controlled at both ends and care taken to keep track of the voltage at the center of the line to see that it does not rise too high. Instead of adding reactance to keep down the heavy current in short circuits, as in the 100,000-volt system, the designer will find that with the superline the short-circuit current may not greatly exceed full-load current and that the securing of enough current over the line to insure the holding of the machines on the two ends of the line in synchronism at times of disturbance becomes a serious problem. Other features bring forward novel conditions.

It is the purpose of this paper to discuss the nature of the super transmission system, bringing out some of the peculiarities characteristic of it and to offer some numerical data to give some measures of its economies and limitations. In order to give concreteness to the discussion, a typical but hypothetical example is chosen and the layout worked out in enough detail to develop the novel problems involved and suggest solutions. A sufficient number of calculations are made to determine

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

the performance of the system under all conditions normal and abnormal.

Capacity

Unlike the ordinary 100,000-volt transmission line, chosen for efficiency or regulation, the superline has a substantially definite kilowatt capacity which cannot be practically exceeded. In this use of the term, a "Superline" is to be taken as a long line in which the kilovolt-ampere of charging current is numerically of the same order as the kilovolt-ampere developed by the load current in the reactance of the line, and in which the resistance is small in comparison with the reactance.

The dominating role of this relationship of charging kilovolt-ampere to line reactance kilovolt-ampere, set forth in a paper of my own in 1909, has been well expounded by Mr. Harold Goodwin, Jr.[1]

Very briefly its significance may be stated as follows: Since the resistance component of line drop is proportional only to the resistance, which can be made as small as desired, while the reactive component is proportional to the reactance of the line, which is substantially fixed beyond the control of the designer, the kilowatt capacity of a line cannot be made to exceed the fixed limitation imposed by the reactance unless some additional factor be introduced. The reactance considered alone would greatly reduce the capacity of superlines below that actually available. It would largely eliminate any advantage in the reduction of resistance beyond a certain point.

This situation may be avoided, however, by proper control of the line charging current; which fact may be explained as follows: For any definite section of line the charging current represents a certain kilovolt-ampere value, having a phase 90 deg. in advance of the voltage ($\frac{1}{2}\,C\,V^2$). Similarly in that section of line there is a kilovolt-ampere value due to the current passing through the line reactance ($\frac{1}{2}\,I^2\,X$) which is 90 deg. behind the line current in phase. If now the power factor is unity and the current and voltage are in phase with each other, the phases of these two kilovolt-ampere values will be exactly opposite and if equal they will neutralize each other as far as the rest of the system is concerned. This will leave the resistance as the only quantity causing line drop. That is, by the proper correlating of power factor, line voltage, and load current, the voltage drop may be made to be that due to resistance only. To put it another way. In an excited open-circuited high-voltage line the charging current causes a rise of potential along the line toward the open end. On the other hand, in a loaded line without charging current, the line reactance causes a drop in voltage toward the loaded end. If these two tendencies be made numerically equal by properly choosing voltage and load and be made opposite by establishing unity power factor, the tendency to rise and the tendency to drop will neutralize, leaving the resistance to determine the actual line drop.

1. Qualitative Analysis of Transmission Lines, A. I. E. E. JOURNAL, January 1923.

It goes without saying that in an actual line, some departure must be made from these ideal conditions, and it is the function of the designer of the superpower line to so control these departures as to secure the best compromise between efficiency, regulation, operating quality, etc. and cost.

For carrying large loads obviously a high voltage is necessary, but for any given load a particular voltage is most suitable. In this particular relation frequency plays little part, since the neutralization described above is not affected by change of frequency. Neither does the length enter as a factor theoretically, except to the extent that the consequences of a departure from ideal conditions will have a smaller effect with a short line and for the effect of ohmic resistance. Similarly frequency is of great importance when the ideal neutralization is not secured, as occurs with light load short circuits, etc.

Having chosen the load to be carried and the proper voltage, or having chosen the voltage and the proper load corresponding, the resistance can be chosen to determine the energy loss or efficiency. The designer does not, however, have a free hand to vary the resistance, as it is the resistance that is one of the potent factors tending to upset the balance of reactance and capacity, and is thus closely linked with power factor. The formula given by Goodwin, viz., kv-a. = $e^2/.04$ Where "e" is the line kilovolts gives a good idea of the equalizing capacity corresponding to various voltages.

In my paper of 1909 above referred to, I have suggested certain methods of increasing the load capacity of a super line without increasing the voltage, such as using divided conductors. While I see no reason why this method is not perfectly feasible, so far no occasion seems to have arisen in which there is not some other method less novel which would serve to secure the necessary capacity. This method is not a part of the subject matter of the present paper and will not be further touched on.

Regulation

In the superpower line, voltage regulation is naturally a most important function and fortunately, thanks to the competent means available, may be very satisfactorily controlled.

In the first place it will be necessary to have control of the voltage at both ends of the line independently. Since synchronous type apparatus is used on both ends and since the voltage drop is extremely sensitive to power factor, no single setting of the field current on the synchronous machines on either end of the line would serve to secure satisfactory voltage at that point.

While not theoretically necessary, usually the most satisfactory regime for regulation will be to maintain voltage constant automatically at each end at whatever voltage may be most suitable at that end. The

voltage, if necessary, may even be somewhat higher at the receiving end without serious additional expense. To arrive at the nature of voltage regulation in a superline, we may assume that the line is carrying full load with the capacity kilovolt-amperes and the reactance kilovolt-amperes equalized. If now a small leading current be made to flow from the generating to the receiving end, this leading current passing through the line reactance will cause a tendency for a rise in potential toward the receiving end. By choosing the amount of this leading current the amount of rise can be controlled. The effect of the resistance is of course, such as to cause a drop due to this leading current, but since in the superline the reactance is much greater than the resistance, and since the resistance component of the leading current voltage effect will be out of phase with the leading current, it will be substantially negligible; conversely with a lagging current.

To put this in another way. If we establish a voltage at each end of the line corresponding to the condition corresponding to the leading current just described, the line currents must flow as described to produce these voltages. Since any constant potential synchronous machine has a definite voltage and will supply, within its capacity, any current to its circuit required to maintain its voltage, such machines are entirely suitable for superpower line regulation especially in connection with field regulators.

Connected to the receiving end of such a line, a synchronous machine will tend to supply whatever current the transmission line takes at that voltage and at the same time to supply the load current required by the system connected to the line. The synchronous condenser actually takes, however, only the difference between these currents, which may be large or small and positive or negative as the case may be. In case the power factor of the load is low and the power factor required by the line close to unity, there will be a large out-of-phase kilovolt-amperes to be supplied by the synchronous machine at the receiving end and this is the most salient fact about the use of the synchronous machines, usually synchronous condensers.

Thus it is clear that any fixed voltage at either end may be easily maintained and for any load up to full load if proper synchronous condensers are available. This voltage will be held fixed by automatic regulators.

Equation of Typical Line

To illustrate numerically where these fundamental principals lead, I have assumed a superline of rather an ambitious capacity, but still an entirely feasible one for our present day knowledge, and have made the necessary calculations.

This line is 500 miles long, this being taken as an exceptionally long line and is insulated for 250,000 volts, 60 cycles. Its conductor has an outside diameter of 1 3/32 in. and its resistance is 0.015 ohms per thousand feet of cable, or the equivalent of 700,000 cm. The mean conductor spacing is 15.8 feet[2].

Performance of Line

Fig. 1 shows the efficiencies of this line for loads from about 10,000 kw. delivered up to 150,000 kw. on the following four assumptions as to terminal voltage conditions:

(A) that a voltage of 220,000 is maintained at each end.

(B) that a voltage of 220,000 is maintained at each end and that 220,000 volts is also maintained at the middle.

(C) that voltage of 220,000, is maintained steady at the receiving end and of 245,000 volts at the generator end.

(D) that the voltage is maintained constant at both ends at 245,000 volts.

Fig. 1 also shows the power factor at both ends for each of the four assumptions and the voltage at the middle of the line for (A) and (C).

These four cases are chosen to illustrate the relative effect on efficiencies and power factors of these variations of voltage.

As a matter of interest the efficiency of one half the length of this line, giving a transmission of 250 miles is added in Fig. 1 with 220,000 volts maintained on both ends.

Method (*A*) shows the same voltage at both ends, viz. 220,000 with no limitations on the voltage at the middle of the line, which will rise above the ends on light loads. Method (*B*) the same voltage at both ends and in addition the voltage at the middle stabilized at the same value. This can be accomplished by placing a step-down station at the center of the line with synchronous machines of some sort provided with automatic means of fixing the voltage.

The effect of this middle station as far as voltage conditions go is to divide the line into two lines, each of half the total length. Since the voltage at the middle of the line is maintained constant either half of the line may be considered as a line independent of the other half, except that the energy delivered by the receiving end of the first line must equal the energy delivered to the second line (plus the energy loss in the synchronous

2. As a matter of information it may be noted that the "Equations" of this line are

$$V \sin \varphi = .532\, S \sin (\theta + 5° 4') + 606.5\, Q \operatorname{Sin} 84° 58'$$
$$I \operatorname{Sin} \psi = .532\, Q \operatorname{Sin} 5° 4' - 0.00119\, S \operatorname{Sin} (\theta - 88° 56')$$

Where
V = Generator voltage
S = Load voltage
I = Generator current
Q = Load current
θ = Angle of advance of S over Q
$\operatorname{Cos} \theta$ = Power factor of load
φ = Phase of V
ψ = Phase of I
$\operatorname{Cos} (\varphi - \psi)$ = Power factor of generator current

From these equations any desired set of terminal conditions may be calculated.

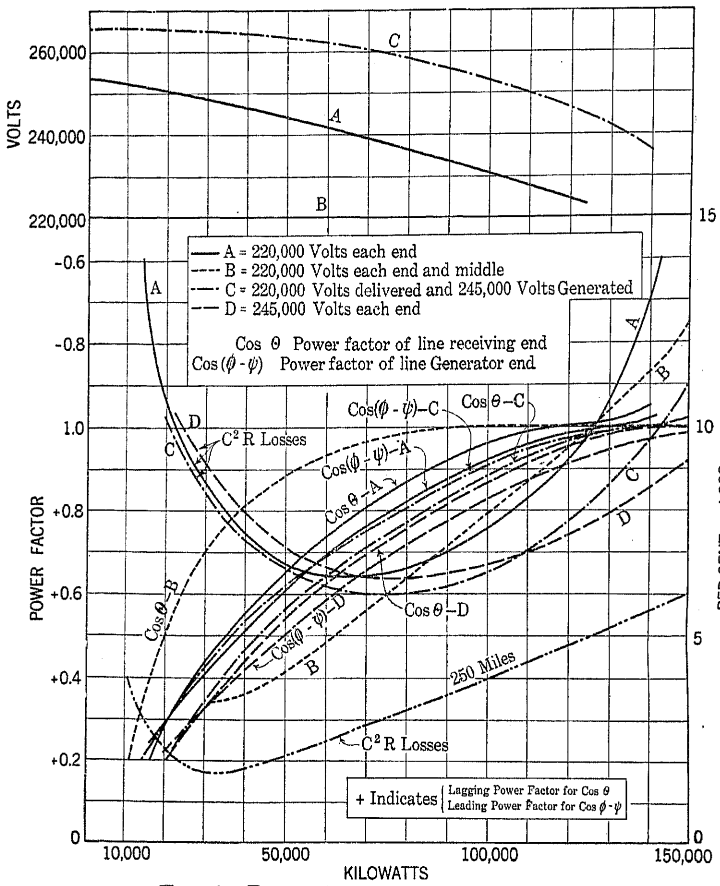

Fig. 1—Power Factor and Line Loss

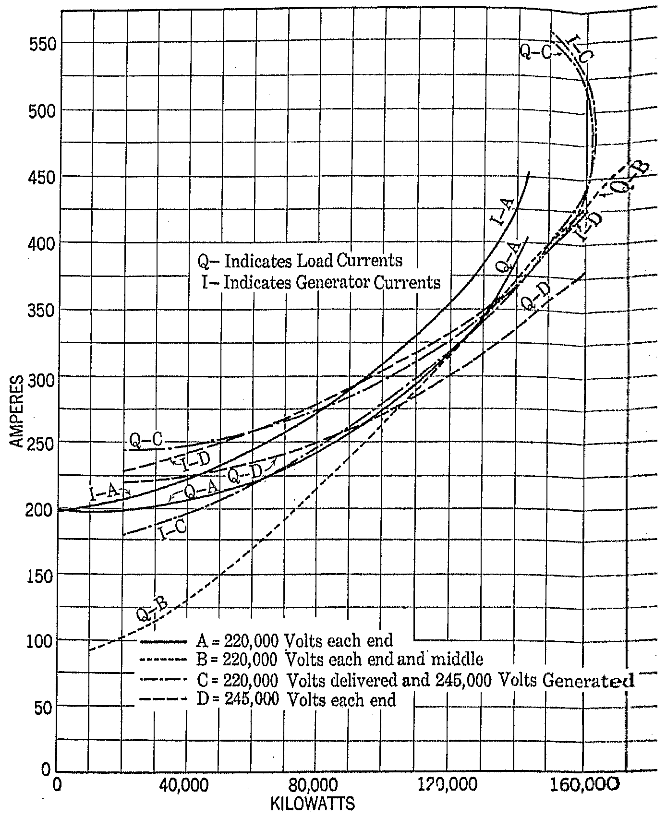

Fig. 2—Generator Currents

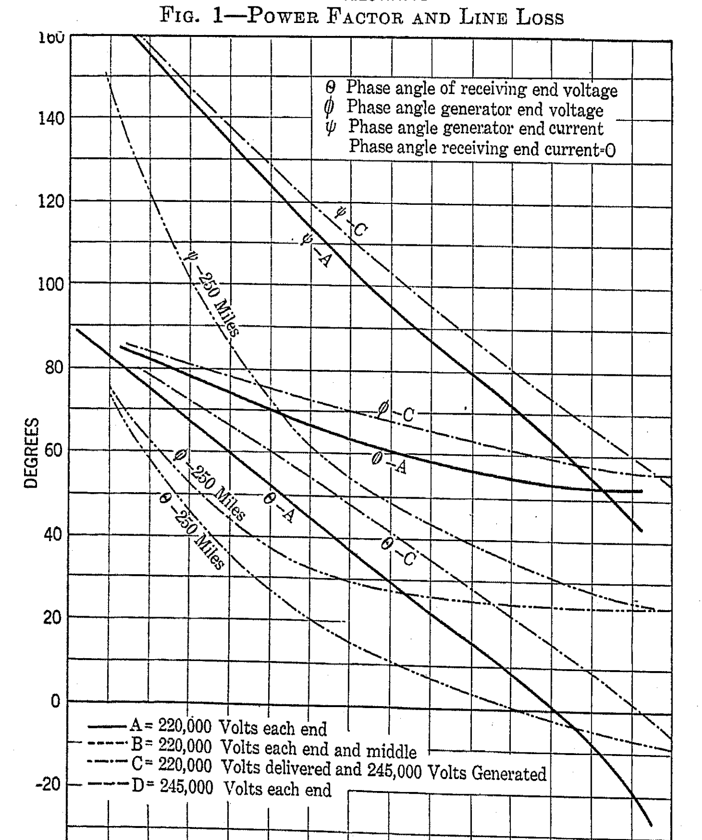

Fig. 3—Phase Position of Voltages and Currents Phase of Load Current Assumed as O

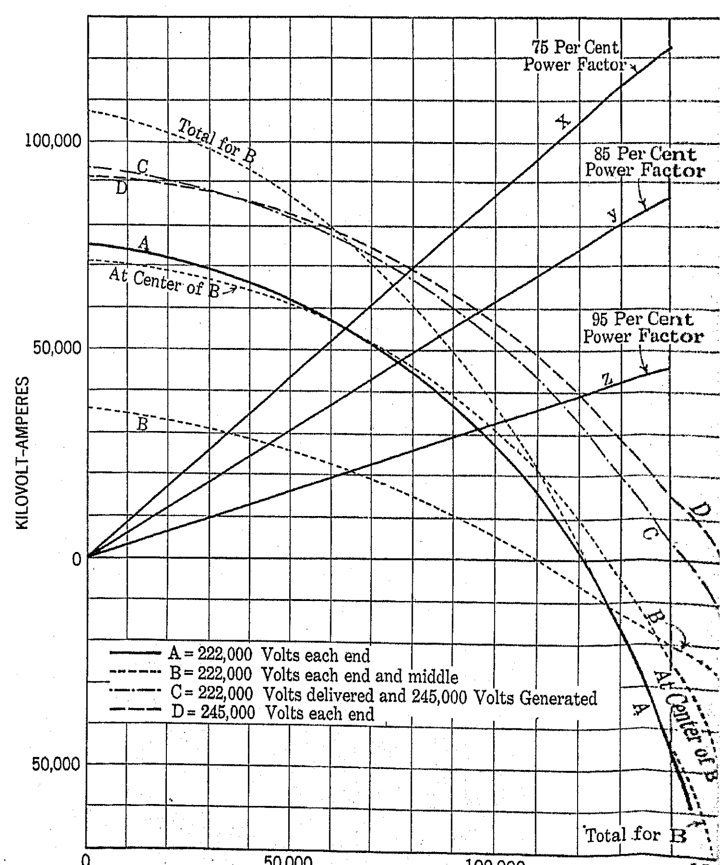

Fig. 4—Out-of-Phase Kilovolt-Amperes for Various Loads, Receiving End

machine) unless some load is taken off or some power supplied at the middle point. It is of course necessary that the synchronous machine at the center supply all the out-of-phase kilovolt-ampere required to maintain the receiving end of the first half at 220,000 volts and all that is required to maintain the sending end of the second half at 220,000. The kilovolts required for these two purposes may be of the same sign or opposite sign according to the load and the power factor and the resultant may be leading or lagging. This is the constant voltage transmission recently recommended by Baum.

Method (C) is to show the effect of a 10 per cent slope of potential in the direction of the load.

Method (D) is to show the effect of a 10 per cent increase in voltage over Method (A), the voltage being 245,000 volts at both ends.

With regard to the power factor curves of Fig. 1 it should be remembered that for any particular value of energy delivered the voltage assumed can be attained only with the load power factors shown.

To further illustrate the relations of these quantities Fig. 2 is added showing the currents at the two ends of the line with varying loads and Fig. 3 to show the relative phase positions of the voltages and currents at the ends of the line, the load current phase being taken as 0.

Since the delivery of any desired load at a definite voltage requires that the power must be delivered at a definite power factor, the synchronous condensers at the end of the line must be prepared automatically to deliver as much leading or lagging kilovolt-amperes as may be required and if they cannot supply this amount of energy the voltage will change appropriately.

As a practical matter of cost, the kilovolt-amperes required to maintain this prescribed power factor is a most important matter. These kilovolt-ampere quantities for controlling the line are shown in the set of curves in Fig. 4.

Three curves are added, marked X, Y and Z, showing the out-of-phase kilovolt-ampere component of the *load* the curve X being for a load power factor of 75 per cent, Y for 85 per cent and Z for 95 per cent. The condenser must supply both of these out of phase quantities.

Some comments may profitably be made on the curves of Figs. 1, 2 and 3. The efficiency curves no longer have the old familiar form. Good efficiencies are obtained only over a short range. The use of a middle point condenser station changes the form of the efficiency curve as seen in Fig. 1 in curve B. While the line losses are less with the middle point station at high and low loads, they are greater over the operating range and this without including transformer and condenser losses.

As would be supposed the maximum output occurs with power factors pretty near to unity.

The voltage at the middle of the line runs 15 per cent high at no-load with both ends at the same voltage, but only 10 per cent high when the sending voltage is 10 per cent higher than the receiving voltage.

The phases of the voltages and the corresponding phase positions of the machine armatures vary over an astonishing range, some 135 deg. for different conditions.

Special Conditions

The following special conditions on this line are of interest.

If the receiving end of this line be open-circuited and the generated voltage maintained at 220,000 volts, the open end will rise to 413,000 volts and the charging current will be 302 amperes, case 4, Table "A".

If the receiving end be short-circuited and 220,000 volts maintained at the generator, the generator current will be 223 amperes and the current at the receiving end will be 420 amperes. The power at the generator will be 7470 kw. at a power factor of 0.176 lag, case 8, Table "A".

Should the synchronous condenser pass out of step with the voltage at each end 220,000 volts, the maximum possible current that would be developed would be about 640 amperes approximately, the same on both ends. At the moment of maximum current the power factor would be 0.182 lag at the generator, giving a drag of 44,000 kw. with a negative load of 12,700 kw. at the receiving end with a power factor of 0.053 lead.

This condition is transitory but existing momentarily as the synchronous machines pass the condition of maximum current, case 7, Table "A".

The minimum line current with the voltage of 220,000 at both ends will be 196 amperes as shown in Fig. 2, with a load delivered of 10,000 kw.

The maximum power that can be delivered by the generator theoretically with its voltage kept at 220,000 as distinguished from the maximum current, is 166,000 kw. and will occur with the generator current about 441 amperes with a power factor of 0.986 lagging and the load delivered would be about 143,000 kw., the load current about 405 amperes at a power factor of 0.925 lead, if the load voltage is kept at 220,000 volts, case 3, Table A.

If in this last case the load voltage drops to 110,000 the maximum power that can be delivered by the generator will be about 94,000 kw. and will occur when the generator current is approximately 332 amperes and power factor 0.745 lagging and the energy at the load end will be about 75,000 kw. with current of 433 amperes and a power factor of 0.90 leading; case 6, Table A.

These conditions and several other special conditions are fully tabulated for convenience in Table "A".

Important as are the above features of the superline, the operating characteristics are more so and involve some most interesting discussions. Various aspects will be considered in turn.

STARTING

When one end of a super transmission line is open and the other end excited, the voltage at the open end rises very high; in our case to 413,000 volts from 220,000 volts. This is an impracticable operating condition and the open-circuiting of either end of the line cannot be permitted. Fortunately the maximum current that can be gotten steadily by any combination of conditions is not greatly in excess of full-load current at the receiving end so that for the duration of a starting period or an emergency, such as a short circuit or falling out of step, no damage would be done to apparatus permanently connected to the line, even if capacity be considerably less than the full curren the line, while an excessive rise of potential woul prevented.

If it be then assumed that the synchronous appar at the receiving end of the line be permanently nected to the line the problem of starting may be c for in several ways.

(a) The generator may be excited and started from rest and the synchronous condenser will fall i step as the generator comes up to speed.

(b) The generator may be brought up to speed v

the field open and then the exciting of the field will start the synchronous motor, if properly designed, which will then pull quickly into step.

(c) If means for revolving the synchronous condenser be provided, both this machine and the generator while still connected may be brought up to speed and they lock into step when their speeds become equal.

It is not the purpose of this paper, however, to discuss the details of starting, but merely to point out how the starting may be practically accomplished.

Synchronizing

Synchronizing may be accomplished in the low tension at either end. As a matter of fact, as a first approximation this superline is in some ways the equivalent of a very high reactance connected between the synchronous machines at the two ends of the line, so great in value that to get full power over the line it is necessary for the two synchronous machines to swing out of step by a very wide angle, thus developing enough voltage to support full-load current.

Considering "*A*" in Fig. 3, the difference in phase of the voltage of the two synchronous machines at the two ends of the line changes from about 5 deg. at a load of 8500 kw. to about 70 deg. with a load of 140,000 kw. That is, if a line with synchronous condensers carrying no load is connected at one end to a similar line loaded, there will be a very wide phase difference between the voltages at the unconnected ends of two lines. When these are connected, however, their phases will come together and the load will divide between them. However, while under the assumed conditions the line conditions can adjust themselves without disturbance on synchronizing at the second point, the condenser must adjust its position more slowly and may cause some heavy current interchange with other condensers but it will very likely be possible to accomplish synchronizing in a manner to avoid such a violent change in the phase position of the condenser. This is a matter of interest rather than a serious difficulty of operation. However, syncroscopes used in the ordinary way would not indicate at all correctly, as to the proper moment for closing the synchronizing switches. Of course, if one end of the two lines is already connected, the other may be also connected without use of a synchroscope, provided it be proper to make this connection at all.

Synchronizing a lone line with an operating substation works differently. If the line be idling the phase of the voltage at the receiving end will be nearly in phase with that at the generator end, as there is little load passing over the line. If it then be synchronized with the load system already operating there will be no immediate change, for the phase of the generator must advance relatively by many degrees before it can take much load. This will occur in a few cycles if the governor of the generator prime mover be set to take such load. It must also drop behind many degrees to take power from the main system. This adjustment of position will occur very quickly in actual practise.

Presumably this connecting of an idle line to the substation is the proper condition for synchronizing. The governor of the generator prime mover can be set for higher speed to cause it to take load when the synchronizing has been accomplished. If one line thus synchronized to a substation is then to be paralleled on the generator end with other already synchronized lines, it should be so loaded (the voltage being maintained constant automatically) that the generators are all in phase before closing the synchronizing switch at the generator end.

While synchronizing is not likely to cause much difficulty, the matter of pull-out torque and holding in synchronism through electrical trouble is much more difficult. If a generator feeds a superpower line synchronized at the receiving end with a load system and a sudden increase of load comes the load system will tend to slow down momentarily. To escape losing synchronism the generator must slow down also, but to accomplish this slowing down, more load must be passed over the transmission line. If now the generator be already loaded as far as the line will permit *by efficiency and voltage* considerations, as for example to 140,000 kw. it will be found by examining the curves of Figs. 1 and 2 and case 3 Table "A" that very little more load can be got over the line. If, however, a certain margin exists so that the normal full load over the line may be increased by perhaps 50 per cent when called upon by a load increase, then a sudden increase of load and slowing down of the load system will cause an increase of power delivered over the line and the generator will slow down, if properly designed, especially if it be a waterwheel with the usual small overload capacity and if its governor have a wide range of speed variation with load.

Again, if a local short circuit occur in the load system near the receiving end of the line, the local voltage will drop, which greatly limits the power that can pass over the line as shown in cases 6, 15 and 16, Table "A" and the generator will immediately tend to pull out of step if the rest of the system *tends to slow down.* Obviously this is a more serious matter and at first sight a most difficult one to handle.

Cases 21 and 22 of Table "A" show that a line of half the length is considerably better and that the maximum power that can theoretically be delivered is greater than for the full length of line with the same terminal voltages. A further treatment of this subject will be found below:

Typical System Diagram

The determination of the best arrangement for the use of breakers on the superpower line and its connected load network, when taken in connection with automatic relay protection for short circuits, will be found to be a very complex matter. The purposes of this paper,

which is largely illustrative, will be best served by assuming a layout which is well suited to the usual conditions and discussing its action under various normal and abnormal conditions. Such an arrangement is shown in the one line diagram in Fig. 5.

It will be assumed that the line voltage is normally maintained automatically at 220,000 volts 60 cycles, at each end by regulators working on the fields of the generators and condensers. The amount of synchronous capacity required for various cases is shown in Fig. 4.

The four circuits, which may well be carried by two two-circuit tower lines, make a well rounded super transmission installation. One circuit may be taken out for repairs and the other three lines be made to carry the total or nearly the whole power.

This overloading of the three remaining lines calls for a very large capacity of synchronous condensers. By reference to Figs. 1, 2 and 4, it will be seen that the demands on the synchronous condensers will be less excessive if at the same time the voltage at the generating end be raised even by such a small amount as 5 per cent and this should be permissible for temporary operation. In this case account is being taken of the requirements of the load as well as the line. This resultant will be the difference between the *X*, *Y* and *Z*, and the *A*, *B*, *C* and *D*, curves.

Synchronous Condensers

We may take as an illustration 400,000 kw. as the total normal load on the transmission with 220,000 volts at each end. This means 100,000 kw. delivered per circuit. From the curves, case 1, Table "A" it will be seen the normal generator power factor is 0.92 leading. An approximate capacity of 115,000 kv-a. is required, but to cover somewhat less favorable contingencies and some overload, 130,000 kv-a. may be taken at a power factor of 90 per cent. If the prime movers are waterwheels they will presumably be given a *maximum* continuous rating corresponding to about 140,000 kw. per circuit.

As to the condensers, we must always satisfy the condition when the line is disconnected from the load circuit, which calls for out-of-phase kilovolt-amperes of about 75,000 kv-a. lag (see Fig. 4) on the line. This means 78,000 kv-a. lag on the condenser terminals. Condenser capacity to meet this no-load condition must be furnished, whatever loading may be assumed for full load. The effect of raising the voltage of the sending end of the line is seen from case *C*, Fig. 4, viz., to increase the no-load kilovolt-amperes required. The *full load* kilovolt-ampere requirements, however, will be less with the higher generator voltage.

Strangely the major part of the charging current is fed from the lower voltage end. This is because the voltage naturally rises along an unloaded line away from the generator. By referring to case 4, Table "A", it is seen that if the receiving voltage were raised to 413,000 volts, this end would supply no charging current at all.

In order, however, to take account of the effect of transformers and condensers we may assume that if the load at the receiving low-tension bus bars is 100,000 kw. at 85 per cent power factor the load will be 105,000 kw. in the high tension, allowing for transformer and condenser losses. The high-tension out-of-phase component of the *load* will be 71,500 kv-a. lagging, assuming the transformer has 8 per cent reactance e. m. f. The line delivering 105,000 kv-a. requires 22,500 of lagging kv-a., giving 49,000 kv-a. lead to be supplied by the condenser in the high tension. Therefore, the kv-a. required from the condenser in its low-tension circuit is 51,500 kv-a. lead, assuming a 5 per cent reactance in the transformer tertiary winding. This is well within the capacity required for the light line running, *viz.*, 75,000 kv-a., the difference being available as overload capacity.

If one line be down and each of the remaining lines deliver 133,000 kw. low tension, the high-tension, out-of-phase kv-a. of the *load* (85 per cent power factor) on the 220,000-volt busbars is 94,000 lag. The out-of-phase high tension required by the line is 47,000 leading, giving a total condenser requirement of 141,000 kv-a. lead on the high-tension side and 5 per cent in excess on the low-tension side or 148,000 kv-a. lead. The amount is far in excess of that required for light line and this is not a desirable operating condition.

Various expedients may be used to reduce this requirement of 148,000 kv-a. For example:

(1) If one line is taken out, the total load required of the system may usually be somewhat reduced, say to 120,000 kw. per circuit, which will naturally reduce the requirements from the condensers.

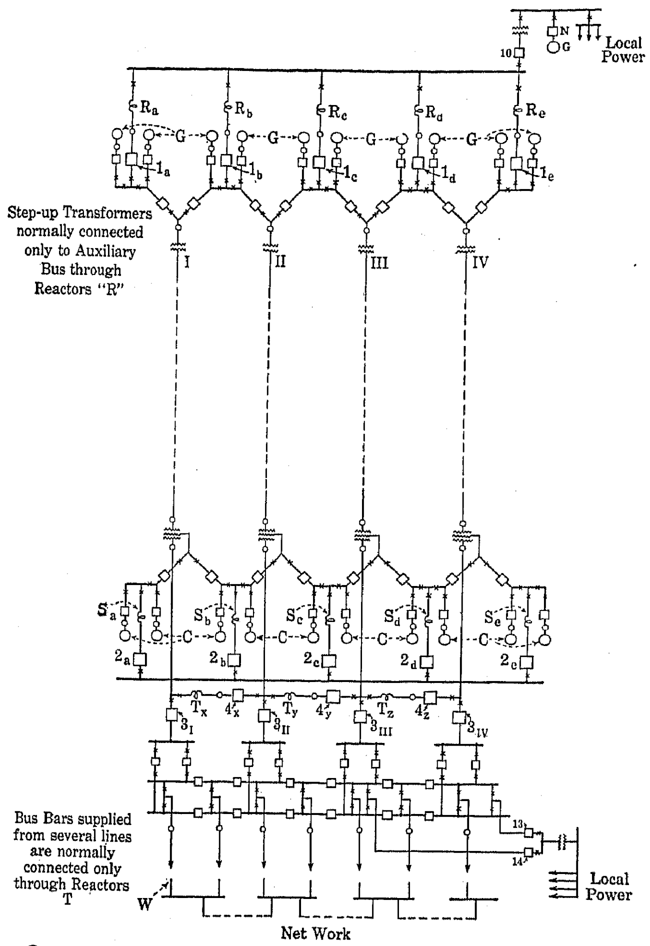
(2) If the generator voltage be raised 10 per cent to 245,000 volts, the requirements of the condensers will be reduced to 95,000 kv-a. lead which is somewhat more than the no-load requirement.

(3) If the power factor of the load at the step-down bus bars be raised to 95 per cent, the kv-a. out of phase of the load is 55,000 high tension, giving with the 47,000 required by the line, $102,000 \times 105 = 107,200$ lead.

(4) Since when one line is down its condensers are not in use, these may be added to give additional capacity to the three good lines. This will bring the available condenser capacity for each of the three operating lines to 133 per cent of normal, or 100,000 kv-a. if normal be taken as 75,000 kv-a.

(5) Normally spare capacity will be provided for condensers, and if it be assumed that this may be used when one line is out and the spare be 20 per cent of the total as in the system of Fig. 5, there will be capacity of two extra condensers for the three circuits which will provide the requisite capacity for 133,000 kw. delivered, counting somewhat on overloading.

However, it would no doubt be more practicable



Ⓖ —Main generator and prime mover, 65,000 kw-95 % P. F. units.
Ⓒ —Synchronous condensers, 75,000 kv-a.
[1] —Automatic oil circuit breaker.
□ —Oil switch, non automatic.
× —Disconnect switches, air break.
○ —Relays for breakers—actions as described below.

—Reactors—at generator station—to pass 400,000 kv-a. on full voltage at condenser end—to pass 300,000 kv-a.
—Step up transformers—130,000 kv-a. Internal reactance as low as practicable, say 8 per cent.
—Step down transformers, 110,000 kv-a. on secondary, and 75,000 kv-a. on tertiary, reactance between primary and secondary say 8 per cent. Between primary and tertiary—very low—say 5 per cent and between tertiary and secondary very high say 12 to 15 per cent.

Fig. 5—One Line Diagram of Typical System Superpower Transmission

In generator leads, relay kills the field of its own generator but only while short lasts; inverse time limit 0.2 seconds on 750,000 kv-a.,—0.5 seconds on 400,000 kv-a.

In lead to breaker [1], relay overload instantaneous, minimum setting 160,000 kv-a.

In high-tension of step up transformers, relay instantaneous to ring a bell as long as power factor is below 50 per cent, lagging.

In primary of step down transformer, (or a combination of currents representing tertiary and secondary windings to give the same result) relay to open breakers [2]. [3] and [4], instantaneous, minimum setting 175,000 kv-a. Also opening [2], [3] and [4] when power factor drops below 50 per cent leading (as motor), in 3 seconds.

In leads to step-down transformer secondary, relay opening [3] in 0.4 seconds.

In leads to synchronous condensers or to transformer, relay opening [2] inverse time limit 0.2 seconds on 400,000 kv-a., and minimum operating value 100,000 kv-a.

In leads to switch [4]—relay definite time limit 0.75 seconds—minimum operating kv-a., 125,000.

In feeders, relay inverse time limit but clearing any short as high as 100,000 kw. in less than 0.25 seconds.

Standard protection for short circuits for generators and local station power.

to count on operating only 120,000 kw. on each of the three remaining circuits when one goes out, thus requiring 95,000 kv-a. lead from each synchronous condenser, this being based on a network load power factor of 85 per cent. Even with this arrangement some of the idle condenser capacity should be used for continuous running at 120,000 kw. generator.

Apparently a very effective arrangement could be secured by providing to have the generator voltage automatically run lower on light load and higher on heavy load. A change of 5 per cent would be an important help and one of 10 per cent would greatly reduce the required condenser capacity.

Thus it is seen that for economic conditions involving the transmission of very heavy loads, capacity in synchronous apparatus may be required numerically in the neighborhood of the amount of the load transmitted. On the other hand a number of simple expedients may be used to materially curtail these requirements. It should be clearly understood that the values so far given are not intended to indicate that these are practicable for an actual installation. They are offered as a basis for discussion. No doubt more consideration will be given to these subjects before such an installation will be made.

It should be noted that to maintain constant voltage on the high tension at full load or with the overload condition, that voltages on the condenser circuits must be regulated to be a little above or a little below the line voltage according to whether the passing of power causes a rise or a fall of voltage in the transformers. For this line and normal full load there will be a drop through the step down transformer and the condenser voltage should be at a lower value than the ratio of turns of the transformer and the line voltage would indicate. This refers to the ratio of turns of primary and tertiary windings. If the load be increased for example, to the point where three lines will carry the load of four or under the conditions when a sudden disturbance calls for a still larger flow of current the condenser will be forced to supply a leading current and the drop in the step-down transformers will become a rise, so that the condenser terminal voltage must be higher than the ratio of turns would call for. The synchronous condenser must be adapted to sustain this condition. Since the primary and tertiary windings are closely related magnetically, these voltage variations will be small.

Similarly at the generating end the voltage regulator must be laid out to correct for the voltage drop or rise of the step-up transformer. Space will not permit a fuller discussion of this point at this time.

As a matter of good design, it is likely that it will be more favorable to provide most of the power factor correction as far as it is required to raise the power factor of the load by synchronous apparatus in the neighborhood of the load itself as this will improve the regulation and efficiency performance of the network as well as adapting the load to the requirements

of the line. It will also reduce the kv-a. load on the step down transformers. For this purpose any available existing synchronous apparatus would serve. The part of the corrective kv-a. that must be varied during changes in operation should be under immediate control and should be supplied by condensers at the step-down station.

For spares add a fifth unit to generators and condensers.

The original assumption of the loading of the line may now be modified to give a favorable layout as follows:

Normal full-load 400,000 kw., 100,000 per circuit on the distribution bus bars (requiring 420,000 kw., 105,000 per circuit on the high-tension side at power factor of 98 per cent lagging). Condenser kv-a. required per circuit 24,000 kv-a. lagging including requirement of step-down transformer, assuming *load* corrected in the network to *unity power factor* at the high-tension side.

Kilovolt-ampere required for no-load condition 79,000 lag per circuit on condenser terminals (only occasionally and for brief periods).

Maximum steady load provided for on three lines 360,000 total, 120,000 per circuit on distribution bus bar (380,000 kw., 127,000 per circuit on high-tension side at power factor 0.995 per cent leading) calling for 11,400 kv-a. per circuit leading on condenser terminals assuming the load corrected in the network to unity power factor at the high-tension side.

Capacity of condensers provided 75,000 kv-a. per circuit. Note that when the 79,000 kv-a. above is required on no-load that the spare condenser can be called upon should this condition continue indefinitely. The extra condenser capacity on the over load condition is highly desirable as a margin for operating reasons. Sufficient corrective capacity must be provided in the network (or at the condensers) to bring the load power factor to unity. The amount of this is shown for various power load factors in Fig. 4.

Efficiency of line, normal 92 per cent, loss 8 per cent; add transformer loss 2×1.5 per cent and condenser losses 4 per cent of 75,000 kw. total 14 per cent loss.

Step-up transformer capacity 130,000 kv-a. per circuit, step-down transformers capacity for load winding 110,000 kv-a., for tertiary winding 75,000 kv-a. This apparatus will carry the overload corresponding to one line out as above, until additional capacity can be added, but will be sensitive to voltage drop.

Generator capacity 130,000 kw. per circuit at 95 per cent power factor.

It should again be noted that this layout is proposed for discussion as a maximum and optimum system and no doubt a more conservative design would be adopted in any particular installation.

Switching

Considering the layout of Fig. 5 more particularly from the point of switching, the most conspicuous characteristic is the omission of all breakers or automatic oil switches in the high-tension circuits. This will be seen to have several important advantages and few disadvantages.

(a) It protects the line from accidental open-circuiting at either end and the very high voltage resulting at the open point.

(b) It eliminates a number of high-tension insulation points and greatly simplifies the high-tension layout.

(c) It eliminates a large item of cost and maintenance. Such a system as in Fig. 5 laid out in accordance with the usual practise would call for from 25 to 30 high-tension breakers at a cost of perhaps over a half a million dollars.

(d) The principle disadvantage of the omission of high-tension switches is the limitation of flexibility; for example, if a line is down in the layout of Fig. 5, its transformers are also down and similarly with the line if its transformer is down. If high-tension disconnect switches are installed any desired reconnection of lines and transformers may readily be obtained, but only at the expense of shutting down another line to make the change in the case of some operations. This use of disconnects in this particular situation offers several very interesting possibilities which space will not permit discussing here.

It may well be argued that for such a system as Fig. 5, feeding into a large network with other generating stations of large aggregate capacity, the simplicity of this layout is of great advantage. Here there is the one function of carrying a large block of power, 24 hours a day with no occasion for changing of connections except in case of some accident and for the regular inspection of generators and condensers. This inspection is provided for by the spare units shown which can be switched in and out one at a time without disturbing load. In case of emergency or to make the infrequent inspections of transformers and lines (that is—such line inspection and testing as cannot be done alive), three lines can be made to carry nearly the load of four. Ordinarily, however, when one line is to be shut down it will be feasible to arrange for a reduction of the load by 10 or 15 per cent on the transmission system. With careful line inspection and maintenance it may be confidently expected that trouble in the major elements of the system will be very rare. This favorable result assumes a very careful design, with the most painstaking scrutiny of details, but not an elaborate or excessively conservative design. The important thing is not to have an extreme factor of safety, but to insure an adequate factor of safety at *all* points. In making this statement as to the rarity of major trouble, reservation must be made to cover the possibility of some unusual and unexpected local disturbance. Such a condition might be malicious interference or one of the rare locally occurring fog belts which coat insulators or (possibly but very improbably) extreme lightning severity, etc.

At this point I would like to state that the practise of working on live lines at 100,000 volts and higher is worthy of most serious consideration on these super lines. While at first thought this practise seems dangerous, a more careful analysis does not bear out this appearance; neither does the experience with such work. I think there is little question that live line testing of high-tension insulators is feasible and reasonably safe. It has already been carried out very extensively. The question then arises whether very simple line operations are not also feasible. The best example of such a simple operation is the changing of an insulator string and this is the most useful operation in practise. A little consideration will show what a wonderful advantage the possibility of changing defective insulators without taking load off the line would be, especially in a line of the length of the one under discussion. In my judgment this advantage is so great as to warrant very considerable exertions. Some superintendents who do not care to do this work with their own crews may obtain more or less the same result by contracting to have their defective insulators changed periodically by outside expert crews as has already been done in many cases. While there will naturally be a great inertia of conservatism holding back the adoption of live line work, such as insulator changing, it is difficult to see how it can be logically ruled out in the end, when the live line testing is already pretty well accepted.

Automatic Relay Protection

Most of the features of the relay protection of Fig. 5 involve the standard use of standard apparatus but there are a number of novel features. The most satisfactory way of bringing out the intended operation will be the analyzing of the effect of various possible accidents. Single-phase grounds and short circuits will have the same effect on these lines since the high-tension neutral is assumed substantially dead grounded at a sufficient number of points. Assume all the generators except the right hand pair are operating, each pair on its own line and all breakers [1] closed, also all condensers except the left hand pair operating, each pair connected to its own transformer and all switches [2] closed; also all breakers [4] closed but distribution bus bars all operated in four groups.

A—Short Circuit on Generator End of Line I

The relays in the leads of the generators feeding the short circuit kill the generator fields, operating in 0.6 seconds. The breaker [1-*a*] will open instantaneously opening about 300,000 arc kv-a.; the other breakers [1] do not open as the current will be too small. The short circuit is then killed as far as the generating end is concerned. Meanwhile the only effect at the receiving end is to develop a current of 223 amperes and to change the power factor of the line to say 18 per cent leading (Table A, Case 8) (current would be lagging if condenser is considered a generator) and to drop the delivery of power that had been passing over this line. Through the action of a relay designed for this purpose, this low leading power factor in the step down transformer primary will open the breaker [3-I] in 3 seconds and at the same time [2 *b*] and [4 *x*]. This disconnects the line entirely from the system but leaves both generator and condensers connected and running. If this renews the short circuit the generator fields will be restored and the condensers fall into step again or, if so designed, once opened, the generator field circuit may remain open in which case the condenser will come to rest and restarting will be necessary. The delay of three seconds is to give the short circuit a chance to clear. No harm is done, since the short circuit will not pull more than about 7500 kw. to 15,000 kw., (Table "A", case 8) and less than full-load current. When the operators see that one line is out they should immediately connect in the spare generators and condensers. If the bad line can then be put in again this may be done at once, but otherwise the full load or a suitable portion can be taken over the three good lines. In case of the dropping out of line *I*, the three waterwheels still on the line will open up their governors and may take load up to the extent of their capacity—say 20 per cent excess making, 60 per cent excess in all of the loss from the bad line and the rest of the load will be taken by the generators in the network. If the latter have more sensitive governors they may take still more of the load. The steady distribution of the load between line circuits can be controlled at will by hand adjustment of the speed of the generator governors.

When the opening of [3-I] cuts off certain feeders to the network, the corresponding load will presumably be supplied around through the network by other routes over the good circuits.

B—Short circuit on primary leads of step up transformers

Substantially the same actions as in Case *"A"*, but currents will be 50 per cent heavier.

C—Short circuit on auxiliary bus, generator station

All breakers [1] go out instantaneously and before the relay in the generator leads can open the fields, since these are inverse time limit and the short circuit is limited by the reactances. No other effect will be produced as the line units can all run perfectly well without the auxiliary connection. A short circuit on the auxiliary bus should be very rare.

D—Short circuit at condenser end of line I

Breaker [3-I] opens instantaneously from relay on primary of step-down transformer and [2 *b*] and [4 *x*] are open by the same relay. Nothing happens at the generator end until the attendant cuts off this line at his leisure. The generator end current will be only 223 amperes (Table "A", case 8) and the current at the load end only 420 amperes. It might be well to have the low generator power factor 0.176 lag, ring a bell to call attention to the condition.

E—Short circuit at the middle of the line 1

This will pull 640 amperes at the generator end and cut off the generator fields, which will open [1-*a*] in 0.5 seconds clearing this end. It will act the same as *A* at the receiving end, [3-1], [2-*b*] and [4-*x*] going out by the same relay.

F—Short circuit on left hand operating condenser leads

Corresponding breaker [2] opens in 0.2 seconds leaving line to go down as in *A*– [3-*I*] opens in 0.4 seconds and [4-*x*] in 0.75 seconds.

G—Short circuit on condenser auxiliary bus

Breakers [2] go out in 0.2 seconds clearing the trouble without disturbing the operation, provided synchronism can be held. If reactances are used with switches [2], conditions will be much easier.

H—Short circuit on distribution feeders

[3 *x*] opens in 0.4 seconds on overload leaving the power from line 1 to pass through [4 *x*] to the other feeders and into the network where it would find its way to the original destination. The time limit of 0.4 seconds is to permit a feeder breaker to clear the individual feeder before [3 *x*] opens. If [3-I] fails to clear the circuit [4-*x*] opens in 0.75 seconds and line I will be disconnected.

The protection of the local station power circuits involves no particularly difficult problems and need not be discussed here.

Synchronizing Power in Typical System

As already pointed out, the characteristics of the superline for efficient full-load transmission of power are so extremely favorable on account of the neutralizing of the reactance effect by the capacity effect, that for other conditions when this neutralization does not occur to the same favorable extent, as for example with overloads, very light load or low voltage, transmission becomes very unfavorable. The very light load condition has been considered above. The overload condition, as an overload problem, is the least serious and easiest to meet, but the low voltage or short-circuit condition is serious and difficult from the point of view of holding synchronism.

Before discussing this matter with regard to the system of Fig. 5, I will consider a single superline circuit such as one of the four here shown. It will transmit considerably more power than full-load power if the voltage at both ends be kept at normal even as high as 145,000 kw. (See Table "A", case 3). If, however, this voltage drop below normal, even if at the receiving end only, the amount of power that can be delivered is greatly reduced as seen in Table "A", case 6. For example, in this case the actual power delivered with half voltage at the receiving end is less than the full load, viz., only 75,000 and this condition gives nearly the maximum deliverable power for this voltage. Since, however, there is little likelihood that the failure to deliver *power* under conditions of abnormal voltages (due presumably to short circuits) will be *per se* of importance, since such conditions can exist for a period of perhaps only one or two seconds, we have only to consider the danger of loss of synchronism or the opening of breakers.

Several cases occur which have to be considered independently.

First, when a short circuit occurs at the receiving end of the system on the step-down side. In this case there is a tendency for the receiving end voltage to drop, which will tend to limit the amount of power delivered by a line. But the full input to the generator continues to be delivered by the prime mover, and the only thing that prevents its speeding up to the light load speed of the governor (considering now one circuit by itself) is such power as may be taken by the line. This is the most serious condition to be met in maintaining synchronism and will be critical when the short circuit is such as to tend to cause the network machines to *slow down;* for example, when the short circuit is through a feeder line with very little armature reaction drop in the generator voltage. Of course, the overspeed governor on the generator prime mover will prevent any dangerous increase of speed, but it will be useless for preserving synchronism.

It follows from the above that for this case the critical factor will be the load developed by the generator, not the load delivered by the line and this generated power may be considerably greater than the delivered power. For example, the drag on the generator in Table "A", case 6, is 94,000 kw. compared with 75,000 kw.

But short circuits are of many varieties. If of such a sort that the actual kw. developed in the short is less than at full load, on account of low power factor in the short circuit, the generators in the network and the main generators, at opposite ends of the line will tend to *speed up* and the load that can be delivered over the line in one direction or the other may be sufficient to hold them in step, even if less in amount than full load power. In this case the governors of the prime movers will have to ultimately control the speeds and the more nearly their speed curves are alike the better the chance of staying in step. The range through which synchronism would be retained would be, on the one hand that condition in which the receiving end prime movers speed up more rapidly than the main generators and are only restrained from exceeding the speed of the latter by the load sent backward over the line helping the prime mover to speed up the main generators and on the other hand the condition in which the main prime movers are just able to pull up the speed of the receiving end machines until equilibrium is reached. This is presumably a very wide range and successful operation through this range is not limited to line voltage conditions in which full load may be passed over the line.

In the case of a single line and a condition such that the prime movers in the net work at the receiving end tend to slow down, synchronism cannot be maintained if the receiving voltage on the line drops to the point

where full load cannot be delivered over the line. In this case it must be noted, however, that the critical voltage is the high-tension line voltage and not the step-down voltage. This is a very important distinction for the drop in the step-down transformer will be considerable on a short circuit especially if the design of the step-down transformer is such that the magnetic interlinking of the tertiary with the primary is much closer than that of the tertiary with the secondary, for the short-circuit kv-a. supplied by the condensers must go through this step-down transformer before reaching the short circuit and this tends to sustain the line voltage. As a matter of fact, if the condensers were connected to taps in the grounded end of the primary windings some gain would result in close interlinkage. A heavy flywheel capacity in the condensers is presumably very helpful in maintaining stable conditions.

is, the restoring torque will develop at least *partially* with the *progressive* separation of the phase positions of the several prime movers generators. The form of curve connecting power transmitted with phase displacement (Fig. 6) shows a condition very favorable for suppressing the pendulum action without the machine getting out of step. Of course, proper *damping* devices will also be of *great* assistance.

Enough has been said to make it clear that for any given case the resultant action is very complex, involving the relative flywheel effects of the different units, their different short-circuit characteristics, their governor speed curves and the damping factor. It may very likely be that in an actual installation the most favorable adjustment of conditions may be secured by providing adjustment in such factors as flywheel effect, short circuit kv-a., etc., and making a

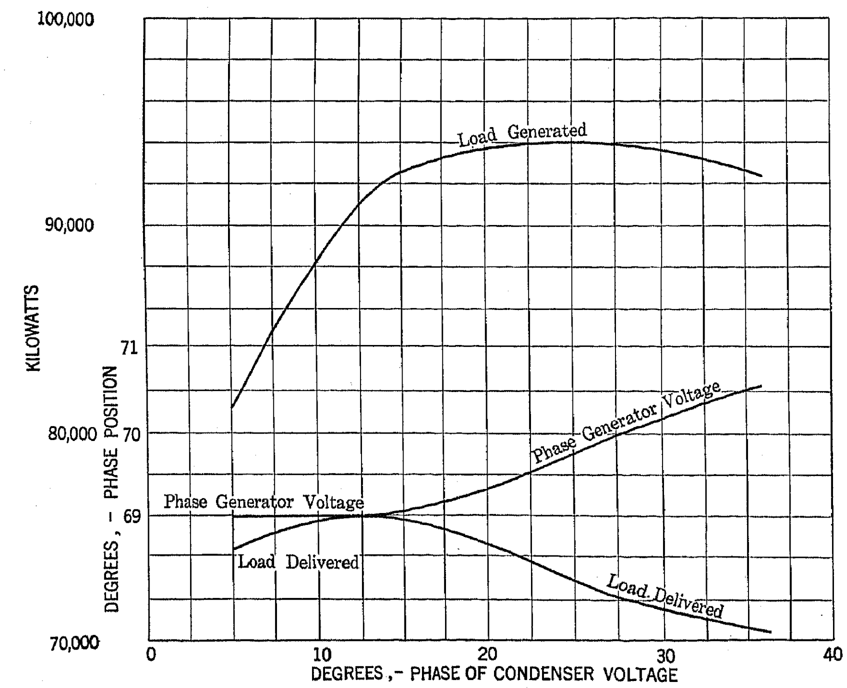

FIG. 6—MAXIMUM POWER TRANSMISSION

final determination in the field. These are matters for the study of specialists and cannot be profitably carried further at this point.

This discussion so far applies to a single circuit or a group of circuits connected directly in parallel. The action of the system of Fig. 5, however, is in effect quite otherwise. There are several critical points of difference.

As has been pointed out by others, the tendency for the various parts of the system to fall apart is theoretically markedly increased by the pendulum effect between two machines starting in equilibrium under normal conditions and subject to a sudden changing in conditions due to a short or even load change due to switching. A new equilibrium position must be assumed and in swinging to this new position there will be a tendency to over run the position of equilibrium and if this position of equilibrium be the maximum torque position also, the temporary over run may cause a falling out of synchronism. The seriousness of this can be determined only after further data are available, for the percentage increase of torque required for maintaining synchronism may not be great and the change will probably not be very sudden, that

First: The four lines while dividing the load freely between one another, are yet sufficiently separate electrically so that a short circuit on one or on the step-down end of one will not greatly disturb the voltage on the others. The high-tension circuits are not directly connected, but the step-down transformers secondaries are connected together through choke coils having a suitable reactance to permit equalization of the loads.

A similar interconnection exists at the generator end.

Second: The synchronous condensers are in parallel and are thus able to hold strongly together at times of disturbance in the network. This serves to hold all four high-tension circuits together. If found desirable to prevent too much disturbance of a condenser by trouble on another line, reactances can be connected between each condenser and the auxiliary bus.

Third: The main generators are connected in parallel through reactances. This serves to tie these generators all in parallel so that no one generator is likely to drop out of synchronism.

Fourth: The feeders on the step down side of the four transmission circuits are so connected through the reactances that a dead short circuit on one will not greatly disturb the voltage of the others, which will, therefore, continue firmly in synchronism through any kind of disturbance, however severe.

Thus this combination of circuits, in addition to providing a simple and practical layout for segregating and disconnecting any circuit suffering a short circuit, will hold itself firmly in synchronism and in synchronism with the network in spite of any breakdown that may occur.

For example should a dead short circuit occur three miles out on the left hand local feeder, *viz.*, at *W*, Fig. 5, current would be discharged into it through the feeder from line *I*, from the condenser bus through the tertiary winding of the transformer and through breaker [4 *x*]. While the voltage would be dropped materially on the local bus fed by line *I*, depending on the reactance of the bad feeder, the high-tension voltage on the line *I* would be dropped to a much less extent and the voltage on the condenser bus very little. The current passed through switch 4 would probably not exceed 200,000 kv-a. which would be supplied partly from the network and partly from the three other lines and would leave the voltage on the three good lines practically undisturbed. Meanwhile the relays would cut off the fault.

This system, to use an analogy, compared to the usual system, is like a locomotive which has an equalized, spring supported frame, compared to the farmer's hay wagon without springs. Every stone in the road causes a shock to the whole wagon while it would be passed over by the locomotive almost unnoticed.

Summary

To give a more concrete idea, numerically, of the effect of abnormal conditions in producing heavy short circuits and to indicate the duty of the oil breakers, the following approximate values are given, assuming a load of 90 per cent power factor at low-tension busses.

	Kw.	Kv-a.
Normal full load per circuit, low-tension bus	100,000	111,000
Maximum synchronous converter load per circuit	3,000	75,000
Normal current in reactors (4) representing interchange of load, estimated	10,000	12,000
Short circuit in high tension at receiving end of high-tension circuit, arc kv-a. from generator, at point of short circuit, 420 amperes		160,000
Kv-a. corresponding at generator, 223 amperes		85,000
Kv-a. through receiving transformer from condensers and network about		1,250,000
of this say 200,000 comes through reactors (*T*) and 350,000 from network. Of the 200,000, part comes from network and part from three good lines, the balance of 750,000 from the condensers and tertiary windings		
Short circuit in high tension at sending end of the line—		
From the generators arc kv-a.		600,000
From the line, amperes 420		160,000
From the network and condensers at receiving end corresponding to 223 amperes high tension		85,000
Short circuit at center of line, from each end 735 amperes		280,000
From generators and also from network corresponding, 642 amperes each		244,000
Short circuit on generator auxiliary bus, each generator 350,000 all		1,400,000
Short circuit on condenser auxiliary bus, each condenser 350,000		
Each tertiary winding 350,000 part from line and part from network—total		2,800,000

Note: If reactances be installed in series with the breakers (2), this value can easily cut in half or less, but little would be gained as no one breaker has to handle more than 700,000 arc kv-a.

The essential features of the system of Fig. 5 have now all been touched upon and the performance of the whole system seems to be very favorable. Of course, many variations can be made and changes introduced to meet special cases, but as long as the essential characteristics are maintained, the good performance should still be retained. The more fundamental features are the maintaining substantially separate of the main units as far as short circuits are concerned, the interconnection for purposes of load equalization, the means of maintaining a high voltage at both ends of the line on the high-tension side even when short-circuits occur, the automatic control of voltage and power factor for purposes of regulation and the proper choice of governor characteristics and flywheel effects for the various units.

Intermediate Condenser Station

An intermediate station at the middle of the line with synchronous condensers materially improves certain features of the line performance as for example, synchronizing power at time of disturbance and variation of voltage along the line. Furthermore, a much smaller synchronous condenser capacity is required at the receiving end. This advantage is more than balanced, however, by the large condenser capacity required at the center of the line.

Considering the layout of Fig. 5 as distinguished from a single transmission circuit, apparently, on the whole, little or nothing would be gained in efficiency or operating performance by the intermediate condenser station. The no-load voltage at the center would be reduced 15 per cent which is a material point, the line efficiency over the working range would be no better and at least 30,000 kv-a. of condensers additional total would be required, representing a loss and expense. The synchronizing power would be materially greater, perhaps 50 per cent greater. On the other hand the extra cost, especially when spare apparatus and interconnections are considered, and the very serious operating handicap of a third station with a third set of operators to be coordinated and the problem of relay protection, make it clear that very considerable sacrifices would be justified in avoiding the intermediate station and retain the simpler layout of Fig. 5.

It is interesting to note from case 18, Table "A", that power can be transmitted backward over the line with 220,000 volts at the condenser end and 245,000 volts at the generator end and at a better efficiency than in the normal direction.

Conclusion

The net upshot of this layout of Fig. 5 is a system delivering regularly 400,000 kw. (perhaps reduced to 360,000 for brief intervals, for work on a transmission circuit) over a distance of 500 miles, with losses including line, transformers and condensers of about 15 per cent, with flexibility such that any unit may be shut down at will without disturbing operation. This is a system in which disturbance caused by short circuits will apparently be less than with the usual transmission system and a system well adapted for automatic relay protection.

On the basis of power generated at $20.00 per kw. year on the switchboard and saleable at the receiving step-down bus bars in quantity at $50.00 per kw. year, an expenditure of something between $75,000,000 and $90,000,000 would seem to be justified, assuming 12 per cent to be sufficient to cover all fixed charges, or $75,000 to $90,000 a mile for a double circuit tower line including cost of condensers and auxiliaries.

It appears from the above discussion that the superline, while it has great possibilities of astonishing efficiency and an extraordinary range of transmission, has also some very distinct limitations and some real problems of its own that will warrant much study and discussion.

Discussion

For discussion of this paper see page 71.

Some Theoretical Considerations
of Power Transmission

BY C. L. FORTESCUE and C. F. WAGNER
Fellow, A. I. E. E. Associate, A. I. E. E.
Both of Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa.

Review of the Subject.—*The following points are developed in the paper:*

1. A proof of the circle diagram maintaining therein the idea of the angle between the generator and receiver voltages.

2. It is shown how the characteristics of the synchronous condenser limit the maximum power that can be transmitted over a line.

3. The effect of character of load on stability.

4. Comparison of 500-mile straightaway line with 500-mile line with condenser at mid-point.

THE power circle diagram of transmission line performance has proved of great value to the line designer and to the analyst. This diagram was first presented by R. A. Philip[1] before the Institute. The circle gives the relation between real and reactive powers, which must be maintained at the receiver to obtain the assumed voltage conditions at the generator and receiver. Mr. R. A. Philip restricted its application to short lines in which the capacity could be neglected, while H. B. Dwight[2] extended its use to the general case of any line. Later H. B. Dwight[3] in a paper presented before the Institute and R. D. Evans and H. K. Sels[4] in a series of articles in the *Electric Journal* developed the diagram still further and indicated simple means whereby the impedances of the transformers may be included. The latter also developed simplified formulas for the calculation and plotting of losses and efficiencies. It is the purpose of the present paper to develop further the uses and properties of the circle diagram.

Let us consider for the present the diagram for the line itself. Let

r = Resistance of line in ohms per mile
x = Reactance of line in ohms per mile
g = Conductance of line in mhos per mile (very small and usually neglected)
b = Susceptance of line in mhos per mile
l = Length of line in miles

then $Z = l\,(r + j\,x)$
$Y = l\,(g + j\,b)$

The familiar steady state line equations may be written

$$\begin{aligned} \breve{E}_s &= A\,\breve{E}_r + B\,\breve{I}_r \\ \breve{I}_s &= A\,\breve{I}_r + C\,\breve{E}_r \end{aligned} \qquad (1)$$

Where $\breve{E}_s$ = Voltage (phase-to-neutral) at generator end
$\breve{I}_s$ = Current per line at generator
$\breve{E}_r$ = Voltage (phase-to-neutral) at receiving end
$\breve{I}_r$ = Current per line at receiving end

3. TRANSACTIONS A. I. E. E., Vol. 41, 1922, pp. 781-784.
4. *Electric Journal,* July, Aug. and Dec. 1921 and Feb. 1922.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

$$A = \cosh\sqrt{Z\,Y} = 1 + \frac{Y\,Z}{2} + \frac{(Y\,Z)^2}{24} + \frac{(Y\,Z)^3}{720} + \ldots$$

$$B = \sqrt{Z/Y}\,\sinh\sqrt{Z\,Y} = Z\left[1 + \frac{Y\,Z}{6} + \frac{(Y\,Z)^2}{120} + \frac{(Y\,Z)^3}{5040} + \ldots\right]$$

$$C = \sqrt{Y/Z}\,\sinh\sqrt{Z\,Y} = Y\left[1 + \frac{Y\,Z}{6} + \frac{(Y\,Z)^2}{120} + \frac{(Y\,Z)^3}{5040} + \ldots\right]$$

Mr. R. D. Evans and Mr. H. K. Sels in a companion paper show how the transformer constants may be included in the above constants.

Equations (1) may be written in the form:

$$\left.\begin{aligned} \breve{I}_s &= (\alpha + j\,\beta)\,\breve{E}_s - (\gamma + j\,\delta)\,\breve{E}_r \\ \breve{I}_r &= (\gamma + j\,\delta)\,\breve{E}_s - (\alpha + j\,\beta)\,\breve{E}_r \end{aligned}\right\} \qquad (2)$$

where

$$\left.\begin{aligned} (\alpha + j\,\beta) &= A/B \\ (\gamma + j\,\delta) &= 1/B \end{aligned}\right\} \qquad (3)$$

PROOF OF THE CIRCLE DIAGRAM[5]

From this point a proof of the circle diagram is readily derived. The conjugate equations of (2) may be written:

$$\begin{aligned} \hat{I}_s &= (\alpha - j\,\beta)\,\hat{E}_s - (\gamma - j\,\delta)\,\hat{E}_r \\ \hat{I}_r &= (\gamma - j\,\delta)\,\hat{E}_s - (\alpha - j\,\beta)\,\hat{E}_r \end{aligned}$$

Multiplying $\hat{I}_s$ by $\breve{E}_s$ and $\hat{I}_r$ by $\breve{E}_r$ we obtain the power at generator and receiver respectively.

$$\begin{aligned} P_s + j\,Q_s &= \breve{E}_s\,\hat{I}_s = (\alpha - j\,\beta)\,\breve{E}_s\,\hat{E}_s - (\gamma - j\,\delta)\,\hat{E}_r\,\breve{E}_s \\ P_r + j\,Q_r &= \breve{E}_r\,\hat{I}_r = (\gamma - j\,\delta)\,\hat{E}_s\,\breve{E}_r - (\alpha - j\,\beta)\,\hat{E}_r\,\breve{E}_r \end{aligned}$$

but $\breve{E}_s\,\hat{E}_s = E_s^2$ and $\breve{E}_r\,\hat{E}_r = E_r^2$.

If we let $\breve{E}_r$ be the datum line and $\breve{E}_s = E_s\,\epsilon^{j\,\theta}$ then

5. An alternate simpler proof not involving conjugate imaginary quantities is given in the companion paper by Evans and Sels. The idea of the angular displacement between generator and receiver voltages, however, is lost.

$\hat{E}_r \check{E}_s = E_r E_s \epsilon^{j\theta}$ and $\check{E}_r \hat{E}_s = E_r E_s \epsilon^{-j\theta}$. Substituting in above

$$P_s + j Q_s = (\alpha - j \beta) E_s^2 - (\gamma - j \delta) E_s E_r \epsilon^{j\theta} \quad (4)$$

$$P_r + j Q_r = (\gamma - j \delta) E_s E_r \epsilon^{-j\theta} - (\alpha - j \beta) E_r^2 \quad (5)$$

With E_s and E_r constant, equation (4) is the equation of a circle with its center at $(\alpha - j \beta) E_s^2$ and radius equal to $\sqrt{\gamma^2 + \delta^2}\, E_s E_r$. For different values of E_r with E_s constant the equation may be represented by a family of concentric circles. These are the so-called "supply circles."

For $\theta = 0$

$$P_s + j Q_s = (\alpha - j \beta) E_s^2 - (\gamma - j \delta) E_s E_r$$

Operating by $\epsilon^{j\theta}$ merely rotates the vector $-(\gamma - j \delta) E_s E_r$ through an angle θ in a positive (counterclockwise) direction. Similarly $P_r + j Q_r$ may be

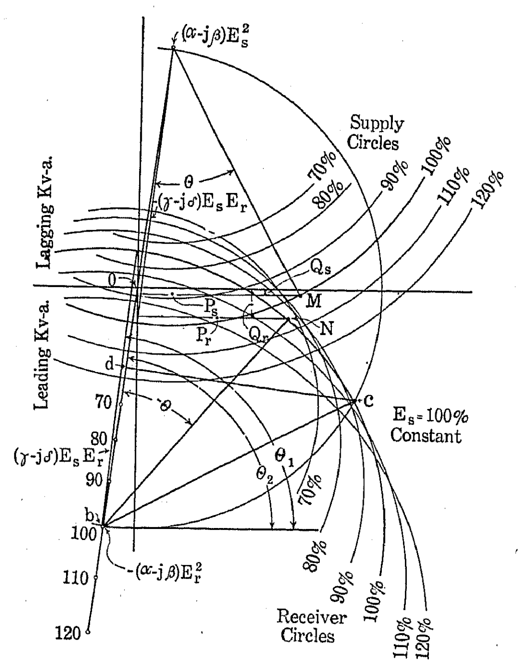

FIG. 1

Showing family of supply and receiver circles, relation between $P_r + j Q_r$ $P_s + j Q_r$ for any angle θ between E_s and E_r, and graphical determination of envelope.

represented by a circle locus, the center of which is given by $-(\alpha - j \beta) E_r^2$ which changes with each value of E_r and whose radius is $\sqrt{\gamma^2 + \delta^2}\, E_s E_r$. The vector $(\gamma - j \delta) E_s E_r \epsilon^{-j\theta}$ makes the angle $-\theta$ with $(\gamma - j \delta) E_s E_r$ as datum. For different values of E_r the equation may be represented by a family of non-concentric circles. These are the so-called "receiver circles."

Fig. 1 shows such a family of "supply" and "receiver" circles. These circles indicate the relation between inductive and real power which must be maintained to obtain the voltage conditions assumed for each circle, *viz.*, E_s constant and giving E_r the values indicated in each circle. It will be noted in this proof that the idea of the angle between the generator and receiver voltages has not been lost. Therefore, for any given value of $P_r + j Q_r$ the value of $P_s + j Q_s$ at the sending end may be obtained by using the same scalar values of voltage and laying off the same angles from their respective datum lines. For example suppose we are operating at the point N on the 100 per cent receiver circle. By laying off the same angle θ on the 100 per cent supply circle as that corresponding to $-\theta$ on the receiver circle the point M is obtained. This gives the value of true and reactive power at the generator end necessary to maintain the given conditions at the receiver end. $P_s - P_r$ represents the true line loss. This method does not offer very great accuracy, but for most work should be close enough.

The circle diagram could be made more complete by plotting thereon loci of constant angle between generator and receiver circles. It can be shown that these loci are parabolas. However, the angle loci are relatively unimportant and of academic interest only.

GRAPHICAL DETERMINATION OF ENVELOPE

In the analysis of transmission line problems, it is sometimes convenient to know the envelope of the receiver circles. One of its applications is developed in the companion paper by Evans and Sels. Equation (5) may be rewritten as follows:

$$(P_r + \alpha E_r^2 + j (Q_r - \beta E_r^2) = (\gamma - j \delta) E_s E_r \epsilon^{-j\theta} \quad (6)$$

Its conjugate is

$$(P_r + \alpha E_r^2) - j (Q_r - \beta E_r^2) = (\gamma + j \delta) E_s E_r \epsilon^{j\theta} \quad (7)$$

The product of the two gives

$$(P_r + \alpha E_r^2)^2 + (Q_r - \beta E_r^2)^2 = (\gamma^2 + \delta^2) E_s^2 E_r^2 \quad (8)$$

It is shown in works on the differential calculus that the envelope of such a function having E_r as the parameter determining consecutive loci, is the locus of the equation obtained by differentiating (8) with respect to the parameter E_r and eliminating E_r from the resulting equation and equation (8). This truth may not at first be evident. That it is so may be shown in a crude way as follows: Consider two power circles determined by the parameters E_r and $(E_r + \Delta E_r)$ respectively. As ΔE_r approaches zero the intersection of the two circles approaches and finally coincides with the envelope as a limit. E_r and $E_r + \Delta E_r$ substituted in equation (8) furnishes two equations from which the point of intersection could be calculated, two equations, two unknowns, *viz.*, P_r and Q_r. Subtracting the two equations and dividing by ΔE_r furnishes a third dependent equation. This third equation when ΔE_r approaches zero forms the differential of equation (8). It is evident then that the point of intersection or the envelope may be obtained by the simultaneous solution of one of the first two equations, *i. e.*, equation (8) and the third equation, *i. e.*, the differential. Since the envelope must be independent of the parameter E_r and since the simultaneous solution of equation (8) and its differential must be the envelope,

the latter operation may be accomplished by eliminating E_r from equation (8) and its differential.

Differentiating (8) with respect to E_r

$$2\,\alpha\,(P_r + \alpha\,E_r^2) - 2\,\beta\,(Q_r - \beta\,E_r^2) = (\gamma^2 + \delta^2)\,E_s^2 \qquad (9)$$

Let

$$(\gamma - j\,\delta) = \sqrt{\gamma^2 + \delta^2}\,\epsilon^{j\,\theta_1} = \sqrt{\gamma^2 + \delta^2}\,(\cos\theta_1 + j\sin\theta_1)$$

$$(\alpha - j\,\beta) = \sqrt{\alpha^2 + \beta^2}\,\epsilon^{j\,\theta_2} = \sqrt{\alpha^2 + \beta^2}\,(\cos\theta_2 + j\sin\theta_2)$$

Substituting in equation (6) and equating reals and imaginaries, we obtain

$$P_r + \alpha\,E_r^2 = \sqrt{\gamma^2 + \delta^2}\,E_s\,E_r\cos(\theta_1 - \theta)$$

$$Q_r - \beta\,E_r^2 = \sqrt{\gamma^2 + \delta^2}\,E_s\,E_r\sin(\theta_1 - \theta)$$

Substituting these values in equation (9)

$$2\sqrt{\gamma^2 + \delta^2}\,E_r\,[\,\alpha\cos(\theta_1 - \theta) - \beta\sin(\theta_1 - \theta)\,] = (\gamma^2 + \delta^2)\,E_s$$

Now since

$$\frac{\alpha}{\sqrt{\alpha^2 + \beta^2}} = \cos\theta_2 \text{ and } \frac{\beta}{\sqrt{\alpha^2 + \beta^2}} = -\sin\theta_2$$

then $2\,E_r^2\sqrt{\alpha^2 + \beta^2}\cos(\theta_1 - \theta_2 - \theta) = \sqrt{\gamma^2 + \delta^2}\,E_s\,E_r$ (10)

This relation must be true for every point on the envelope. Now from Fig. 1 it will be seen that $(\theta_1 - \theta_2 - \theta)$ is the angle between $b\,N$ and the line of center $\overline{o\,b}$, $E_r^2\sqrt{\alpha^2 + \beta^2}$ is the length $o\,b$ and $\sqrt{\gamma^2 + \delta^2}\,E_s\,E_r$ is the radius of the power circle. How can we determine the particular position of N such that equation (10) will also hold true? With O as center draw a circle through b. The diameter of the circle will be $2\,E_r^2\sqrt{\alpha^2 + \beta^2}$ and $b\,c$ is $2\,E_r^2\sqrt{\alpha^2 + \beta^2}\cos(\theta_1 - \theta_2 - \theta)$. The point c, therefore, satisfies equation (10) and lies on the envelope. To determine the envelope locus lay off $o\,c$ equal to $o\,b$ for the different receiver power circles.

Point where Envelope Cuts Line of Centers

It is sometimes convenient to know the point at which the envelope cuts the line of centers. This point is determined when $\theta_1 - \theta_2 - \theta = O$.

From equation (10) we then have

$$E_r = \frac{\sqrt{\gamma^2 + \delta^2}}{2\sqrt{\alpha^2 + \beta^2}}\,E_s$$

The distance of the point of tangency from the origin is the radius of the $(P_r + j\,Q_r)$ circle or $\sqrt{\alpha^2 + \beta^2}\,E_r^2$ which is equal to

$$\frac{\gamma^2 + \delta^2}{4\sqrt{\alpha^2 + \beta^2}}\,E_s^2$$

This is also the smallest circle which touches the envelope.

Equation of the Envelope

Let us take the point where the envelope cuts the line of centers as origin (e in Fig. 1) and the line of centers as the X axis. The abscissa x of any point c on the envelope is then

$$x = c\,o + o\,b - d\,b$$

$$= \frac{\gamma^2 + \delta^2}{4\sqrt{\alpha^2 + \beta^2}}\,E_s^2 + \sqrt{\alpha^2 + \beta^2}\,E_r^2 - \frac{\gamma^2 + \delta^2}{2\sqrt{\alpha^2 + \beta^2}}\,E_s^2$$

$$= \sqrt{\alpha^2 + \beta^2}\,E_r^2 - \frac{\gamma^2 + \delta^2}{4\sqrt{\alpha^2 + \beta^2}}\,E_s^2$$

The ordinate $y = d\,c$

$$= \sqrt{\gamma^2 + \delta^2}\,E_s\,E_r\sin(\theta_1 - \theta_2 - \theta)$$

$$y^2 = (\gamma^2 + \delta^2)\,E_s^2\,E_r^2\sin^2(\theta_1 - \theta_2 - \theta)$$

$$= (\gamma^2 + \delta^2)\,E_s^2\,E_r^2\left[1 - \frac{\gamma^2 + \delta^2}{4\,(\alpha^2 + \beta^2)}\,\frac{E_s^2}{E_r^2}\right]$$

$$= \frac{(\gamma^2 + \delta^2)\,E_s^2}{\sqrt{\alpha^2 + \beta^2}}\left[\sqrt{\alpha^2 + \beta^2}\,E_r^2 - \frac{\gamma^2 + \delta^2}{4\,(\alpha^2 + \beta^2)}\,E_s^2\right] = \frac{(\gamma^2 + \delta^2)\,E_s^2}{\sqrt{\alpha^2 + \beta^2}}\,x$$

This equation is one of a parabola referred to its apex as origin.

Maximum Power Delivered by Line

The maximum power that may be drawn over a transmission line depends upon the line constants, generator and receiver voltage and also upon the characteristics of the synchronous condenser. With a condenser of infinite capacity the maximum power is determined when $\dfrac{d\,Q_r}{d\,P_r}$ is equal to infinity. From the geometry of the circle diagram this value is seen to be

$$\sqrt{\gamma^2 + \delta^2}\,E_s\,E_r - \alpha\,E_r^2$$

However, with a condenser of finite size the characteristics of the condenser must be taken into consideration.

Maximum Power Delivered by Line with Finite Condenser

Let us consider a definite case. Fig. 2 shows the receiver circle diagram of a single 220-kv., 3-phase, 250-mile line, 600,000-cir. mil copper conductor with 22 ft. triangular spacing. The condenser characteristics which we will choose for this line are represented by the full lines in Fig. 3, terminal voltage being plotted against leading and lagging kilovolt-amperes for constant field current. The transformer reactance is included in the condenser characteristics. Assuming for the time being a dead resistance load, the loci of constant field current may be plotted on the circle diagram as shown in Fig. 2. For the case in which all or part of the load consists

of inductive apparatus, the variation of reactive power with voltage must be considered in plotting the loci of constant field current on the circle diagrams. Care must be exercised in reading such a graph. The loci of constant excitation are not double valued functions of voltage, as might appear at first, since some of the curves cut the same voltage circle twice. The inter-

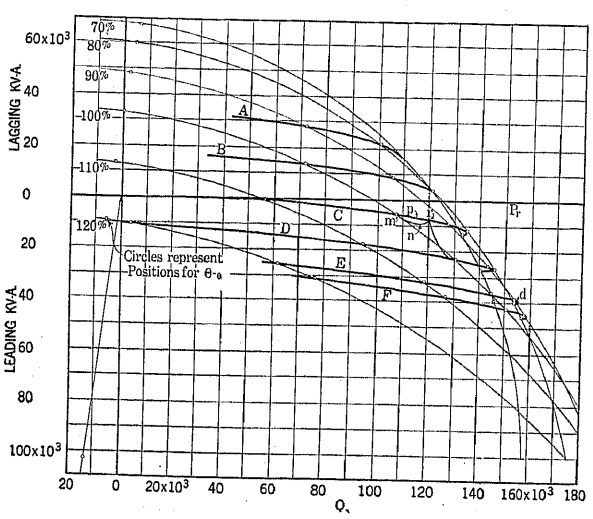

Fig. 2—250-Mile Line with 35,000 Kv-a. Leading and Lagging Condenser

sections of the upper portions of the curves with voltage circles refer to the higher values of voltage while the intersections of the lower portions refer to the lower values of voltage. The maximum power that may be drawn over the line for a given field excitation is determined when $\frac{d P_r}{d Q_r}$ is zero. Another relation[6]

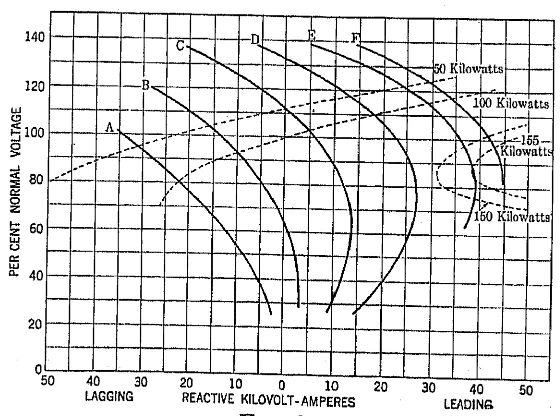

Fig. 3

Full lines represent condenser characteristics with constant excitation. Dotted lines represent reactive kv-a. relation for constant power as taken from circle diagram.

which must be satisfied at the maximum power is that $\frac{\partial Q_r}{\partial E_r}$ for the circle diagram (constant real power) be simultaneously equal to $\frac{\partial Q}{\partial E_r}$, where Q is the combined reactive kilovolt-amperes of the condenser and the load. The truth of this relation is shown graphically in Fig. 3, by plotting the values of reactive power against voltage for constant true power (dotted lines). As can be seen the maximum power which permits of a solution for a fixed excitation occurs for that value of power the curve of which is tangent to the excitation curve.

Stability with Load of Constant Resistance

The physical significance of what occurs when an increment of load is applied may be best illustrated by

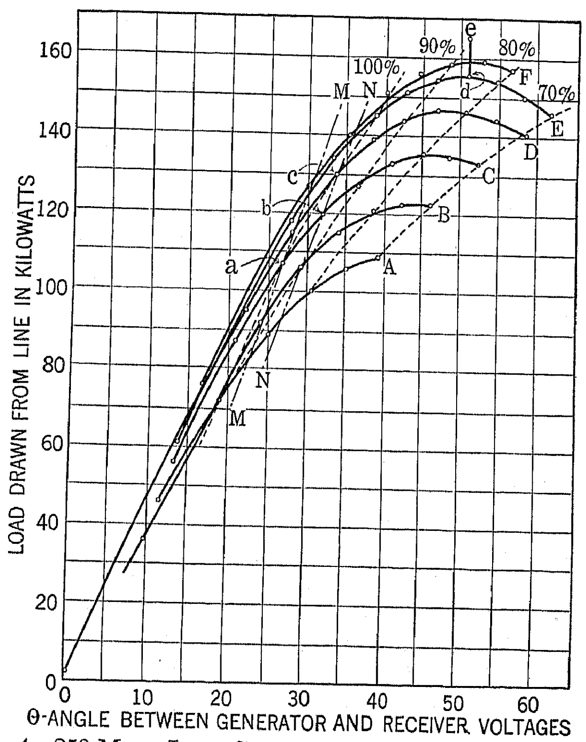

Fig. 4—250-Mile Line Characteristics with 35,000 Kv-a. Condenser

Full line—constant excitation.
Dotted line—constant voltage.
Dot-dash—constant load resistance.

still another curve. Fig. 4 shows the synchronous condenser curves of constant field current plotted with angle between generator and receiver voltage as abscissas and power drawn from the line as ordinates. These values were obtained from the constant field current loci in the circle diagram. Fig. 4 also shows loci of constant voltage and constant load resistance for the transmission line. The former represent the relation between the power drawn from the line and the angle between the generator and receiver voltage for constant voltage and the latter express the power taken by the load as a function of the angle between the generator and receiver voltage for constant load resistance. For our present discussion let us assume the generator voltage fixed in magnitude and phase posi-

6. The companion paper by Evans and Bergvall discusses this relation in greater detail.

tion, *i. e.*, a generator of zero impedance and armature reaction.

Suppose we are operating at the point a on Fig. 4, the intersection of the curve of constant field current C, of constant voltage 100 per cent normal and of constant resistance $M - M$. Now reduce the load resistance to that corresponding to the locus $N - N$ still maintaining the same field current. The operating point tends to move to the new point b, but in doing so the angle between the generator and receiver voltages increases; *i. e.*, with fixed generator voltage the terminal voltage of the condenser lags behind its original position a. Due to its inertia the rotor is unable to follow the terminal voltage instantly. This condition requires the condenser to function as a generator and supply part of the increase in load during the period in which the rotor is slowing down to its new position approximately in phase with the terminal voltage.

The division of load between the condenser and line accompanying a decrease in load resistance (constant field current) is explained as follows. With a dead resistance load such as we are considering all of the change in reactive power even during the transition period must be supplied by the condenser. This latter quantity is approximately equal to

$$\frac{E_r^2 - E_n E_r \cos \phi}{X}$$

Where E_r = Terminal voltage
E_n = Rotor voltage
X = Leakage reactance of condenser
ϕ = Angle between E_r and E_n

For steady state and also for the small angular swings during the transition period $\cos \phi$ will be very nearly equal to unity. For our present discussion we may then assume the reactive power to be a function of X and the scalar value of E_r. This shows that the terminal voltage during the transition period must vary along a locus similar to those of constant excitation shown on Fig. 2. These new loci differ from those of constant excitation only in the fact that the latter use leakage reactance and the former use synchronous impedance. For zero leakage reactance the loci coincide with the voltage circles. The true loci lie between the loci of constant voltage and the loci of constant excitation in which the synchronous impedance were used. In this way the relation between voltage and angular position of the terminal voltage which must be maintained during the early part of the transition period is determined. After the field in the condenser has built up, the synchronous impedance must be used. To state these facts slightly differently. Suppose we are operating at the point m in Fig. 2. With a condenser of zero impedance the operating point would be constrained to lie on locus of constant voltage $m\,p$ even during the transition period. With a condenser of zero armature reactance, *i. e.*, the leakage reactance equal to the synchronous reactance the operating point would be constrained to lie on the locus of constant field current during the transition period. But with a practical condenser, as the load resistance is changed with constant excitation the operating point will be constrained to lie on the curve $m\,n\,r$. The exact curve is a complex function of time, varying as the effective reactance changes from the leakage valve to the synchronous value and also varying with the speed the rotor changes its angular position. Immediately after the load resistance is changed the operating point will jump to an intermediate point which can be definitely determined. In the determination of this point the leakage reactance shall be used.

Now coming back to Fig. 4. Suppose we are operating at the point a and the load resistance is decreased. The operating point will be constrained to move along a curve lying between the locus of constant voltage and the locus of constant excitation. With a condenser impedance other than zero the receiver voltage drops with increasing angular displacement between the generator and receiver voltage as we move along the constraint. For every value of angular displacement there is a definite value of voltage. The power taken by the load can then be determined by the relation E_r^2/R where R is equal to the new load resistance. Fig. 5A shows an enlarged view of the section of Fig. 4 in the vicinity of point a Curve $a\,d\,b$ is the receiver voltage constraint and $e\,g\,f$ is the power taken by the load. The vertical distance between $e\,f$ and $a\,d\,b$ represents the excess of the power required by the load over that supplied by the line.

Due to its inertia the rotor cannot follow the terminal voltage instantly as it moves from a. Neglecting the effect of damper windings the power supplied by the condenser for an angle ϕ lag of terminal voltage behind the rotor is equal to $\frac{E_n E_r}{X} \sin \phi$. Draw $a\,g\,h$ such that the vertical distance between it and $a\,d\,b$ is equal to the above quantity where ϕ is measured from a. The angle to which the terminal voltage will jump is then determined by the intersection g. At this point the excess of the power required by the load over that supplied by the line is equal to that supplied by the condenser.

In supplying this energy the rotor of the condenser begins to lag behind its original position. This requires the curve $a\,g\,h$ to move to the right taking the positions shown by the dotted lines. In doing so the intersection moves from g downward along $e\,f$, the power supplied by the rotor steadily decreasing until the point b is reached. The rotor may overshoot but oscillates about b as a limiting position.

The locus $a\,d\,b$ is drawn assuming the field had built up and developed the full synchronous reactance. The dot-dash line shows the locus when the field has not had time to develop. Under certain conditions of low-frequency oscillations in the field the operating point

might even encircle the point b. With an extremely heavy rotor the operating point will move slowly from point d and with a light rotor correspondingly faster. In the above discussion the effect of the damper windings was neglected. As soon as the receiver voltage leaves a relative motion between the terminal voltage and the rotor takes places in such a manner as to convert the condenser into an induction generator. The damper windings and induced currents in the field coils and field structure determine the rate at which the operating point moves from a. We thus have the double effect of synchronous generator and induction generator action in retarding the rotor as it moves to its position b. Beyond the point b both effects reverse,

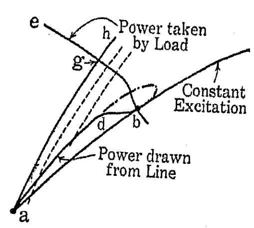

Fig. 5A

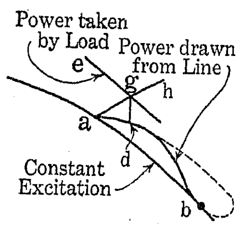

Fig. 5B

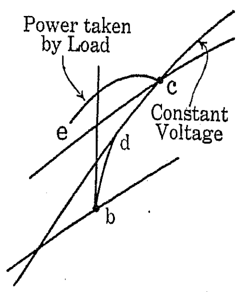

Fig. 5C

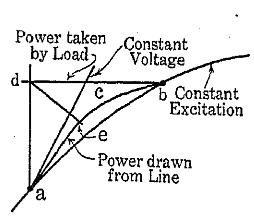

Fig. 5D

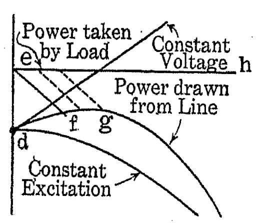

Fig. 5E

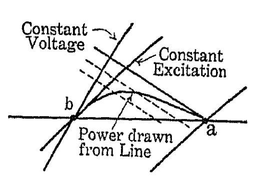

Fig. 5F

thus tending to bring the rotor back to b. There appears to be no reason in this case for suspecting a condition of instability as far as the condenser is concerned.

Referring to Fig. 2, the question sometimes arises as to the stability with a dead resistance load of operating at a point on the lower side of a locus of constant excitation. Fig. 5B shows a diagram similar to that of 5A except that it represents a point on the under side of the constant excitation locus. There appears to be no tendency toward instability. This condition alone, is then insufficient to determine the limit of instability with a dead resistance load. The true limit of instability appears to be at that point where $\frac{dP}{d\theta}$ for constant excitation is equal to $\frac{dP}{d\theta}$ for constant load resistance. If this angle is exceeded by decreasing the load resistance further the amount of power supplied by the rotor increases as the rotor lags and finally pulls out of step.

Now it will be noted that in decreasing the load resistance with constant excitation the terminal voltage drops. This brings the voltage regulator of the condenser into action. Let us then consider the distribution of power as the load resistance is kept constant and the field current is increased. Let the operating point be b Fig. 4 and increase the excitation from that corresponding to C to that corresponding to D. Fig. 5C shows an enlarged view of that part of the section. Inasmuch as it is the field of the condenser itself which produces the change, the operating point will not jump to an intermediate point immediately. The process is more gradual, the point moving from b toward c by the line $b\,d\,c$. The exact position of $b\,d\,c$ depends upon the inertia of the rotor, the magnetic circuit, etc. The power absorbed by the load is $e\,c$. This line is conditioned by the variations in voltage imposed by the locus $b\,d\,e$. The rotor in retarding supplies the differences in power designated by the vertical distance between $b\,d\,c$ and $e\,c$.

Stability with Inductive Load

The foregoing considered the conditions pertaining to a dead load. With an induction motor load which is essentially constant power independent of voltage, other factors must be considered. Taking proper cognizance of the variation of its reactive load with voltage, a set of curves similar to those of Fig. 4 can be constructed. However, for our discussion let us use the same curves.

Let us assume again that we are operating at the point a Fig. 4. Let us increase the load from that corresponding to a to that corresponding to b. Fig. 5D shows the transition period. The line $d\,b$ represents the power taken by the load. The line $a\,c$ is determined by the reactive kilovolt ampere relations that must be satisfied, (leakage reactance used instead of synchronous reactance and variation of lagging kilovolt-ampere taken by induction motor load as voltage changes). The initial operating point is constrained to lie upon this line. The vertical distance between any point on $a\,c$ and the line $d\,b$ represents the excess of the power required by the load over that drawn for the line. Draw $d\,e$ such that the vertical distance between $d\,e$ and $d\,b$ represents the power supplied by the rotor as the receiver voltage lags behind the rotor. The intersection of $a\,c$ and $d\,e$ therefor, represents the point to which the operating point will jump (neglecting damping action) as the load is increased. After this point is reached the operating point moves toward b. The exact path taken depends

upon the inertia of the rotor, the magnetic circuit, etc. There is no apparent instability.

But suppose we are operating on one of the excitation curves where the slope is zero (Fig. 4), say at the point d on excitation curve E. Suppose the load is increased to the value corresponding to that of e. Fig. 5E represents the transition diagram. The line $d\,f$ again represents the locus of constant leakage reactance, determining the initial point f to which the operating point jumps. As the rotor lags the line $e\,f$ moves to the right as shown by the dotted lines. After the point g is reached the power supplied by the retardation of rotor, *i. e.*, the vertical distance between $e\,h$ and $d\,g$ begins to increase; the affect becomes cumulative, the more the motor lags the greater the amount of power it supplies and the faster it retards until pull-out occurs. Under these conditions we may then say that stable operation results provided the excitation curve Fig. 4 has a positive slope. Referring to Fig. 2 stable operation results up to the point where $\frac{d\,P_r}{d\,Q_r}$ for constant excitation becomes equal to zero.

Changing the excitation maintaining the load constant produces a transition diagram similar to Fig. 5F This condition is likewise stable until the slope of the particular excitation curve Fig. 4 is zero.

An induction motor load has another effect. It has been observed in low-voltage transmission circuits in which the resistance is about equal to the reactance that hunting of the condenser at the receiver end takes place. It has been further observed that the presence of an unloaded induction motor tended to stabilize the line. This result may be explained as follows: In the foregoing, as instantaneous changes in load or field current occurred the receiver voltage changed instantly to a new position. However, with an induction motor, as soon as the vector of terminal voltage moves from its original position, it represents an increase or decrease in actual vector velocity. This in turn increases or decreases the slip. As a result the rotor of the induction motor momentarily takes care of the increase or decrease of the load. This occurs as soon as the voltage begins to change position. The induction motor then acts as a cushion in absorbing the shocks incident to change of load, excitation, etc. It decreases hunting but does not otherwise affect the power limit.

Considerations Involved in Extremely Long Lines

The question sometimes arises as to the stability of a condenser located at the end of an extremely long line. To investigate this point let us consider a 220-kv., 60-cycle, 500-mile line. Fig. 6 shows the circle diagram of such a line with the loci of constant excitation superimposed thereon. Fig. 7 shows data for the 500-mile line similar to that shown in Fig. 4 for the 250-mile line. Applying the same type of analysis to Fig. 7 as has been applied to Fig. 4 we may arrive at the same conclusion, *viz.*, for a dead resistance load there appears to be no apparent stability even beyond the point of maximum power for fixed excitation, but for an induction motor load the maximum load occurs when the differential of real power with respect to θ for any voltage is equal to zero. This latter condition also

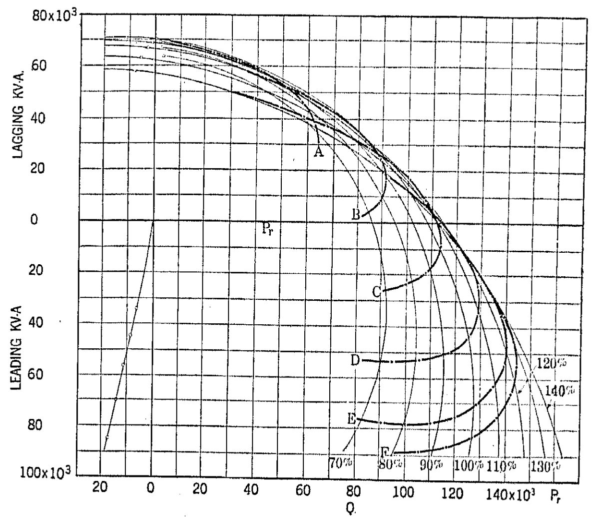

Fig. 6—500-Mile Line with 70,000 Kv-a. Leading and Lagging Condenser

requires that $\frac{d\,P_r}{d\,Q_r}$ for the locus of constant excitation be zero, *i. e.*, when the slope on Fig. 6 is vertical.

The value of plotting the condenser characteristics as on Fig. 6 may be illustrated. A condenser capable of supplying 70,000 kv-a. lagging and 70,000 kv-a. leading

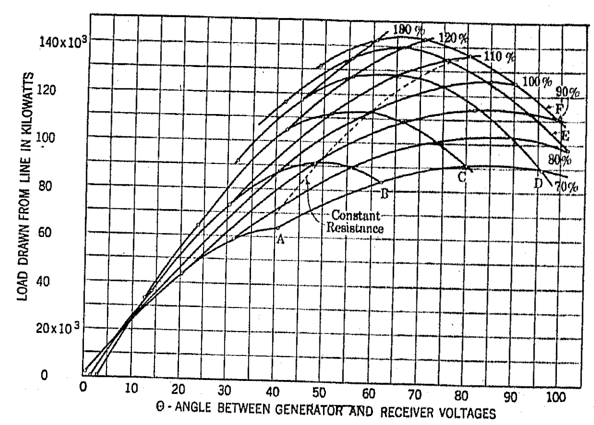

Fig. 7—500-Mile Line Characteristics with 70,000 Kv-a. Condenser

Letters refer to constant excitation. Figures refer to per cent of normal voltage.

at 100 per cent voltage was selected. From the circle diagram alone one would suppose that with 70,000 kv-a. leading capacity at 100 per cent voltage about 126,500 kw. could be drawn from the line. The actual limit, however, as determined by the slope of the constant excitation locus is 110,000 kw.

500-Mile Line with Intermediate Condenser Station

In recent years much thought and analysis have been given to the question of transmission of large blocks of power over great distances. Mr. Frank Baum,[7] in particular, has made a very comprehensive survey of our national resources, power markets, etc. His general solution of the superpower problem suggests placing synchronous condenser stations at intermediate points along the line to supply the charging kilovolt-ampere of the line, maintain constant voltage, and increase the power limit of the line. The first step in the logical development of such a system necessitates the analysis of, say, the 500-mile problem with a condenser station at the midpoint. The circle diagram for the receiving end section assuming constant 100 per cent potential at the midpoint would be the same as Fig. 2. With the given condenser, the maximum power limit at 100 per cent voltage is 151,000 kw. and for reduced voltage the power limit may be extended to 159,000 kw. The questionable element lies in the combined line and condenser characteristics at the

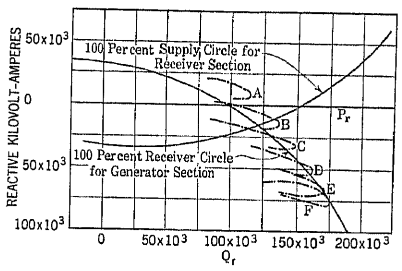

Fig. 8

Constant field current loci of condenser at mid-point of 500-mile line, plotted against power transmitted at mid-point and reactive power drawn from generator section, 100 per cent voltage at generator and at receiver.

midpoint. Fig. 8 shows the loci of constant field current for a 70,000-kv-a. leading and lagging condenser. These loci represent the relation between real and reactive power drawn from the generator section at the midpoint for constant excitation of the condensers, assuming constant normal voltage at the generator and receiver ends. The maximum power limit in this case occurs on the 100 per cent voltage circle at 175,000 kw. This value is more than sufficient to supply the losses in the receiver section. We could probably use a much smaller condenser. In practise this capacity would be built in several units. We can safely say then that the maximum power limit of the 500-mile with a condenser at the midpoint is 159,000 kw. The rated power of such a line allowing for switching power surges, let us estimate at about 120,000 kw. The actual reactive power required at this load is zero at the midpoint and about 15,000 kv-a. leading at the receiver.

Let us compare this line with a straight 500-mile line. Examination of Fig. 6 will show that little can be gained by supplying leading reactive power at the receiver. Let us assume then the power limit to be 115,000 kw. at zero reactive power. The rated power on the same basis as above, *viz.*, 75 per cent of maximum power would be about 86,000 kw. The active reactive power at this load at the receiver is 29,000 kv-a.

What have we gained? The rated capacity of the line has been increased from 86,000 kw. to 120,000 kw. an increase of 40 per cent. At the same time the condenser capacity required at these loads has been decreased from 29,000 kv-a. to 15,000 kv-a.

What has it cost? The no-load synchronous condenser capacity is practically unchanged. For the simple line the no load reactive power is sufficient to regulate up to the maximum power limit assumed, but the "compound" line requires 35,000 leading kv-a. at the receiver for load conditions in addition to the 35,000 kv-a. lagging at no load. The midpoint also requires about 70,000 kv-a. leading capacity under load conditions in addition to 70,000 kv-a. lagging under no load. But the greatest disadvantage is the housing of the condensers at the midpoint with all the necessary switching facilities. This last point should, however, be greatly discounted by the greater reliability of service obtained. It is quite improbable that a 500-mile line would be constructed without providing appropriate switching facilities at the midpoint to provide for emergency conditions. Mr. Frank G. Baum has pointed out other advantages of the intermediate condenser station.

Considering the pros and cons it is apparent that the increased line rating and reliability of service is well worth the additional condenser station equipment. For longer lines the need for intermediate condenser stations is still more pronounced. The exact number of stations in longer lines rests upon the economy of the situation,—the amount of power that can be sold, the cost of power at the power-house bus bars and similar questions affecting the problem.

Conclusion

The writers have attempted to bring out the following points:

1. A proof of the circle diagram has been given maintaining therein the idea of the angle between the generator and receiver voltages.
2. A graphical means for the determination of the envelope of the receiver power circles and an analytical proof showing the envelope to be a parabola with its axis as the line of centers of the circles.
3. It has been shown how the characteristics of the synchronous condenser limit the maximum power that can be transmitted over a line.
4. The effect of character of load on stability has been discussed.
5. The characteristics of a 500-mile line have been discussed and compared with the characteristics of the same line with a condenser station at the midpoint. This comparison resulted very favorably for the latter combination.

Power Transmission

BY F. C. HANKER
Member, A. I. E. E.
Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

Introduction

THIS paper briefly reviews the development of power transmission, pointing out the power limitations of long distance, high capacity transmission systems. The paper serves as a general introduction to a group of papers, giving the results of analytical and experimental investigations of the power limits and stability of transmission systems. This group of papers which is to be presented at the A. I. E. E. Midwinter Convention includes, in addition to this paper by Mr. Hanker, papers by R. D. Evans and H. K. Sels; R. D. Evans and R. C. Bergvall; and C. L. Fortescue and C. F. Wagner.

The industrial supremacy of the United States can be traced directly to the general utilization of power in manufacture, transportation and agriculture. In their infancy, prime sources of power, both hydraulic and steam, were utilized directly, and consequently were relatively small in capacity and the use was restricted as to area. Today we can begin to appreciate the remarkable influence our electricity supply systems have had on the industrial expansion and can visualize to some degree the necessity of a national system that would remove any artificial barriers that arise in the path of full and free industrial development.

A similar condition existed in the development of the earlier power systems and the growth from the small isolated stations can be traced through several distinct stages. Initially, the area served was limited by the low voltage available for distribution and as a result only a small capacity station could be utilized. At that time the possibilities of voltage transformation were not recognized and, consequently, transmission and distribution were restricted to very nominal voltages. The advantage of the alternating-current system was soon appreciated, and as a result of the larger area it was possible to supply, the capacity of generating stations increased and the necessity for frequent stations of small capacity eliminated. The load on the early stations was almost entirely lighting and it was not until the advantages of the new power for industrial use became generally recognized that electricity supply systems became an important factor in the industrial expansion. As a result of the more general utilization of electric power through the development of higher voltages for transmission and distribution, small companies operating in adjacent districts were merged and the advantage of generation in larger units secured. In addition, there was the advantage accruing from the ability to supply diversified industries with less capital investment than by individual plants. From this condition, the second stage developed, and we had what may be termed group operation.

We are now at the beginning of the third stage, where the advantages of group operation have been fully realized and the desirability of the expansion of this plan is appreciated. Adjacent groups have interconnected, and with the full development, the economies of regional or national operation will be realized. A scheme of operation that will utilize the hydraulic resources of the country to the fullest extent will undoubtedly show the greatest economy. This cannot be accomplished by independent operation of different power units as it is impracticable to economically develop a number of projects due to the inability to utilize the power in a way that would justify the expense of development. With a well organized and practicable scheme of regional or national development it will be possible to work out a program that will gradually coordinate the available hydraulic resources with steam electric stations, utilizing various types of fuel to the fullest advantage.

The development of the art of generation and transmission soon attracted attention to hydroelectric possibilities located at points removed from the load centers that could utilize them to advantage. Studies of these propositions soon developed that there were definite limitations to the amount of power that could be transmitted over a single circuit without resorting to special conductor arrangements or intermediate regulating stations. Beyond these limitations the voltage conditions were found to be unstable and impossible of control. This situation led to careful analytical studies of fundamentals, so that today there is a fuller appreciation of the limitations of the system as a whole. Previous studies that have been published have dealt largely with individual units, as, for instance, a transmission line, without taking into full consideration the effect of the characteristics of the generating station, the transforming substation and the synchronous condenser equipment that would be required for voltage control. It was during the study of the transmission that was the basis of the general power system covered by the survey made of the districts contiguous to the northeast Atlantic sea-coast that improvements in the system layout were first given consideration by the engineers who have prepared the group of papers on this important problem.

The analytical studies made at that time indicated that the limitations to the amount of load that could be transmitted over a circuit could be increased materially by locating regulating stations at intermediate points along the line. These regulating stations would be

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

essentially the same as terminal stations now in use on transmission systems where synchronous condenser equipment is utilized for voltage regulation. In a similar way the synchronous condensers would be utilized to compensate for the reactive component of the line. As these stations would not be prime sources of power, there was some discussion as to their operating stability. It was fully recognized that a similar system with generating stations located at corresponding points was entirely satisfactory, but with this type of station the prime movers would have drooping speed characteristics and furnish a stabilizing element to the frequency.

With the proposed method of operation utilizing intermediate regulating stations, it was recognized that a number of conditions existed that could not be analyzed completely, as there was no operating experience or test data that were applicable. There was a certain amount of information available from analyses of tests made a number of years ago, from which it was possible to predetermine with a fair degree of accuracy the characteristics of the tie lines necessary to maintain parallel operation of the generating stations. These data apparently indicated a limitation to the amount of power that could be transmitted that would render the scheme under consideration prohibitive. It was realized that the success of the suggested layout was dependent on the stability of the regulating stations, both as to frequency and voltage. For that reason it was felt that a comprehensive experimental investigation should parallel the analytical studies. This was considered essential, due to the numerous assumptions it was necessary to make of the operating characteristics.

The group of papers here presented discuss the subject in all its phases, and the results of the mathematical analyses have been fully checked by the tests made on the experimental lines discussed in the paper presented by Messrs. Evans and Bergvall.

In the papers on "Power Limitations of Transmission Systems" by Messrs. Evans and Sels, the analytical studies leading to an understanding of power limitations are fully outlined. A number of very interesting and valuable conclusions developed through the analytical studies have been fully confirmed by the test results that are given in the companion paper. Analytical studies of the problem, both general and specific, are given in the paper by Messrs. Fortescue and Wagner. All these studies cover important phases of the problem and, supported as they are by experimental data, will be extremely valuable to engineers investigating power projects where the amount of power to be transmitted exceeds present practise. The results have such an important bearing on the economic layout of transmission systems that the importance of the conclusions cannot be over-estimated.

Discussion

Westinghouse Electric & Manufacturing Co.

and

H. K. SELS
Assoc. A. I E. E.
Distribution Department
Public Service Electric Co. of New Jersey

Review of the Subject—*Several independent studies have been made recently to determine the economies of a large, uniform power system. The two studies of more general interest were those conducted by the Department of the Interior, under the direction of W. S. Murray, for the Superpower Zone, and by F. G. Baum for the United States. Both of these investigations are available in published form.*

During the progress of the Superpower Survey, one of the longest transmission lines proposed was that extending 350 miles from the Niagara Falls Development to New York City. Under emergency conditions on this line, the power limit for the maximum amount of power was approached by two twin-circuit tower lines with three circuits carrying the emergency load. The maximum power limit would have been exceeded if two single-circuit tower lines had been employed, even though the transmission voltages and the total copper cross-section were the same as with the two twin-circuit tower lines. Similarly, several long, high-voltage lines will be required in a nation-wide system, especially through the middle western region as shown by Mr. Baum's report. The tendency to extensive transmission systems has emphasized the necessity of considering the factors which will limit the amount of power that can be transmitted any distance with the highest practical transmission voltage. On account of the transmission line characteristics, the power limits will be greater when the system is regulated by synchronous apparatus than when no such apparatus is used so that two power limits will be considered in this paper; first, for an unregulated system; and second, for a regulated system. However, while we are primarily interested in high-voltage systems in this paper, it should be kept in mind that these same methods of calculation may be applied to lower voltages in determining the power limitations of station tie lines.

It is commonly accepted that different types of networks have certain power limitations. For example, a very simple case quite generally known is that of a simple resistance circuit in which the power delivered is a maximum when the resistance of the load is equal to that of the line. Another familiar case is that of the electric arc furnace where the maximum power occurs when the resistance of the furnace arc is equal to the reactance of the electric furnace leads. The general phenomenon of maximum power limit in circuits of fixed reactance and variable resistance or load has been recognized and its theory worked out for numerous cases, such as short transmission lines, rotating machines, and transformers.

A power transmission system may be regarded as a special type of network. Ordinarily it consists of long, high-tension transmission lines and apparatus connecting generating stations with distant load centers which may be either at the terminus or at intermediate points on the high-tension lines. In large systems, the high-tension lines may form a network similar to an ordinary local distribution system.

Where synchronous condensers are not installed, the problem of the maximum amount of power which may be delivered through the system is similar to the simple resistance and reactance cases cited above in that additional load or shunt impedance simply alters the load and voltage in accordance with the relative impedances of the system.

The employment of synchronous condensers at the load centers or along the transmission lines to alter the power factor and maintain the voltage at the load materially increases the maximum amount of power that may be delivered over a given transmission network. The theoretical maximum amount of power, however, cannot be obtained under operating conditions because the synchronous equipment at the receiver drops out of step with the supply. Also, fluctuations in load will produce unstable conditions, which may accumulate sufficiently to cause the momentary swings in load to exceed the power limit, resulting in the receiver falling out of step with the supply at a lower load than it would under steady conditions. This is usually characterized as "hunting out of step."

In order to investigate the power limitations of a transmission system, it was necessary to rearrange and extend the present methods of transmission line calculations to make them more convenient for the study of the practical limit of maximum power. The method which has been found best adapted for this purpose is a development of the power circle diagram combined with the characteristic curves of the synchronous machines used to regulate the system. This power diagram has been made applicable to all the types of transmission systems by including the transmission line, step-up and step-down transformers, series and parallel circuits, so that the most complex transmission system may be represented by a single equivalent set of transmission constants. A general discussion of the methods of calculation, the maximum power limits, the practical operating limit and illustrated examples is given in Part I of the paper, and the analytical development upon which the discussion is based is given in Part II.

Part I

THE POWER DIAGRAM FOR TRANSMISSION SYSTEMS

SEVERAL methods of computing the performance of transmission lines have been developed and published from time to time. A review of numerous methods previously proposed by different authors, with examples illustrating each method of solution and other useful data, has been written by William Nesbit. The methods described employ current and voltage or corresponding vector quantities throughout. However, it has been found more convenient in this study to represent the supply and receiver voltages and receiver loads of a transmission system by means of power circle diagrams, such as illustrated in Fig. 1. A circle diagram may be defined as a graph of all receiver or supply loads that may be transmitted, assuming definite supply and receiver voltages. Various forms of circle diagrams have been presented, notably by R. A. Philip in 1911, followed by H. B. Dwight in 1913. A full analytical treatment of this diagram as applied to a complete transmission system is given in Part II of this paper.

In order to plot the circle diagram, it is necessary to determine only three constants, l, m and n which, when combined with the supply and receiver voltages selected, determine the centers and radii of the circles respectively for the assumed voltage conditions. It may be pointed out that the constant l is determined

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

largely by the resistance of the circuit; the constant m by the reactance of the circuit; and the constant n by the impedance of the circuit.

Referring to Fig. 1, the circle diagram shows at once:

(1) The synchronous condenser capacity required at no load, as indicated by the point x.

(2) The maximum load at unity power factor that may be delivered for the particular voltages assumed, as indicated by the point y.

(3) The maximum power that may be delivered for the particular voltages assumed, as indicated by the point z.

The diagram readily permits the determination of the synchronous condenser capacity required for any particular load condition at the receiver; for example, in Fig. 1, circle a, the receiver load represented by the point U corresponding to 120,000 kw. real power and 74,000 kv-a. reactive power (corresponding to 85 per cent power factor), will require a synchronous conden-

The point z indicates the maximum power limit for 220 kv. at both supply and receiver, which corresponds to the vertical tangent of the receiver circle a.

ser capacity represented by the line $U\,V$, or 85,000 kv-a.

Not only does the circle diagram permit representation of all receiver loads that may be transmitted for certain fixed supply and receiver voltage conditions, but it is readily adapted to represent changes in supply or receiver voltages. If the supply voltage only is varied, the radius of the receiver circle is varied in direct proportion, and the center of the circle is unchanged. In Fig. 1, the circle b represents the conditions with the supply voltage 10 per cent above that shown for circle a. If the receiver voltage only is varied, the radius of the receiver circle is varied in direct proportion and in addition, the center of the circle moves on the line $O\,C$ in proportion to the square of the receiver voltage. In Fig. 1, the circle c represents the conditions with the receiver voltage 90 per cent of that shown for circle a.

For the majority of cases, the transmission supply voltage may be assumed constant, and this leaves only the receiver voltage and receiver load as variables. By plotting the power circles for receiver voltages from

Projection "A" shows the voltage power surface as plotted against real power and reactive power. Projection "B" represents the voltage power surface as plotted against reactive power and receiver voltage expressed in terms of supply voltage. These diagrams are based on a 250-mile, 3-phase, 60-cycle transmission line with 750,000 cir. mil copper conductor, with 21 ft. equivalent spacing. In projection "B", two lines are drawn which indicate the power limits for different characteristics of synchronous machines with respect to their regulating effect.

zero to more than 100 per cent of the supply voltage, it is possible to obtain a very complete picture showing how changes in receiver load affect the receiver voltage and vice versa. In Fig. 2, projection A, a family of such receiver power circles is plotted for various receiver

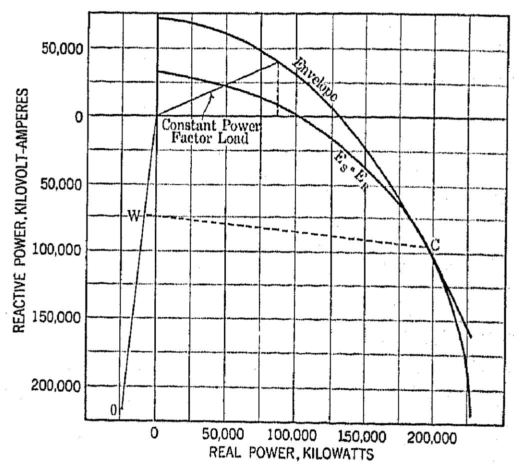

FIG. 3—THE ENVELOPE OF THE RECEIVER POWER CIRCUITS

This figure is based on the transmission circuit described in Figs. 1 and 2, with 220 kv. at the supply end. The circle drawn represents a condition with 220 kv. at the receiver. The power limit at the envelope and the maximum power limit for this transmission system are indicated.

voltages in steps equal to 10 per cent of the supply voltage. It will be observed that a curve can be drawn which will be tangent to the receiver power circles.[1] This curve is important in the study of maximum power

1. An independent investigation has also been made by J. Ossanna, *Electrotechnische Zeitschrift*, August 11, 1922.

limits, and will be designated as the "envelope" throughout this paper. It has not been shown on Fig. 2 as it would tend to obscure the circle diagrams. In Fig. 3, the envelope for the same transmission line as that plotted in Fig. 2 is shown together with the circle diagram for the receiver voltage equal to 100 per cent of the supply voltage.

Delivered power at a definite power factor is represented by a point in Fig. 2. If a point representing delivered power be selected within the envelope two power circles can be drawn intersecting at this point. This means that for any point within the envelope, there are two receiver voltages which will satisfy the receiver load and supply voltage conditions. For a point on the envelope, only one receiver voltage will satisfy the conditions, while for a point outside the envelope, there is no receiver voltage which will satisfy the conditions and consequently a point outside the envelope represents an imaginary operating condition. Therefore, the point at which any particular circle becomes tangent to the envelope is one type of power limit which will be described in greater detail in a separate section.

To understand the true significance of the power circle diagrams, it is desirable to conceive of them as a three-dimensional figure, that is, considering the supply voltage constant, the general equation representing the kilovolt-amperes delivered involves just three variables: The receiver power, the receiver reactive power, and the receiver voltage, which may be plotted along the X, Y and Z axes, respectively. By virtue of its construction, the surface of the figure represents all possible voltage-power conditions with a constant supply voltage. Since this surface has many interesting properties which are worthy of investigation, Fig. 2 has been plotted to show two projections, A and B, of the voltage-power surface; projection A shows the projection on the X-Y plane of inter-sections of the surface with planes parallel to the X-Y plane passing through points representing receiver voltages of 10 per cent, 20 per cent and so on of the supply voltage. Projection B shows the projection on the Y-Z plane of intersections of the surface with planes parallel to Y-Z plane passing through points representing 0 kw., 30,000 kw., 60,000 kw. and so on.

As previously mentioned, varying the supply voltage simply changes the radius of the receiver circle. Unless mentioned otherwise in the following discussion throughout the paper, the supply voltage will be considered constant.

Theoretical Maximum Power Limit

Heretofore, it has been the general practise of transmission engineers to consider only one circle diagram or one set of voltage conditions in their calculations, without relating the solution generally to other circle diagrams or calculations representing other voltage conditions. This interesting relationship is very important and gives the voltage power surface referred to above, which is plotted in Fig. 2. The study of these relationships is facilitated by the graphical conception of a surface which may be represented by an actual model.

The receiver load at any constant power factor may be considered as an impedance connected across the circuit, and if this impedance is varied from infinity to zero, the receiver load increases to a maximum and then decreases to zero. This is shown graphically by the line for constant power factor load in Fig. 3 with the maximum amount of power determined by the envelope.

If synchronous apparatus is available at the receiver for maintaining the voltage and controlling the power factor, the power limit may be increased. With infinite capacity in synchronous apparatus available, the power limit is that determined by the vertical tangent to the receiver circle for the voltages assumed.

Study of the voltage-power surface has developed some very interesting features which are associated with the performance characteristics of the synchronous apparatus used to regulate the system. These features will be further discussed in a subsequent section. For the time being the maximum limits may be considered as falling into two classes:

First: The power limit defined by the envelope for any given power factor of load and resulting voltage conditions. The load will include all kinds of electrical equipment, but if it includes any rotating equipment, this will fall out of step if the voltage drops sufficiently, or reduce load by a drop in speed if sufficient torque is still available when the power limit is passed.

Second: The power limit defined by the vertical tangent to the circle diagram. In addition to the load, synchronous apparatus is required to regulate the voltage-power conditions up to the maximum power point when the receiver will pull out of synchronism with the supply end.

For purposes of illustration, these two power limits have been identified on Fig. 2, the power limit for any given power factor being marked the "Power Limit at the Envelope," and the power limit described by a vertical tangent, the "Maximum Power Limit."

Practical Maximum Power Limit

The usual high-voltage transmission problem involves a regulated system with synchronous machines of limited capacity and commercial design. The Practical Maximum Power Limit, therefore, lies between the limits for an unregulated and a regulated system with infinite condenser capacity, that is, between the power limit at the envelope and a vertical tangent to the receiver circle. The characteristics of the synchronous machines which affect the power limit of a transmission system include not only the capacity in kilovolt-ampere, but also the regulating effect. By "regulating effect" is meant the change in reactive kilovolt-ampere for a definite change in voltage, the greater the change in reactive kilovolt-ampere, the

greater the regulating effect. The relation of the characteristics of synchronous machines to the power limits of a transmission system is indicated by the curves of regulating effects of loads sketched on Fig. 2.

In the discussion so far, no reference has been made to the practical limits of voltage regulation and power loss of transmission. In short transmission lines, the limits of voltage drop require synchronous condenser regulation, and even then the economic limits of power loss are usually reached before the envelope or maximum power limit is reached. However, in a long transmission line, especially above 350 miles, the chracteristics of the transmission system may be such as to make the envelope and maximum power limits within the practical limits of voltage regulation and power loss. In general, then, the discussion of the envelope and maximum power limit should be considered with a large transmission system, or in connection with the synchronizing stability of short lines between power stations where large loads are momentarily thrown on the tie lines so that they exceed the power limits and the stations fall out of synchronism. In this connection, it may be noted that a short circuit on the secondary system may be considered as a shunt loading on the transmission system and the corresponding circle diagram obtained on this basis.

Effect of Transmission Design on the Power Limits

The methods for increasing the Practical Maximum Power Limits of transmission systems will next be considered. These methods may be divided into two classes.

(1) Those which increase the power limits as determined by the envelope and the vertical tangent to the receiver power circles, and

(2) Those which permit stable operation at points closer to the maximum power limit.

The first class depends upon the modification of the circuit constants of the transmission line or increasing the transmission voltage, so that the power limits are actually increased. The second class is dependent upon the characteristics of the rotating machinery in the load, which will be discussed in a companion paper.

The relation between the circuit constants of the transmission line which will give the maximum power limits, has been analyzed in Part II of this paper. The results of this analysis show that for long transmission lines the l constant should be small, and the n constant large; and for short transmission lines, that the resistance should be made as small as practicable, and that the reactance be equal to $\sqrt{3}$ times the resistance. It becomes necessary, therefore, to distinguish between the cases where the reactance of the transmission line is large or small in comparison with the resistance. In general, the reactance of a transmission circuit will decrease very slowly with increase in conductor size, whereas the conductivity increases directly. Consequently, for large capacity, high-voltage circuits, the reactance becomes several times the resistance, and this case will be considered first.

In general, the power limits of a transmission system are increased by the use of larger conductors or increased voltage. However, at any given voltage, an indefinite increase in conductor size will not increase the power limits proportionately, because of the slight effects on the l and n constants, or in other words, when the resistance becomes negligible in comparison with the reactance, and the reactance is only slightly reduced. Curves B and C of Fig. 4 show the two power limits for a group of 3-phase, 60-cycle transmission lines, 250 miles in length, operated with 220 kv. at both supply and receiver ends. It will be noted that the increase in size of copper conductor from 600,000

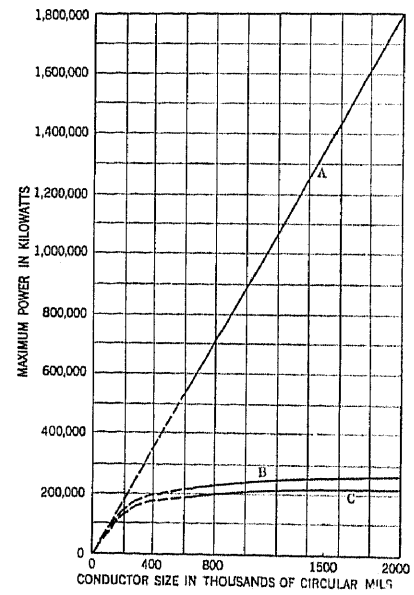

Fig. 4—Relation of Power Limits to Conductor Size

This diagram is based on transmission lines, 250 miles in length, with 3-phase, 60-cycle supply, and 21 ft. equivalent spacing, with 220 kv. maintained at the supply. Curve "A" shows the maximum power limit with unrestricted receiver voltage and condenser capacity, Curves "B" and "C" show the maximum power limit, and power limit at the envelope respectively for the condition with 220 kv. maintained at both supply and receiver. The difference between curves "A" and "B" or "C" indicates the limitation in the transmission of power due to the reactance of the transmission circuit with 60-cycle supply.

cir. mils to 2,000,000 cir. mils only increases the maximum power limit about 20 per cent. Therefore, it is apparent that the conductor size should not be increased indefinitely, except to economically reduce the power loss consistent with the increased cost of line. In a high-voltage transmission system, the corona effect may require a conductor size above which no appreciable gain in power limits will be obtained.

Curve A of Fig. 4, has been plotted as a matter of interest to show the maximum power that can be transmitted with unlimited receiver voltage and synchronous condenser capacity. This curve is given by equation 35 in Part II. By reducing this equation to the short line case, equation 36, it will be seen that

under these conditions of operation, the maximum power is only limited by the resistance of the line as in the case of direct current, the reactance of the line being offset by the leading power factor of the load and high receiver voltage. With small conductor sizes, the resistance is the determining factor of the power transmitted, so that all limits approach curve A, but with increased conductor size and limited receiver voltage the power transmitted is determined by the reactance, so that for large conductor sizes, there is a very large difference from curve A.

One method for increasing the power limit of a single circuit involves the use of a divided conductor. The arrangement would be similar to that proposed by Percy H. Thomas in a discussion on the "Critical Load"[2] of a transmission line. The increase in the power limit that may be accomplished by this method is determined by the limitation in the separation of the individual conductors due to the formation of corona. Wherever practicable, the maximum number of circuits should be employed. For example, double-circuit tower lines instead of single-circuit tower lines, should be used, thus greatly increasing the power limits.

Conductor spacing has an important effect on the power limits; the closer the spacing, the greater the power limits. However, variation in the spacing of conductors is not a practical method of increasing the power limit, for the reason that the closest spacing consistent with the avoidance of interruption to service and possible operation at higher voltages in the future, will always be employed.

The case in which the reactance of the transmission conductor is small in comparison with the resistance rarely occurs with 60-cycle power supply, except possibly with low-voltage, small capacity circuits, or an underground cable system. With 25-cycle power supply, however, this condition is likely to occur with moderate capacity systems. The conditions for obtaining the maximum amount of power in this case require that the resistance be made as low as practicable, and that the reactance be increased to equal $\sqrt{3}$ times the resistance. Hence, in this particular case, increased spacing of the transmission conductors or the use of reactors with underground cable would result in increasing the power limits of the circuits.

The ratio of the resistance to the reactance of a transmission circuit has an interesting effect on the power limits. If the load on a transmission circuit operating under constant voltage conditions is increased from no load, the receiver loads follow along the circle diagram, passing through the point of tangency with the envelope, and through the point of maximum power. If the reactance of the transmission circuit is several times the resistance, the power limit at the envelope is reached before the maximum power limit; on the other hand, if the reactance is small in comparison with the resistance, the maximum pow limit is reached first. Consequently, for transmissi circuits having a low ratio of reactance to resistan the special regulating characteristics of synchrono machines become unimportant.

The frequency of the power supply has an importa effect on power limits, particularly for the transmissi of large amounts of power where high voltage ar large-capacity circuits will be employed. For suc conditions, the 60-cycle reactance is many times tl resistance, and the use of a lower frequency, for exan ple, 25 cycles, would reduce the reactance and increas the power limit by more closely approaching tl theoretical conditions for transmitting the maximu amount of power with a given conductor. The max mum power limit for a 250-mile transmission line wit 636,000 cir. mil aluminum conductors is shown i Fig. 5, with curve B showing the power limit for 6 cycles, and curve D the corresponding power limit for 25 cycles. It will be noted that the power limit is increased at the lower frequency from 35 per cent to 65 per cent, depending upon the distance.

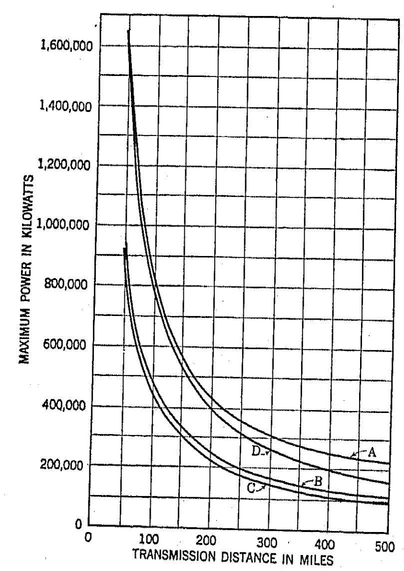

FIG. 5—RELATION OF POWER LIMITS TO LENGTH OF TRANSMISSION LINE

These diagrams are based on a transmission circuit employing 636,000 cir. mil aluminum conductor with 21 ft. equivalent spacing, and with 220 kv. maintained at the supply end. Curve "A" shows the maximum power limit with 60-cycle supply with unrestricted receiver voltage and condenser capacity. Curve "B" shows the maximum power limit with 60-cycle supply and 220 kv. maintained at the receiver. Curve "C" shows the power limit at the envelope with 60-cycle supply and 220 kv. maintained at the receiver. Curve "D" corresponds to curve "B", except that the power supply is 25 cycles.

The effect of considering the reactance of transformers has not been mentioned previously. It is evident from the preceding discussion that the addition of the reactance of transformers might increase the power limit for certain conditions, particularly on moderate-capacity, 25-cycle systems. On the other hand, for high-capacity, high-voltage systems, such as the 220-kv. systems which have been proposed, the

2. Percy H. Thomas, A. I. E. E. TRANSACTIONS, 1910.

addition of the transformer reactance will decrease the power limits appreciably.

Within the last few years, the idea of a loaded transmission line has been developed. By this means, it is possible to obtain equivalent transmission constants which are more favorable for the transmission of power than those that could be obtained by modification in transmission line conductor spacing, arrangement or size. With a loaded transmission line, it is proposed to install at intervals a "lumped" impedance connected either in series or in parallel with sections of the "smooth" transmission line. For the condition in which the reactance of a short transmission line is less than $\sqrt{3}$ times the resistance, the power limit will be increased by adding series reactors connected at intervals in the transmission line, as proposed by R. A. Philip.[3] The method of series loading with inductance, however, is of very limited application, because with the usual transmission problem, the reactance is already in excess of the desired amount.

The use of shunt loading with synchronous machines was proposed in a paper before the A. I. E. E. in 1921, by F. G. Baum. This method of loading for increasing the power limits is, in effect, one of variable shunt capacity. The effect of loading a transmission line with intermediate synchronous condensers which are controlled so as to maintain constant voltage at these points, is to increase the power limits of the system as a whole to the power limit for the individual sections. In other words, a 500-mile transmission line with one intermediate loading point, in effect increases the amount of power that may be transmitted to that of a 250-mile section. In Fig. 5, curve B shows that the maximum power limit with 220 kv. at the supply and receiver ends of a 3-phase, 60-cycle, 636,000 cir. mil aluminum conductor transmission line is about 121,000 kw. for the 500-mile line, and about 180,000 kw. for the 250-mile line. Consequently, a loaded transmission line, 500 miles in length, would be capable of delivering 180,000 kw., less a small amount for losses in the second 250-miles section of the line. In order to bring out quantitatively the present limits of high-voltage transmission, four problems will be worked out which will also show the advantage of loading the transmission circuit.

Examples of High-Voltage Transmission

From an engineering standpoint, it is practically impossible to predict the limits which high-voltage transmission will reach. However, from a commercial viewpoint, 220 kv. and certainly not more than 330 kv. will meet our requirements for some time to come, as good operating practise will limit the amount of power which should be entrusted to a single circuit. As the power systems grow, these limits will be raised, but this will be a process of considerable development.

Assuming a tentative standard of 220 kv. as the present highest transmission voltage, it is interesting to note the characteristics of different lengths of lines. It has been pointed out in Fig. 5 that the power limit is rapidly reduced by increased distance so that considerably more power can be carried by making up a long line of several sections with synchronous condenser loading at intermediate points.

Table I shows the transmission constants for 250, 500 and 750 mile lines, and Tables II, III and IV show

3. R. A. Philip, "Economic Limitations," A. I. E. E. Transactions, 1911. This proposal was based on short lines as the effect of capacity was neglected.

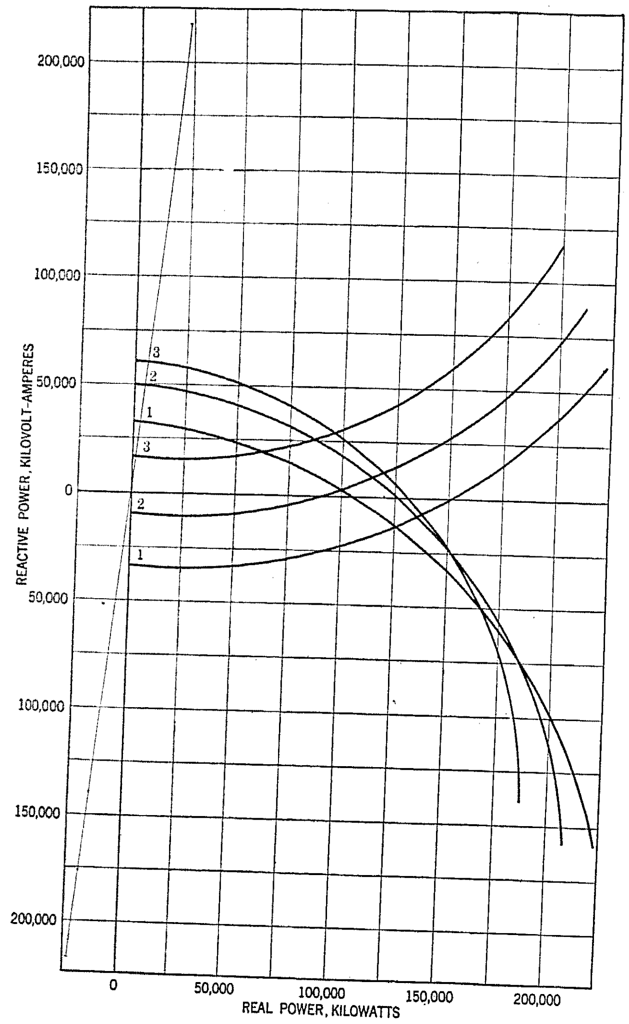

Fig. 6—Circle Diagram for 250-Mile Transmission Line

This diagram is based on 750,000 cir. mil copper conductors, 21 ft. equivalent spacing, with 220-kv., 3-phase, 60-cycle supply. Circle 1 represents the condition for the receiver voltage equal to the supply voltage. Circles 2 and 3 represent the conditions with the receiver voltage equal to 90 and 80 per cent of the supply voltage respectively. The receiver power circles have their centers below the "X" axis, while the supply circles have their centers above the "X" axis.

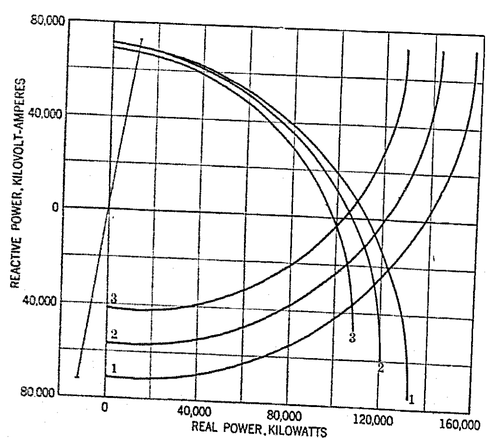

Fig. 7—Circle Diagram for 500-Mile Transmission Line

This diagram is similar to Fig. 6, except for the increase in transmission distance. Curve 1 represents the receiver circle for a voltage equal to the supply voltage of 220 kv. Circles 2 and 3 represent the conditions with receiver voltages 90 and 80 per cent of the supply voltage respectively.

the circle diagram constants for these lines respectivel All of the previous figures except Figs. 4 and 5 ha been plotted from the constants in Table II. Tl circle diagrams for each line have been plotted in Fig 6, 7 and 8 for three-voltage conditions, so as to indicat the general shape of the diagram with respect to tl voltage power surface. The supply power circle di grams corresponding to the receiver power circle di grams are also plotted in Figs. 6, 7 and 8.

Fig. 6 of the 250-mile line corresponds to the usu diagram for a short line indicating the amount of lin charging kilovolt-ampere which must be taken care o The diagram for the 500-mile line, Fig. 7, shows a larg amount of charging kilovolt-ampere which complet

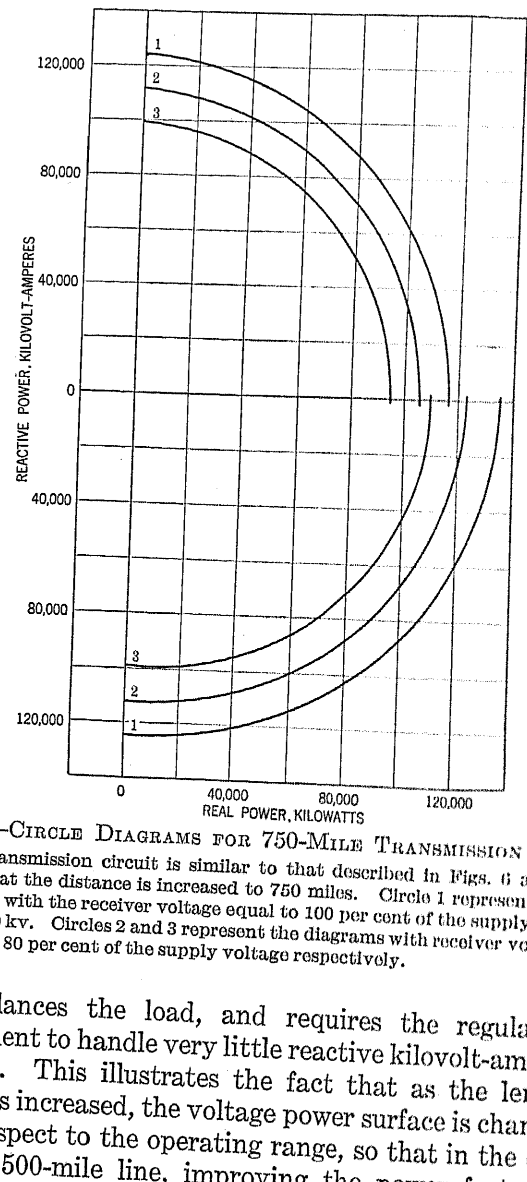

Fig. 8—Circle Diagrams for 750-Mile Transmission Line

The transmission circuit is similar to that described in Figs. 6 and 7, except that the distance is increased to 750 miles. Circle 1 represents the condition with the receiver voltage equal to 100 per cent of the supply voltage of 220 kv. Circles 2 and 3 represent the diagrams with receiver voltages of 90 and 80 per cent of the supply voltage respectively.

overbalances the load, and requires the regulating equipment to handle very little reactive kilovolt-ampere leading. This illustrates the fact that as the length of line is increased, the voltage power surface is changed with respect to the operating range, so that in the case of the 500-mile line, improving the power factor to leading decreases the voltage at all loads and the operating range is at lagging power factor. This imposes a heavy requirement on the characteristics of the regulating equipment, since it must be designed for heavy lagging loads, and hence high reactance when,

in order to obtain maximum stability, the machine should have minimum reactance.

In Fig. 8 for the 750-mile line, which is approximately one-quarter wave length for 60 cycles, the receiver must operate at lagging power factor, and the supply at leading power factor for all loads. This gives a higher voltage throughout the middle of the line at all loads, and the poor operating power factor serves to make the system unsatisfactory aside from all possibility of resonant conditions with either supply or receiver open-circuited or unstable operation of synchronous machines.

From a general consideration of the characteristics of the line, it is apparent that the longest transmission section of a line should not exceed 250 miles, and shorter sections would be preferable to obtain a higher average power factor, and hence lower losses at all loads, and a considerable increase in the power limits and general stability of the system. Based on the economic number of loading points, it is estimated conservatively that 135,000 to 150,000 kw. per circuit can be transmitted from any existing power supply to a load center with equipment commercially available.

Conclusion

To recapitulate on the points of general interest in transmission system design, there are several items to be considered:

(1) Methods of calculation have been developed in the power circle diagram which accurately determines the maximum power limits under various circuit and electrical conditions.

(2) Two types of power limits have been discussed with their relation to the load and regulating equipment.

(3) Methods of increasing the power limits have been discussed in transmission design.

(4) On the basis of economy and stability of operation, it is recommended that a single section of line be less than 250 miles, and longer lines loaded at intermediate stations with synchronous condensers so that no section exceeds 250 miles.

In concluding, it is important to note the general application of the methods developed to any transmission layout and to the determination of the load capacity or synchronizing capacity between stations in studying the performance of a system.

Part II

Theoretical Discussion

General Circuit Constants

In any transmission system[4] the relation between supply and receiver voltages and currents may be expressed in the following form:

$$\left.\begin{aligned} \dot{E}_s &= A_o \dot{E}_r + B_o \dot{I}_r \\ \dot{I}_s &= C_o \dot{E}_r + D_o \dot{I}_r \\ \dot{E}_r &= D_o \dot{E}_s - B_o \dot{I}_s \\ \dot{I}_r &= -C_o \dot{E}_s + A_o \dot{I}_s \end{aligned}\right\} \qquad \textbf{(1-4)}^5$$

the nomenclature for which is fully explained under caption "Nomenclature." These equations are in the familiar form in which A, B and C constants are employed, but the D_o constant has been added to provide for the general case. The use of A_o, B_o, C_o and D_o constants is required when the entire transmission system including transmission line and transformers is considered. The D_o constants has a value different from A_o for all cases where the transmission system is unsymmetrical about its center.

The general circuit constants may be derived from the consideration of the two elementary networks, the series impedance Z and the shunt admittance Y, and their combinations in series or parallel. The value of the general circuit constant as applied to these elementary networks is given in Table V.

TABLE V
GENERAL CIRCUIT CONSTANTS

Constant	Series Impedance	Shunt Admittance
A_0	1	1
B_0	Z	0
C_0	0	Y
D_0	1	1

Two of these elementary networks may be combined in series with constants, voltages and currents as indicated in Fig. 9. The equations are as follows:

$$\left.\begin{aligned} \dot{E}_1 &= A_1 \dot{E}_r + B_1 \dot{I}_r \\ \dot{I}_1 &= C_1 \dot{E}_r + D_1 \dot{I}_r \\ \dot{E}_s &= A_2 \dot{E}_1 + B_2 \dot{I}_1 \\ \dot{I}_s &= C_2 \dot{E}_1 + D_2 \dot{I}_1 \end{aligned}\right\} \qquad \textbf{(5-8)}$$

By eliminating $\dot{E}_1$ and $\dot{I}_1$ from equations (**5**) to (**8**) a solution in the form of equations (**1**) and (**2**) may be obtained where:

$$\left.\begin{aligned} A_o &= A_1 A_2 + B_2 C_1 \\ B_o &= B_2 D_1 + A_2 B_1 \\ C_o &= A_1 C_2 + C_1 D_2 \\ D_o &= B_1 C_2 + D_1 D_2 \end{aligned}\right\} \qquad \textbf{(9-12)}$$

It will be noted that for the general case of two elementary networks in series the constants A_o and D_o are not equal in the combined network though they are both equal to unity for each elementary network. Consideration of equations (**9**) to (**12**) show that an indefinite number of networks may be added in series

4. The term transmission system, as employed in this paper, not only includes the transmission line itself but the remainder of the system as well; the transmission system is equivalent to a general network where each branch has constant impedance characteristics.

5. These equations may be interpreted as follows: In any transmission system, the supply voltages varies with receiver voltage and current. A_o and B_o being proportionality constants dependent upon the particular system involved. Similarly the supply current varies with receiver voltage and current, C_o and D_o being proportionality constants dependent upon the particular system involved.

and the form of equations (1) and (2) will not be changed. The constants of the smooth transmission line may be obtained with this method by combining an infinite number of elementary sections of series impedances and shunt admittances. It will also be noted that equations (9) to (12) cover the series combinations of two general networks and the process may be extended to cover all cases. Hence the use of A_o, B_o, C_o and D_o constants is applicable to all networks made up of elementary networks in series.

Elementary networks may similarly be combined in parallel. The equation for the case with constants,

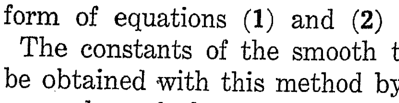

FIG. 9—TWO NETWORKS IN SERIES

voltage and currents as indicated in Fig. 10, are as follows:

$$\dot{E}_s = A_1 \dot{E}_r + B_1 \dot{I}_r' = A_2 \dot{E}_r + B_2 \dot{I}_r'' \quad (13)$$

$$\dot{I}_s = C_1 \dot{E}_r + D_1 \dot{I}_r' \quad (14)$$

$$\dot{I}_s'' = C_2 \dot{E}_r + D_2 \dot{I}_r'' \quad (15)$$

$$\dot{I}_s' + \dot{I}_s'' = \dot{I}_s \quad (16)$$

$$\dot{I}_r' + \dot{I}_r'' = \dot{I}_r \quad (17)$$

By eliminating $\dot{I}_r'$, $\dot{I}_r''$, $\dot{I}_s'$ and $\dot{I}_s''$ from equations (13) to (17), the equations may be written in the form of equations (1) and (2) with:

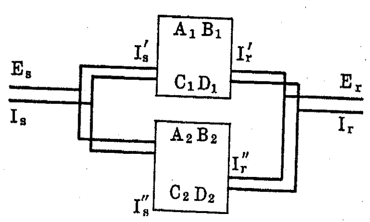

FIG. 10—TWO NETWORKS IN PARALLEL

$$\left.\begin{aligned}
A_o &= \frac{A_1 B_2 + A_2 B_1}{B_1 + B_2} \\
B_o &= \frac{B_1 B_2}{B_1 + B_2} \\
C_o &= C_1 + C_2 + \frac{(A_1 - A_2)(D_2 - D_1)}{B_1 + B_2} \\
D_o &= \frac{B_1 D_2 + B_2 D_1}{B_1 + B_2}
\end{aligned}\right\} \quad (18\text{-}21)$$

It will be noted that for the general case of two elementary networks in parallel that the A_o and D_o constants are equal, and further that if two general networks are paralleled, the A_o and D_o constants are unequal if the same constants are unequal in either branch, and the equations are similar to equations (1) and (2).

By the combination of series impedances and shunt admittances any network may be formed. Hence the use of A_o, B_o, C_o and D_o constants covers the general case of a transmission system.

It may be stated from an observation of equations (10), (11), (19) and (20) that the B_o and C_o constants are identical, whether calculated from the receiver end or supply end. On the other hand constants A_o and D_o when calculated from the receiver end are equal to the D_o and A_o constants respectively, when calculated from the supply end.

The preceding discussion has shown the applicability of general circuit constants to the solution of transmission problems not only for the smooth transmission line itself but also for the transmission line with transformers, the loaded line and transmission lines in parallel. For certain important cases, the solutions of the general circuit constants are given in Table VI.

DEVELOPMENT OF THE POWER DIAGRAM

For the analysis of the power limitations of transmission systems, the use of the power or circle diagram has been found very desirable. The circle diagram may be derived from the equations for the general case of transmission systems employing general circuit constants in the following manner; equation (1) and its conjugate may be written as follows:

$$\dot{E}_s = A_o \dot{E}_r + B_o \dot{I}_r \quad (1)$$

$$\bar{\dot{E}}_s = \bar{A}_o \bar{\dot{E}}_r + \bar{B}_o \bar{\dot{I}}_r \quad (22)$$

After multiplying these two equations together and simplifying the product by recalling that

$\dot{E}_s \bar{\dot{E}}_s = E_s^2$ and $\dot{E}_r \bar{\dot{E}}_r = E_r^2$ and $\dot{E}_r \bar{\dot{I}}_r = P_r + jQ_r$

the following equation may be written

$$E_s^2 = A_o \bar{A}_o E_r^2 + (A_o \bar{B}_o + \bar{A}_o B_o) P_r + j Q_r (A_o \bar{B}_o - \bar{A}_o B_o) + B_o \bar{B}_o \left(\frac{P_r^2 + Q_r^2}{E_r^2} \right) \quad (23)$$

The above expression may be written in the form of a circle as follows:

$$(P_r + l E_r^2)^2 + (Q_r + m E_r^2)^2 = n^2 E_r^2 E_s^2 \quad (24)$$

Where

$$l = \frac{A_o \bar{B}_o + \bar{A}_o B_o}{2 B_o \bar{B}_o} \quad (25)$$

$$m = j \frac{A_o \bar{B}_o - \bar{A}_o B_o}{2 B_o \bar{B}} \quad (26)$$

$$n = \frac{1}{\sqrt{B_o \bar{B}_o}} \quad (27)$$

Equation (24) is expressed in terms of line to neutral voltage and apparent power in each phase. For the usual case of three-phase transmission it is more convenient to use line voltage and total apparent power.

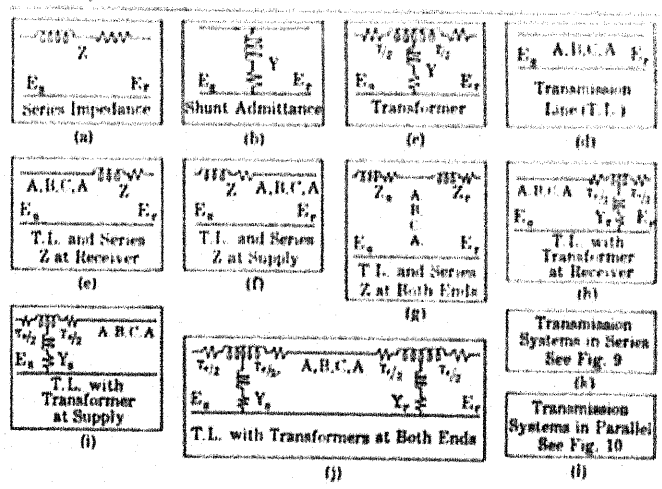
(l)	$A_0=\frac{A_1\,B_2+B_1\,A_2}{B_1+B_2}$	$B_0=\frac{B_1\,B_2}{B_1+B_2}$	$C_0=C_1+C_2+\frac{(A_1-A_2)(D_2-D_1)}{B_1+B_2}$	$D_0=\frac{B_1\,D_2+D_1\,B_2}{B_1+B_2}$



General Equations

$E_s = A_0\,E_r + B_0\,I_r$

$I_s = C_0\,E_r + D_0\,I_r$

$E_r = D_0\,E_s - B_0\,I_s$

$I_r = -\,C_0\,E_s + A_0\,I_s$

Nomenclature

E_s = Supply Voltage to neutral

E_r = Receiver Voltage to neutral

I_s = Supply Current per line

I_r = Receiver Current per line

Z = Total Impedance

Y = Total Admittance

T = Transformer impedance

s and r subscripts refer to supply and receiver ends

For this condition equation (24) becomes:

$$(P_R + l\, E_R^2)^2 + (Q_R + m\, E_R^2)^2 = n^2\, E_R^2\, E_S^2 \qquad (28)$$

the equation of the Receiver Power Circle Diagram.

The circle diagram is plotted with real power along the X axis and with reactive power along the Y axis. A point in the first quadrant represents $P_R + j\, Q_R$, a positive load at lagging power factor. Some prefer to plot the power diagram with positive values of $P_R + j\, Q_R$ representing leading power factor.[6] The A. I. E. E. Standardization Rules do not cover the method of plotting power diagrams. However, if the voltage vector is chosen as reference then positive values of $P + j\, Q$ should represent lagging power factor. Also it would appear that the following expressions are mutually consistent when positive numerical values represent lagging power factor:

$R + j\, X$ for impedance

$I_1 - j\, I_2$ for current

$P + j\, Q$ for power

For the receiver power circle the center is located at $-\, l\, E_R^2,\ -\, m\, E_R^2$ and the radius is equal to $n\, E_R\, E_S$.

The scale for the circle diagram from Equation (28) is expressed in volt amperes which is usually changed to kilovolt-amperes for plotting.

The corresponding circle diagram for the load at the supply end and for definite supply and receiver voltages may be derived in a similar manner from equation (3). The equation for the supply power circle diagram is as follows:

$$(P_S - l'\, E_S^2)^2 + (Q_S - m'\, E_S^2)^2 = (n'\, E_S\, E_R)^2 \qquad (29)$$

which represents a circle with center at $l'\, E_S^2,\ m'\, E_S^2$ and with radius equal to $n'\, E_R\, E_S$.

Where

$$l' = \frac{D_o\, \overline{B}_o + \overline{D}_o\, B_o}{2\, B_o\, \overline{B}_o} \qquad (30)$$

$$m' = j\frac{D_o\overline{B}_o - \overline{D}_o B_o}{2\, B_o\, \overline{B}_o} \qquad (31)$$

$$n' = \frac{1}{\sqrt{B_o\, \overline{B}_o}} \qquad (32)$$

It should be noted that the constants given by equations (25-27) are the same as those given above by equations (30-32) except that the A_o and D_o constants are used respectively.

Formulas for Power Limits

The formulas for determining the power limits for different conditions can be derived from the equation of the Receiver Power Circle Diagram. The relation between the receiver apparent power, supply and receiver voltage is given by equation (28). If unlimited condenser capacity at the receiver is considered available then for maximum power the condenser capacity Q_R may be chosen as equal to $(-\, m\, E_R^2)$ and equation (28) may be reduced to the following form—

$$P_R = n\, E_R\, E_S - l\, E_R^2 \qquad (33)$$

This equation shows that the receiver power is unlimited if the supply voltage is not restricted in value. Hence the formulas for power limits are based on a fixed supply voltage. By differentiating equation (33) with respect to P_R and E_R and considering E_S as a constant the value of E_R for maximum power is obtained which is

$$E_R = \frac{n}{2\, l}\, E_S \qquad (34)$$

Hence the theoretical maximum power that may be delivered over a given transmission system is given by the following equation—

$$P_R = \frac{n^2}{4\, l}\, E_S^2 \qquad (35)$$

which for short lines reduces to the familiar form of

$$P_R = \frac{E_S^2}{4\, R} \qquad (36)$$

The formulas for the theoretical maximum power derived above assumes a fixed supply voltage and a receiver voltage unrestricted in value. In the practical case, however, the receiver voltage must be restricted to a value approximately equal to the supply voltage. If the receiver voltage is made equal to the supply voltage then the expression for maximum power under this condition may be derived from equation (33) with the following result:

$$P_R = (n - l)\, E_S^2 \qquad (37)$$

which for short lines becomes

$$P_R = \frac{\sqrt{R^2 + X^2} - R}{R^2 + X^2}\, E_S^2 \qquad (38)$$

The formulas given above have been derived on the assumption that condenser capacity was available to deliver the maximum power over the transmission line for the different voltage conditions. It is sometimes desirable to determine the maximum power that may be delivered over a circuit without condensers. The maximum power for this condition is obtained graphically by the intersection of a line corresponding to the power factor of the receiver load and the envelope of the receiver circles as shown in Fig. 3. The equation of the envelope is obtained by taking the partial derivative of equation (28) with E_R as the parameter and eliminating E_R between the new equation (39) and the original equation (28).

$$2\, P_R\, l + 2\, l^2\, E_R^2 + 2\, Q_R\, m + 2\, m^2\, E_R^2 = n^2\, E_S^2 \qquad (39)$$

The equation of the envelope of the receiver circles is as follows:

$$4\, m^2\, P_R^2 + 4\, l^2\, Q_R^2 - 8\, l\, m\, P_R\, Q_R + 4\, l\, n^2\, E_S^2\, P_R + 4\, m\, n^2\, E_S^2\, Q_R - n^4\, E_S^4 = 0 \qquad (40)$$

6. See Discussion by J. R. Dunbar and H. B. Dwight, A. I. E. E. Journal December 1922, page 1027.

The maximum load at any power factor with $Q_R = \theta P_R$ may be obtained by eliminating Q_R from equation (**40**) and solving for P_R which gives

$$P_R = \frac{\sqrt{(l^2 + m^2)(1 + \theta^2)} - (l + \theta m)}{2(m - \theta l)^2} n^2 E_S^2 \quad (\mathbf{41})$$

The maximum load at unity power factor that may be delivered over a given line with fixed supply voltage is obtained by letting $\theta = 0$ in equation (**41**) which gives

$$P_R = \frac{\sqrt{l^2 + m^2} - l}{2 m^2} n^2 E_S^2 \quad (\mathbf{42})$$

which for short lines reduces to

$$P_R = \frac{\sqrt{R^2 + X^2} - R}{2 X^2} E_S^2 \quad (\mathbf{43})$$

The envelope also determines the power limit for a regulated transmission system employing synchronous apparatus of negligibly small capacity at the receiver. The power limit at the envelope is the point common to the particular circle corresponding to the supply and receiver voltages and the envelope of the receiver circles. This point is obtained from the simultaneous equations (**28**) and (**40**). In solving these equations it was found convenient to use the center of the receiver circle as origin and to rotate the axes using the following substitution:

$$P_R = \frac{W l}{\sqrt{l^2 + m^2}} + \frac{Z m}{\sqrt{l^2 + m^2}} - l E_R^2 \quad (\mathbf{44})$$

$$Q_R = \frac{W m}{\sqrt{l^2 + m^2}} - \frac{Z l}{\sqrt{l^2 + m^2}} - m E_R^2 \quad (\mathbf{45})$$

The solution of the equation to determine the power limit at the point on the envelope and a particular circle in Fig. 3, gives the following value for

$$W = \frac{n^2 E_S^2}{2\sqrt{l^2 + m^2}} \quad (\mathbf{46})$$

The corresponding value of P_R is as follows:

$$P_R = - l E_R^2 + \frac{n^2 l E_S^2 + m\sqrt{4 n^2 E_S^2 E_R^2 (l^2 + m^2) - n^4 E_S^4}}{2(l^2 + m^2)} \quad (\mathbf{47})$$

Although the above expression is rather complicated, there is fortunately a simple graphical construction for obtaining the value of P_R. This construction is based on equation (**46**), and it is necessary only to measure from the center of the receiver circle a distance

$$O - W = \frac{n^2 E_S^2}{2\sqrt{l^2 + m^2}} \quad \text{and}$$

to erect a perpendicular $W C$. The intersection of the perpendicular with the particular voltage circle gives the power limit at the envelope as shown in Fig. 3.

In order to emphasize the significance of the several formulas for Power Limits it is convenient to summarize them as follows:—

Equation 35. Maximum power that can be transmitted with unlimited receiver voltage and condenser capacity. (Regulated system).

Equation 37. Maximum power that can be transmitted with unlimited condenser capacity but with the receiver voltage equal to the supply voltage. (Regulated System)

Equation 41. Maximum power that can be transmitted at any given power factor with the resulting receiver voltage condition at the envelope (Unregulated System).

Equation 47. Maximum power that can be transmitted at the envelope with any given supply and receiver voltage condition.

Synchronous condensers may be required to maintain the receiver voltage assumed.

Effect of Variation in Circuit Constants on Power Limits

The formulas for the Power Limits have been derived and the effect of changes in circuit constants on these limits will next be considered. Equation (**35**) shows that with unrestricted receiver voltage that (1) for long transmission lines the values of l should be made small and the value of n should be made large, (2) for short lines the resistance should be made as small as possible in order to transmit the maximum amount of power.

For the condition with equal supply and receiver voltage but with unrestricted condenser capacity, the equation (**37**) shows that n should be made large and l should be made small. For this same condition the solution of equation (**37**) with (**1**) the resistance R assumed fixed, the value of X should equal $\sqrt{3}\,R$ and (**2**) with the reactance X assumed fixed, the value of R should equal $(= X/\sqrt{3})$ and for the practical case R should have as small a positive value as possible.

The effect of variation in the value of the circuit constants on the envelope will next be considered. For the condition with unrestricted receiver voltage and condenser capacity it may be shown that the maximum value of the envelope coincides with the power limit and the formulas for this condition are the same as derived for power limit, namely, equation (**35**) and (**36**). Hence for this condition the value of n should be made large and the value of l should be made small, which for short lines reduces to the requirement that the resistance should be made small.

For the condition with equal supply and receiver voltage the maximum load from the standpoint of the envelope is given by equation (**47**) with $E_R = E_S$. For short lines this condition reduces to the following expression

$$P_R = \frac{\sqrt{3}\,X - R}{2(R^2 + X^2)} E_S^2 \quad (\mathbf{48})$$

For the practical cases of positive values of X and R the value of P_R is a maximum with R as small as possible and with $X = \sqrt{3}\,R$.

Nomenclature

The following nomenclature has been used in this article:

E_S = Supply line voltage
E_s = Supply voltage to neutral
E_R = Receiver line voltage
E_r = Receiver voltage to neutral
I_s = Supply current per line
I_r = Receiver current per line
P_R = Three-phase power in watts
P_r = Phase to neutral power in watts
Q_R = Three-phase reactive volt-amperes
Q_r = Phase to neutral reactive volt-amperes
R = Circuit resistance per phase
X = Circuit reactance per phase
Z = Circuit impedance per phase
Y = Circuit admittance per phase
A_o, B_o, C_o, D_o = General circuit constants for fundamental equations. See Table 6 for different networks
l, m, n = Receiver circle diagram circuit constants
l', m', n' = Supply circle diagram circuit constants
A_R, B_R, C_R = Receiver circle diagram constants
A_S, B_S, C_S = Supply circle diagram constants

Discussion

Experimental Analysis of Stability and Power Limitations

BY R. D. EVANS and R. C. BERGVALL
Associate, A. I. E. E. Associate, A. I. E. E.
General Engineers, Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa.

Review of the Subject.—*A method of determining the power and voltage stability limit of a transmission system taking into account the characteristics of the synchronous condenser and load in conjunction with the characteristics of the line is described.*

The power limit of a straight 500-mile transmission line is calculated by this method. The power limit is also calculated for the same line with a synchronous condenser at the mid-point which divides the line into two sections. The addition of the synchronous condenser at the mid-point increased the power limit 42 per cent.

Tests were made on a 625 kv-a. transmission system operated at 2300 volts to determine experimentally the power and voltage stability limit of a transmission line with a synchronous condenser at the mid-point. The tests check closely with the calculated values.

Tests on hunting caused by prime mover pulsations, line characteristics and voltage regulator adjustment were made.

It was found that the damper windings on synchronous condensers do not have much effect in reducing hunting, particularly at resonant points. There was practically no difference between the standard high-resistance windings used for starting purposes and low resistance copper damper windings.

On a high-resistance and low-reactance transmission line hunting was found to occur at high condenser field excitations. The addition of reactance stabilized the system. On high-voltage transmission lines the reactance is high as compared to resistance and no difficulty from hunting due to line characteristics is to be expected.

A loose adjustment of the voltage regulator dash pot was found to set up hunting.

Short circuits were applied through reactance to a system carrying load to determine the severity and duration of a short circuit required to cause the system to pull out of synchronism.

The time element between the application of the short circuit and pull out was found to be due to the time required to reduce the voltage to a point where the power limit of the system was exceeded at the reduced voltage.

INTRODUCTION

DUE to the rapid growth in the use of electrical energy economic conditions have made it necessary to consider the transmission of large blocks of power over great distances. Theoretical investigations of these transmission problems have indicated that there is a definite limit to the amount of power which can be transmitted over a given line.

On high-voltage transmission lines this limit is determined principally by the reactance, which is large as compared to the resistance, on account of the wide conductor spacing. Previous investigations have mainly considered the limitations of the transmission line alone. In an actual transmission system the nature of the load and the size and characteristics of the synchronous condensers must be taken into account in determining the maximum amount of power which can be transmitted without hunting, loss of synchronism, or voltage instability taking place.

The maximum amount of power which can be transmitted over a given line may be increased by "loading the line" with synchronous condensers at intermediate points. The use of synchronous condensers in this manner was given consideration for the transmission lines from the St. Lawrence and Niagara developments of the Superpower Survey. This subject has been presented before the Institute by F. G. Baum in a paper published in the August 1921 A. I. E. E. JOURNAL.

The present paper covers an investigation, supplemented by actual tests, of the factors affecting the stability of transmission systems. The tests were made on two artificial "*T*" transmission lines which were built up of resistors, reactors, and static condensers, and operated normally at 2380 volts. Power was obtained from a 625-kv-a. generator and two 425-kv-a. synchronous condensers were available, thus permitting the "loaded line" operation to be tested. Standard voltage regulators of the vibrating type were used with the generator and each of the synchronous condensers. The tests were carried out on a large scale so that results comparable with those in actual operation could be obtained.

DETERMINATION OF THE POWER LIMITATIONS OF A TRANSMISSION SYSTEM

Use of circle diagrams. Power Limit of Transmission Line Alone.

An actual transmission line with its step-up and step-down transformers is quite a complicated network, since it involves series impedances and exciting admittances of the transformers in addition to the distributed resistance, inductance, and capacity of the line itself. The characteristics of this complicated network can conveniently be represented by means of circle diagrams. An exact method of combining the constants of the line with those of the transformers to obtain the general circuit constants of the entire network is described in the companion paper entitled "Power Limitations of Transmission Systems." From the general circuit constants thus derived the mathematically exact circle diagrams can be obtained. The method of calculating circle diagrams and their characteristics has been covered in other papers[1] and there-

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

R. D. Evans & H. K. Sels, *Elec. Journal* for July, August, Dec. 1921 and February 1922.

fore only a brief review of their characteristics will be given.

Consider the conditions at the receiver end of the transmission system shown in Fig. 1, with the generator voltage regulator set to maintain a constant voltage of 100 per cent at the supply end of the line. If the voltage regulator for the synchronous condenser is set to maintain the same voltage (100 per cent) at the receiver end of the line independent of the load, then as the kilowatts drawn over the line are gradually increased

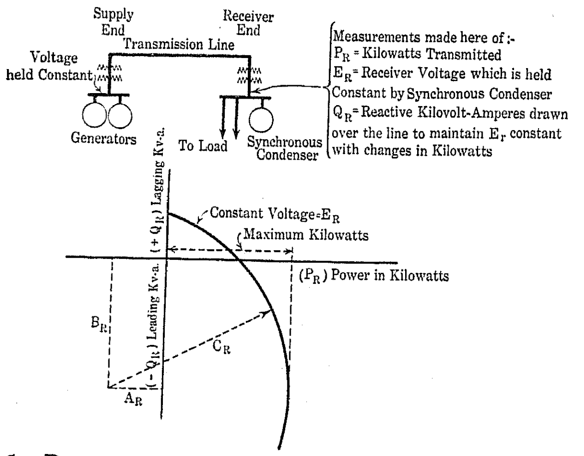

FIG. 1—RECEIVER VOLTAGE CIRCLE FOR THE LINE SHOWN ABOVE

the reactive kilovolt-amperes drawn over the line must be varied to maintain the receiver voltage constant. The relation between kilowatts and reactive kilovolt-amperes for a constant receiver voltage is a circle whose center has the coordinates A_R and B_R and whose radius is C_R.

The maximum amount of power which can be delivered over the line with 100 per cent voltage maintained at both ends of the line is indicated on the circle diagram. It should be noted that the line is unable to deliver more than the maximum kilowatts shown even though normal voltage is maintained at both the supply and receiver ends of the line. Power is transmitted over the line due to a difference in phase between the supply and receiver voltages. The power limit of the line itself as determined from the receiver circle diagram corresponds to the point at which a further increase in the phase displacement between the ends of the line results in a decrease in the amount of power which can be delivered.

With the supply voltage still maintained at 100 per cent and the synchronous condenser voltage regulator set to maintain 90 per cent voltage at the receiver end of the line the relation between kilowatts and reactive kilovolt-amperes at the receiver is still a circle, the coordinates of its center being $\left(\frac{90}{100}\right)^2 = 81$ per cent of the A_R and B_R for the 100 per cent receiver circle. The radius is reduced to 90 per cent of the C_R for the 100 per cent circle. In this manner a family of circles showing the relation between kilowatts and reactive kilovolt-amperes at the receiver for different receiver voltages with a constant supply voltage can be drawn. Fig. 16 shows the 90—100—110 per cent receiver circles for one of the line conditions tested and Fig. 2 shows a large number of receiver circles for a typical 250-mile transmission line. The relation between kilowatts and reactive kilovolt-amperes at the supply end of the line is also a circle. The supply circle for 100 per cent receiver voltage is also shown on Fig. 2.

The maximum amount of power at various constant receiver voltages, which the line (with transformers) *considered by itself* can deliver, may be determined from the receiver circle diagrams. The power limit of the entire system, taking into account the characteristics of the apparatus connected to the line will, in general, be less than the power limit of the line alone.

Power Limit of Entire System. Stability of Receiver Voltage. The necessity for considering the characteristics of the synchronous condensers and load as well as the characteristics of the line in determining the maximum amount of power which a system can deliver has already

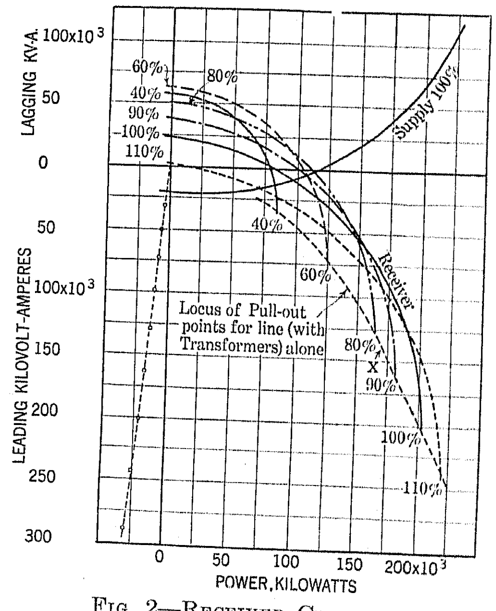

FIG. 2—RECEIVER CIRCLES

Receiver voltages expressed in per cent of 220 kv.

been pointed out. The power limitations and stability of the receiver voltage are so closely related that it is best to consider them at the same time. When a constant amount of power is being delivered at the receiver, the usual conception is that an increase in lagging kilovolt-amperes drawn over the line will decrease the receiver voltage, or conversely, an increase in leading kilovolt-amperes will increase the receiver voltage. On most transmission lines this is not true beyond a certain load.

Fig. 2 shows the receiver circle diagram for a 250 mile transmission line with step-down transformers included as a part of the line. The voltage has been assumed to be held constant at 220 kv. at the high-tension side of the step-up transformers. The various circles show the relations between kilowatts and reactive kilovolt-amperes for different voltages at the receiver end expressed as a percentage of 220 kv.

It is apparent that, with a constant kilowatt load being transmitted, the receiver voltage (with constant supply voltage) depends on the reactive kilovolt-amperes drawn over the line. For a particular load this relation can be determined from the receiver circles in Fig. 2, for example, at 175,000 kw. the 90 per cent circle requires 105,000 kv-a. leading, the 100 per cent circle requires 90;000 kv-a. leading and the 110 per cent circle requires 100,000 kv-a. leading. The power limit of the line alone when transmitting 175,000 kw. occurs at point x when the receiver voltage has been reduced to 86 per cent. The reactive load then is 145,000 kv-a. leading. The curves drawn in full on Fig. 3 were derived from Fig. 2 in the foregoing manner and show the relation between receiver voltage and reactive kilovolt-amperes at a number of constant loads.

Referring to Fig. 3, when a 175,000 kw. are being delivered at 100 per cent voltage 90,000 leading kilo-volt-ampere must be drawn over the line to maintain this voltage. It appears that at 90,000 kilovolt-amperes leading a considerable fluctuation in receiver voltage could take place, namely, from 98 per cent to 102 per cent. Below 100 per cent voltage an *increase in leading kilovolt-amperes* produces a *decrease* in receiver voltage, which is exactly the reverse of the usual action. *If* an increase in excitation of the synchronous condensers were always accompanied by an increase in the leading kilovolt-ampere drawn over the transmission line, the operation of the voltage regulator set to maintain 100 per cent voltage, would become unstable at 175,000 kw., because with a drop in voltage the regulator would increase the condenser excitation, causing more leading kilovolt-amperes to be delivered and still further decreasing the line voltage. However, voltage instability in general does not occur at this point because, as will be shown later, an *increase* in excitation of a synchronous condenser is not always accompanied by an increase in the leading kilovolt-amperes delivered by the condenser, or if operating in the lagging kilovolt-ampere range of the condenser an increase in excitation does not always reduce lagging kilovolt-amperes drawn over the line as will be shown later. A 500-mile line would be inoperative if this were true.

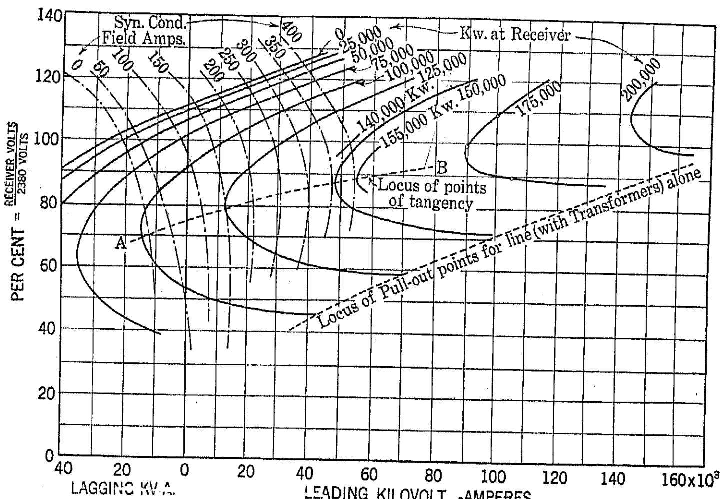

Fig. 3—Transmission Line and Synchronous Condenser Characteristics

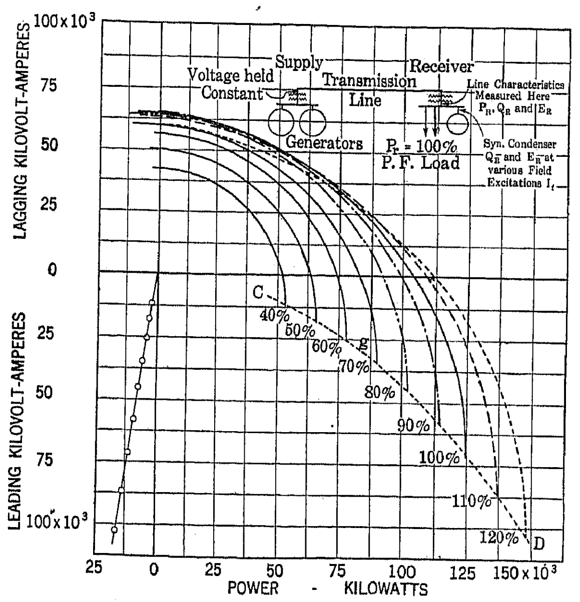

Fig. 4—Receiver Circles

500-mile transmission line. with stepdown transformers; 750,000 cir. mil copper, 19 ft. equivalent spacing; 90,000 kv-a. transformer bank; supply voltage constant at 220 kv.; receiver voltages expressed in per cent of 220 kv.

From the circle diagrams for the receiver end of a 500-mile transmission line shown by Fig. 4 it may be noted that a load of 100,000 kw. an *increase* in the lagging in the kilovolt-amperes, or what amounts to the same thing a *decrease* in the leading kilovolt-amperes, will actually raise the receiver voltage. The curves shown in full lines in Fig. 5 were obtained from the receiver circles in Fig. 4 by plotting the relation between receiver voltage and reactive kilovolt-amperes at a number of constant kilowatt loads in the same manner as previously described in detail for the 250-mile line. When delivering 50,000 kw. at 100 per cent voltage 50,000 lagging kilovolt-amperes are required. At this

point with the lagging kilovolt-amperes *remaining very nearly constant* at 50,000 kilovolt-amperes a variation of the receiver voltage from 94 per cent to 102 per cent could take place. If voltage instability occurred at this point as might be expected from a cursory consideration of the synchronous condenser characteristics, only 50,000 kw. could be delivered over the line. Actually there will be no difficulty in operating at this point because with other factors such as the excitation of the synchronous condensers remaining constant the fluctuation in voltage is always accompanied by a variation in reactive kilovolt-amperes and this variation tends to prevent the change in voltage.

To determine the point at which voltage instability will occur it is necessary to devise some means of plotting the variation in receiver voltage with a change in synchronous condenser excitation at different kilowatt loads. The fundamental condition for successful voltage regulator operation is that an increase in the

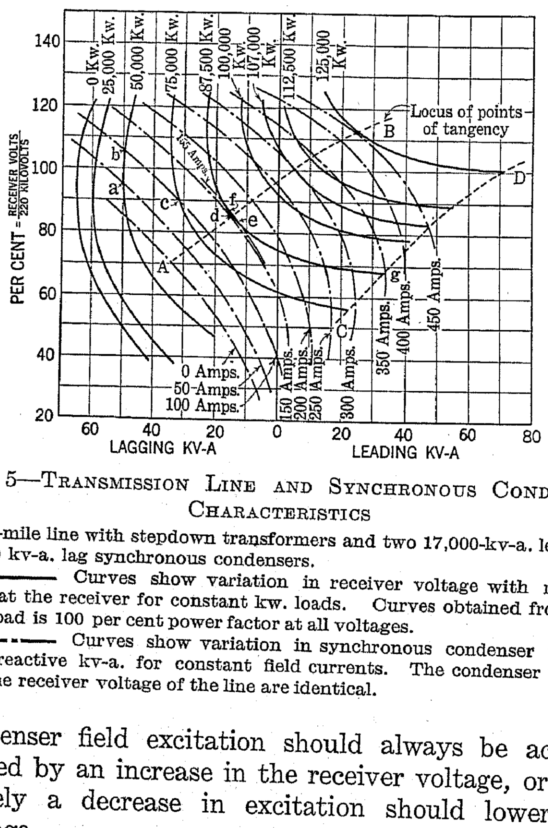

FIG. 5—TRANSMISSION LINE AND SYNCHRONOUS CONDENSER CHARACTERISTICS

500-mile line with stepdown transformers and two 17,000-kv-a. lead and 30,000 kv-a. lag synchronous condensers.

——— Curves show variation in receiver voltage with reactive kv-a. at the receiver for constant kw. loads. Curves obtained from Fig. 4. Load is 100 per cent power factor at all voltages.

–·–·– Curves show variation in synchronous condenser voltage with reactive kv-a. for constant field currents. The condenser voltage and the receiver voltage of the line are identical.

condenser field excitation should always be accompanied by an increase in the receiver voltage, or conversely a decrease in excitation should lower the voltage.

In investigating the relation between receiver voltage and condenser excitation a load, whose kilowatts remain constant and at 100 per cent power factor independent of the voltage, will be used for convenience. Synchronous motor load simulates such a load in that the kilowatts are independent of the voltage since the load remains constant as long as the frequency (speed) does not change. The power factor will of course vary with the voltage provided the field excitation is constant. The hypothetical 100 per cent power factor load is only used for convenience and modifications to take care of practical cases will be introduced after the theory is developed.

Since the load power factor is always constant at 100 per cent, all of the reactive kilovolt-amperes required to maintain the line voltage comes from the synchronous condenser. Referring to the sketch on Fig. 4, when constant voltage is maintained at the supply end of the line the conditions at the receiver end of the line are completely determined provided the following quantities are known:

P_R—The kw. transmitted over the line.

E_R—The receiver voltage.

Q_R—The reactive kilovolt-amperes drawn over the line to maintain the voltage.

Likewise the synchronous condenser point of operation is determined by the following variables:

I_F—The field current.

E_R—The terminal voltage.

Q_R—The reactive kilovolt-amperes supplied by the condenser.

The reactive kilovolt-amperes drawn over the line and the reactive kilovolt-amperes delivered by the condenser are equal since the load has been assumed to remain at 100 per cent power factor. The terminal voltage of the condenser is also identical with the receiver voltage of the line. This suggests plotting for the line a family of curves showing the variation in receiver voltage with reactive kilovolt-amperes at a number of kilowatt loads and superposing on them another family of curves which show the terminal voltage of the synchronous condenser plotted against the reactive kilovolt-amperes delivered by the condenser at a number of different field currents. Such a diagram could then be used to determine the change in receiver voltage and reactive kilovolt-amperes drawn over the line when the field current of the condenser is varied while the kilowatts transmitted remain constant. Similarly, a study of variations in the receiver voltage and reactive kilovolt-amperes for a constant value of field current as the power drawn over the line is changed will be of value.

The curves in Fig. 5 drawn in full lines show the relation between the receiver voltage and reactive kilovolt-amperes at the end of the 500-mile transmission line in Fig. 4. The chain dotted curves show the relation between synchronous condenser voltage, which is the same as the line receiver voltage, and the reactive kilovolt-amperes delivered by the condenser at a number of different field currents. These curves are for two synchronous condensers operating in parallel, each having a rating at 100 per cent voltage of approximately 30,000 kv-a. lagging at the minimum excitation and 17,000 kv-a. leading at the maximum excitation. The method of obtaining these curves from the no-load and zero per cent power factor saturation curves of a synchronous condenser will be described subsequently.

When supplying a constant load of 50,000 kw. the receiver voltage will be 95 per cent when the syn-

chronous condenser excitation is 50 amperes. This corresponds to point *a* on Fig. 5. With the load remaining constant at 50,000 kw. and the excitation of the synchronous condenser increased to 100 amperes, the receiver voltage will rise to point *b* or 106 per cent. Notice during this change in voltage the lagging kilovolt-amperes remained practically constant at 50,000 kv-a. Voltage instability does not occur even though a large change in voltage can occur with the lagging kilovolt-amperes constant, because a *considerable change in excitation* of the synchronous condenser is required to produce the change in voltage.

To investigate the variation in voltage with variation of load in kilowatts when the excitation of the synchronous condenser is constant, consider the operation at point "*b*," which corresponds to 50,000 kw. at 106 per cent voltage with 100 amperes of synchronous condenser excitation. Keeping the synchronous condenser excitation constant at 100 amperes and gradually increasing the load from 50,000 to 75,000 kw. point *c* is reached by following the 100 ampere field current curve as the load is increased. During this change in load the receiver voltage dropped from 106 per cent to 90 per cent.

Starting at point *c* and keeping the load constant at 75,000 kw. the voltage will rise from 90 per cent to 104 per cent if the excitation is increased from 100 amperes to 150 amperes. It should be noted particularly that the lagging kilovolt-amperes has been increased from 31,500 kv-a. to 34,400 kv-a., that is, *an increase in the lagging kilvolt-amperes drawn over the line actually increased the receiver voltage.* By keeping the load constant and increasing the excitation to 250 amperes the voltage will rise to 122 per cent. In Table *A* the variation in receiver voltage and reactive kilovolt-amperes drawn over the line as the synchronous condenser excitation is changed from 100 to 250 amperes with a constant load of 75,000 kw. is tabulated from the points taken on the 75,000-kw. curve.

TABLE A

Kw. Load	Syn. Cond. Field Amps.	*Receiver Voltage	Lagging Kv-a.	Lagging Current
75,000	100	90%	31,500	91.6 amps.
75,000	150	104%	34,400	86.5 "
75,000	200	114.5%	34,400	78.6 "
75,000	250	122%	33,300	71.6 "

*100 per cent voltage = 220 kv.

The lagging component of current drawn over the line, which was calculated from the receiver voltage and lagging kilovolt-amperes at the different points, is also tabulated. By increasing the receiver voltage from 90 per cent to 104 per cent, the lagging kilovolt-amperes drawn over the line are increased from 31,500 to 34,000 kv-a. while the lagging current drawn over the line decreased from 91.6 amperes to 86.5 amperes. The decrease in lagging current drawn over the line as the synchronous condenser excitation is increased accounts for the rise in line voltage even though the lagging kilovolt-amperes goes up. The lagging kilovolt-amperes increase because the line voltage is going up faster than the lagging current is going down.

Assume that the load is constant at 87,500 kw. and the condenser field excitation is 200 amperes, thus giving a receiver voltage of 105.5 per cent. If the power remains constant and the field excitation of the condenser is gradually decreased to 155 amperes point *d* will be reached and the voltage will be 85.5 per cent. At this point the line and synchronous condenser characteristic curves are tangent, and the voltage will be unstable because, with a constant condenser excitation of 155 amperes and a practically constant load of 87,500 kw. the voltage and the reactive kilovolt-amperes would fluctuate in the region from *e* to *f*.

If it were possible to get beyond the point of tangency between the two families of curves an increase in synchronous condenser excitation would actually decrease the receiver voltage, for example, an increase in the excitation from 155 to 200 amperes would reduce the voltage from 84.5 per cent to 73.5 per cent, with the load remaining constant at 87,500 kw. A still further increase in the excitation to 350 amperes would reduce the receiver voltage to 68 per cent as is indicated at point *g*, which corresponds to the pull-out point of the line alone for 68 per cent voltage. By referring to Fig. 4 it can be seen that point *g* corresponds to the maximum power point of the 68 per cent voltage circle.

If a voltage regulator set to maintain 85.5 per cent receiver voltage at all loads were in use, the regulator would operate satisfactorily at all loads up to 87,500 kw. At loads higher than this with the voltage maintained at 85.5 per cent, an increase in condenser excitation would decrease the voltage, which in turn would cause the regulator to still further increase the excitation and the action would be cumulative until the voltage dropped sufficiently for pull-out to occur.

It is even impossible in practise to get beyond point *d* with hand operation of the synchronous condenser field because, in order to get below *d* (the load remaining constant at 87,500 kw.), the synchronous condenser excitation must be decreased to 155 amperes and then increased. If the rheostat steps were such that the field current would be reduced to slightly less than 155 amperes, for example to 150 amperes, pull-out of the synchronous condenser and load would take place because the synchronous condenser with 150 amperes excitation can not deliver sufficient reactive kilovolt-amperes required for the transmission of 87,500 kw. at any voltage.

This discussion has dealt with the pull-out point of the entire system for a receiver voltage of 85.5 per cent. At a higher receiver voltage more power could be transmitted without this point being reached. The line *A B* (Fig. 5) is the locus of points of tangency between the family of line characteristic curves and

synchronous condenser characteristic curves, and is therefore the locus of pull-out points of the entire system for different receiver voltages.

When operating *with 100 per cent receiver voltage* 107,000 kw. is the maximum power that can be transmitted because the 107,000-kw. curve becomes tangent to the 300-ampere excitation curve of the synchronous condenser. In actual operation pull-out could be expected to occur slightly before this point of tangency. For example, when operating at 100,000 kw., and 100 per cent voltage, if the load suddenly increased to 107,000 kw., the voltage regulator would not have time to make a corresponding increase in the excitation. This gives the effect of an increase in load at a constant field excitation so that the voltage would drop down enough to reach the point of tangency and cause pull-out to take place before the regulator had time to get into action.

The locus of the pull-out points *of the line alone* is along the line $C\,D$, which corresponds to the pull-out point determined from the various receiver voltage circles shown in Fig. 4.

The voltage regulator is not directly affected by the reactive kilovolt-amperes. It merely operates to increase the condenser excitation when the receiver voltage should be increased, or to decrease the excitation when the receiver voltage should be decreased. Fig. 5 shows the change into reactive kilovolt-ampere during the regulating operation, and Fig. 6, which is derived therefrom by eliminating the reactive kilovolt-amperes, shows the variation in receiver voltage with

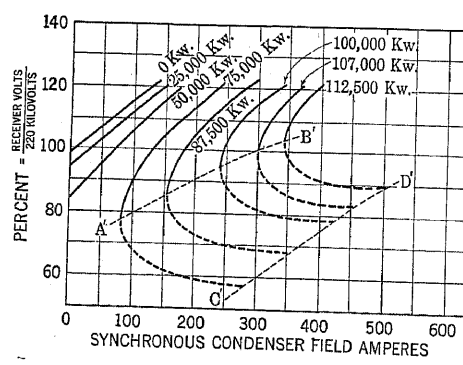

FIG. 6

These curves were obtained from Fig. 5. Curve $A'\,B'$ is the locus of points at which voltage instability and pull out will occur. It corresponds to $A-B$ on Fig. 5. Curve $C'\,D'$ is the locus of the maximum power points of the line alone as determined from the various receiver voltage circles. Corresponds to $C-D$ on Figs. 4 and 5.

condenser excitation at a number of constant kilowatt loads.

The line A'—B' in Fig. 6 corresponds to the line $A\,B$ on Fig. 5 where voltage instability and pull-out of the system occur. The dotted portions of the curve cover the range between the lines $A\,B$ and $C\,D$ in Fig. 5 where an increase in excitation would decrease the receiver voltage, provided it were possible to operate in this range. The line C'—D' in Fig. 6 is the locus of the maximum power points of the transmission line (with transformers, considered *alone* and is identical with the locus of maximum power points determined from the receiver diagrams and shown as the line $C\,D$ in Fig. 4.

The transmission line and synchronous condenser characteristic curves for a 250-mile line controlled by two synchronous condensers having a total capacity of 50,000 kv-a. leading and 21,000 kv-a. lagging at 100 per cent voltage are shown by Fig. 3. These curves are based on a hypothetical load which remains constant at 100 per cent power factor independent of the

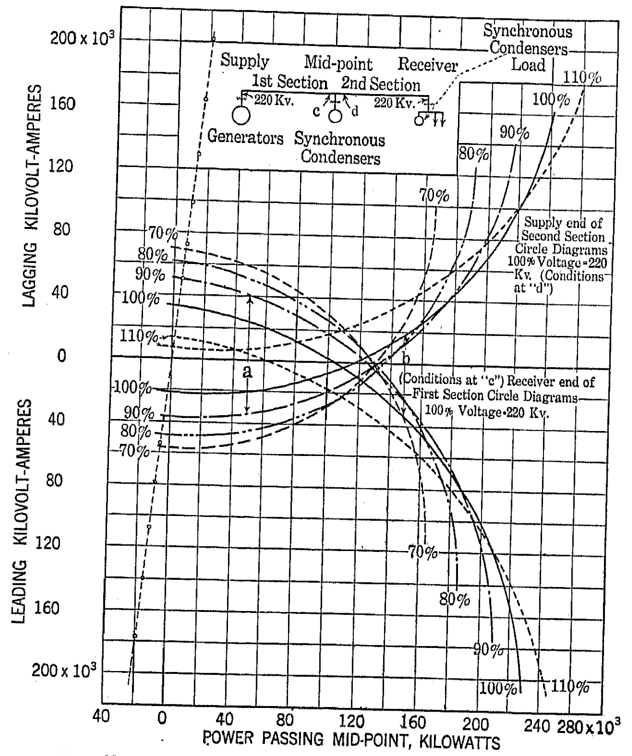

FIG. 7—MID-POINT OF 500-MILE LINE

220 kv. maintained at supply end of first section and receiver end of second section.

voltage. The locus of the points of tangency between the two families of curves is shown by the dotted line $A\,B$ and was obtained in the same manner as for the 500-mile transmission line previously investigated.

With the voltage maintained constant at 100 per cent the maximum load that can be drawn over the line is 140,000 kw. because the maximum synchronous condenser excitation is reached at this load. Pull-out will not occur at this point, but additional load can only be drawn over the line by leaving the condenser excitation constant at 400 amperes and allowing the voltage to drop as the load is increased. When the load reaches 155,000 kw. the voltage will be reduced to 89 per cent which corresponds to the point of tangency between the two families of curves and the system will pull out of synchronism.

The synchronous condenser characteristics happened to be such that the point of tangency occurs almost exactly where an increase in leading kilovolt-amperes drawn over the line would decrease the line voltage.

This is merely a coincidence and the point where the line curves turn back on themselves can not in general be considered as a point where instability will occur.

Power Limit of Loaded Line. By "loading" the 500-mile transmission line covered by Fig. 4 with synchronous condensers at the mid-point, the maximum amount of power which can be delivered to the receiver end will be increased. The sketch shown on Fig. 7 gives the schematic diagram of the system. By installing synchronous condensers at the mid-point, the 500-mile line is divided into 250-mile sections. The voltage is assumed to be maintained constant on the high-tension side of the step-up transformer at the supply end, thus making the two sections slightly different because transformers are not included with the first section while the step-down transformers are included with the second section since the voltage is held constant on the low-voltage side.

As the load at the receiver end is gradually increased some means must be devised for determining the amount of reactive kilovolt-amperes which the condenser at the middle of the line must supply to maintain any desired value of voltage at the mid-point. This can be done by considering the receiver end of the first section and the supply end of the second section independently; the only tie between them being that their voltages are always equal and if the losses in the synchronous condensers are neglected the power delivered at the receiver end of the first section is the same as the power supplied to the second section. The reactive kilovolt-amperes will be different and the synchronous condenser must supply the difference in the reactive kilovolt-amperes required for each section.

In determining the reactive kilovolt-amperes which must be supplied by the synchronous condenser at the mid-point under different conditions of voltage and load, the supply and receiver voltages at each end of the 500-mile line will be considered as being maintained constant at 220 kv. as is indicated on the sketch in Fig. 7. The losses in the synchronous condenser will be neglected.

Assume that it is desired to maintain 100 per cent voltage at the mid-point under all loads. The reactive kilovolt-amperes which the synchronous condenser must supply at any kilowatt load may be obtained in the following manner. The 100 per cent receiver circle for the first section (*i. e.* at *c* on sketch in Fig. 7) shows the reactive kilovolt-amperes which must be drawn over this section to maintain 100 per cent voltage as the power *passing the mid-point* is increased. The 100 per cent supply voltage circle (*i. e.* at *d*) for the second section shows the variation in reactive kilovolt-amperes taken by the second section with a change in power passing the mid-point.

At any particular kilowatt load passing the middle of the line the synchronous condenser must furnish the difference in reactive kilovolt-amperes between the 100 per cent receiver and supply circles in order to maintain 100 per cent voltage. As an example it is shown at *b* on Fig. 7 that the condenser must deliver 53,000 kv-a. leading to maintain 100 per cent voltage at 150,000 kw.

To obtain a perspective of the entire situation at the mid-point, consideration must be given to the conditions where mid-point voltages are above and below 100 per cent, with the voltage at both ends of the 500-mile line still constant at 220 kv. (100 per cent).

As an example the conditions at 90 per cent voltage at the mid-point can be determined in the same manner as for 100 per cent voltage by drawing the 90 per cent receiver and supply circles for the first and second sections respectively. As is shown at *a* on Fig. 7 the synchronous condenser must supply 75,000 kv-a. lagging to maintain 90 per cent voltage when 50,000 kw. are being transmitted past the middle of the line.

By drawing a considerable number of circles and obtaining a large number of points in the manner just described, the curves drawn in full on Fig. 8 were

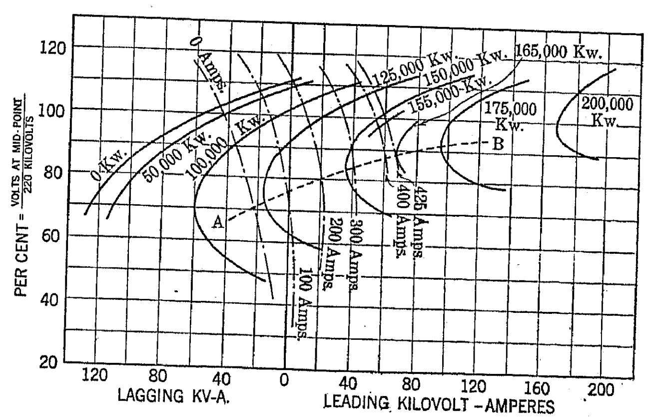

FIG. 8—MID-POINT OF 500-MILE LINE

Constant voltage = 220 kv. maintained at each end of the line.

——— Curves show relation between volts at mid-point and reactive kv-a. which must be supplied by the mid-point synchronous condenser for different amounts of power passing the center of the line. Obtained from Fig. 7.

–·–·– Curves show relation between synchronous condenser voltage and reactive kv-a. delivered (at high voltage side of transformer bank) for different values of field current.

Curve *A B* is locus of points of tangency between line and synchronous condenser curves. It is impossible to operate below *A B*.

obtained. These curves show the variation in voltage at the mid-point for different amounts of reactive kilovolt-amperes delivered by the synchronous condenser at a number of different kilowatt loads passing the middle of the line. The kilowatts actually delivered at the receiver end of the 500-mile line can be obtained by subtracting the losses in the second section from the kilowatts passing the middle of the line.

The chain dotted curves show the characteristics of the synchronous condensers used at the mid-point. These curves are for two synchronous condensers each of 30,000 kv-a. leading and 20,000 kv-a. lagging capacity operating in parallel.

The line *A B* (Fig. 8) is drawn through the points of tangency between the two families of curves and is the locus of points at which voltage instability and

pull-out of the synchronous condenser at the mid-point will occur.

With 100 per cent voltage maintained at the mid-point the limit of the synchronous condenser excitation is reached at 155,000 kw. corresponding to 425 amperes of excitation. The pull-out will not occur at this point and load may be increased to 165,000 kw. by keeping the field current constant at 425 amperes and allowing the voltage at the middle of the line to drop. At 165,000 kw. the voltage at the mid-point will have dropped to 89 per cent at which the line and condenser curves become tangent and voltage instability and pull-out will occur. The load at the receiver end of the 500-mile line at the time of pull-out is 152,000 kw. as obtained by subtracting the losses in the second section from the load of 165,000 kw. at the middle of the line.

Loading the 500-mile line with 60,000 kv-a. in synchronous condensers at the mid-point, therefore increases the power limits of the system from 107,000 kw. to 152,000 kw. an increase of 42 per cent.

From the foregoing it may be noticed that the power limit of the loaded line is to a large extent determined by the characteristics of the synchronous condensers at the mid-point. If a sufficiently large synchronous condenser were used, the power limit of the system would closely approach that of the first section.

In this investigation the voltages at both ends of the line were assumed to be constant. Actually the voltage regulators at the generator and receiver synchronous condenser cannot change the voltage instantaneously and some variation in voltage will occur. This does not appreciably effect the pull-out point as can be seen from the tests.

Method of Investigating Different Types of Load. The preceding discussion was based on a kilowatt load which remained constant and at 100 per cent power factor independent of the voltage. Synchronous motors simulate such a load in that a change in frequency (speed) is required to alter the kilowatt load. A variation in voltage merely changes the reactive kilovolt-amperes taken by the synchronous motors. Within certain limits, the same may be said of induction motor load.

In investigating the pull-out point of a system whose entire load consists of synchronous motors with a synchronous condenser for regulating the voltage, no change need be made in the line characteristic curves previously used for showing the relation between receiver volts and reactive kilovolt-amperes at constant kilowatt loads. Instead of superposing on these curves only the synchronous condenser characteristics, a new set of curves showing the variation in reactive kilovolt-amperes of the entire load (synchronous condenser and motors) with voltage at different synchronous condenser field excitations should be used.

A reactor or static condenser connected in parallel with a synchronous condenser can be handled in the same manner by plotting the variation in reactive kilovolt-amperes of the combination with voltage at a number of condenser field currents.

Reactors, static condensers, or resistors at the load end of a transmission line can also be combined to form a part of the transmission line by use of the general circuit constants. New circle diagrams can then be calculated for the transmission line with a part of its load, considered as a unit, and the characteristics considered in conjunction with those of the synchronous condenser. This method has the disadvantage that a new set of circle diagrams would be required for every change in load.

Another method of handling a purely resistance load with the receiver voltage controlled by a synchronous condenser can best be illustrated by considering a resistance load on the 250-mile transmission line shown by Fig. 2. With an amount of resistance which would draw 100,000 kw. at 100 per cent voltage, the synchronous condenser would have to supply 10,000 kv-a. leading as determined from the 100 per cent circle. With the same resistance remaining in use, if the voltage were reduced to 90 per cent, the load taken by the resistor will drop to 81,000 kw., and at this load the synchronous condenser must supply change to 12,500 kv-a., lagging to maintain 90 per cent voltage. By continuing this process for other voltages a curve giving the variation in line voltage with reactive kilovolt-amperes for this *particular value of resistance* can be obtained. A family of such curves for different amounts of resistance at the load may be calculated. These curves can be used for investigating the stability of the system by superposing on them the characteristic curves of the synchronous condenser in the same manner as for the constant power (kw.) curves drawn in full on Fig. 3.

Stability Tests on an Artificial Transmission System

An artificial transmission system on a sufficiently large scale so that results could be obtained comparable with those expected in actual operation was used for making tests on the power limitations, voltage stability, hunting, and effect of short circuits in causing the system to pull out of step.

Transmission System. Two artificial lines of the T type constructed of reactance coils, resistance grids, and static condensers were used. The lines were operated normally at 2380 volts. Power was obtained from a 625-kv-a. generator driven by a direct-current motor, which made the proportion between the capacity of the power plant and the load approximate that of an actual power system.

Two 425-kv-a. synchronous condensers were available thus permitting the two transmission lines to be operated either alone or in series with an intermediate condenser station for actually testing a "loaded" line. Voltage regulators for use with the generator and each of the synchronous condensers were provided.

Two 200-kw. synchronous motor-generator sets were

used as loads. The direct-current generators of these sets were connected to resistance racks to provide a dead load instead of loading back on the direct-current shop system. The fields of the direct-current generators were separately excited so that the load could be varied gradually by raising or lowering the d-c. voltage.

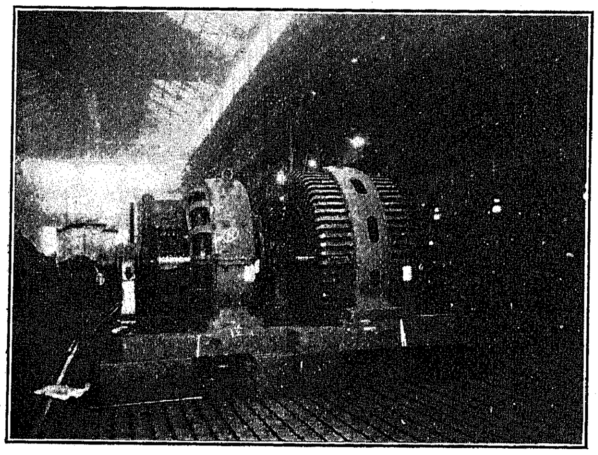

Fig. 9

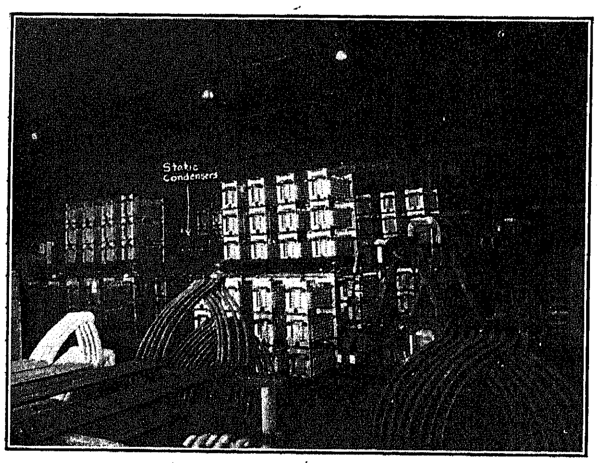

Fig. 10

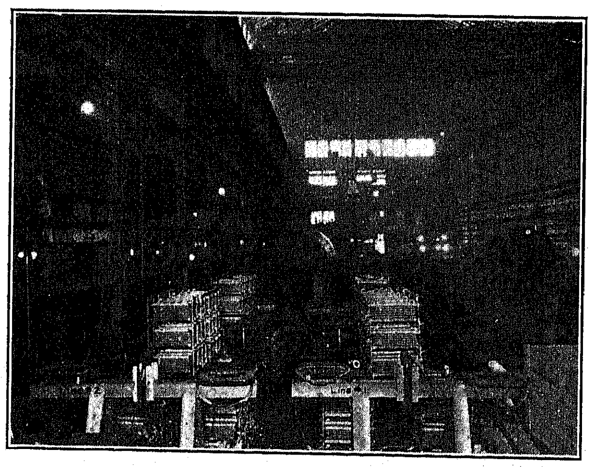

Fig. 11

The motor-generator set used as a source of power is shown by Fig. 9, and Fig. 10 and 11 show views of the two transmission lines. Fig. 12 is a photograph of one of the static condenser banks. One of the synchronous condensers with its belted exciter is shown in Fig. 13.

The photographs show how the reactance coils were grouped to minimize the mutual effects. From measurements made during operation, it was ascertained that the mutual effects were negligible. The reactance and effective resistance of the coils at 60 cycles were obtained from measurements. It happened that the $I^2 R$ loss and the eddy current loss at normal temperatures were about equal thus making the effective resistance of the coils practically constant over the temperature range at which they were operated during the test.

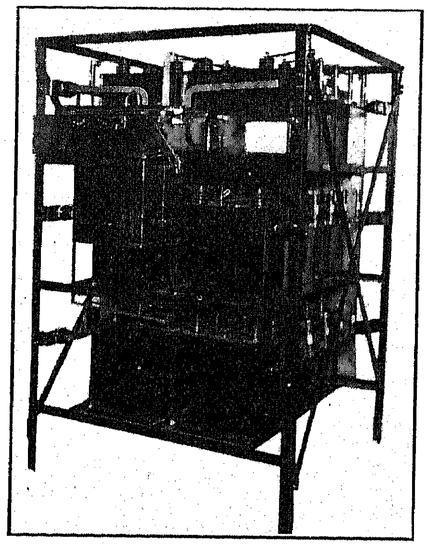

Fig. 12

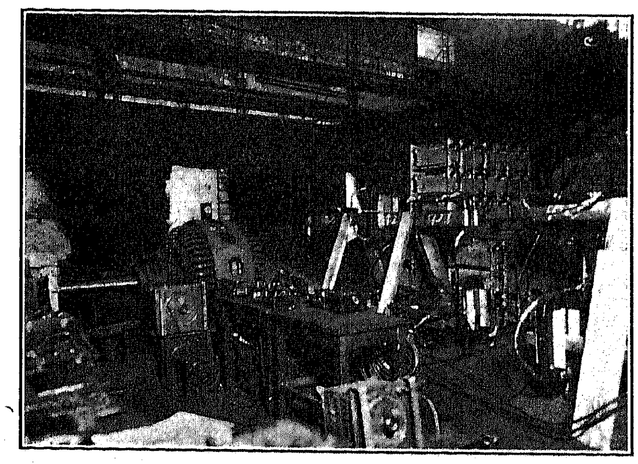

Fig. 12a

The resistance grids were arranged so that the amount of the resistance in the circuits could be varied. The resistance of the grids changed considerably with the temperature and in order to obtain the actual resistance the voltage drop across the grids was taken at each reading. In actual tests sufficient time was

allowed for a steady temperature state to be reached before any readings were taken.

The static condensers used with each transmission line had a capacity of 171 kv-a. at 2380 volts as determined from measurements. The condensers were

Y = Admittance to neutral of static condensers.
Measurements made at "a" and "B".

connected in star and arranged so that a smaller number of units could be used if desired. The admittance to neutral of the entire bank was $Y = +j\ 0.0302$ mhos.

Based on the generating capacity of 625 kv-a. the

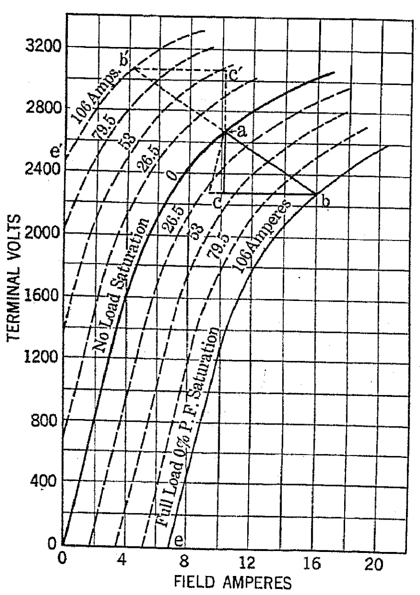

FIG. 14—SATURATION CURVES OF THE SYNCHRONOUS CONDENSERS USED IN MAKING TESTS

425 kv-a.; 0 per cent power factor; saturation curves obtained from tests. The other curves drawn with equal spacing on lines parallel to bb'.

following range of line constants was available in each transmission line:

Resistance 0 per cent to 72 per cent
Reactance 0 per cent to 134 per cent

For comparative purposes the constants based on 150,000 kv-a. transmitted over 250 miles of 220 kv. transmission line are as follows:

Resistance 7 per cent
Reactance 70 per cent

In analyzing the tests the constant field current characteristic curves of synchronous condenser No. 1 and No. 2, which are identical, are required. These curves may be obtained from the no load and zero per cent power factor saturation curves shown in Fig. 14 in the following manner. The curve $e\ b$ is usually spoken of as the zero per cent power factor saturation curve at full-load lagging current, or looking at it from the other point of view the condenser is at its maximum excitation and delivering full-load current leading. Draw in the triangle $a\ b\ c$ of which $a\ c$ is the reactive drop at 106 amperes and $c\ b$ is the field current necessary to overcome the armature reaction at 106 amperes. By inverting this triangle to the position $a\ b'\ c'$ the 106

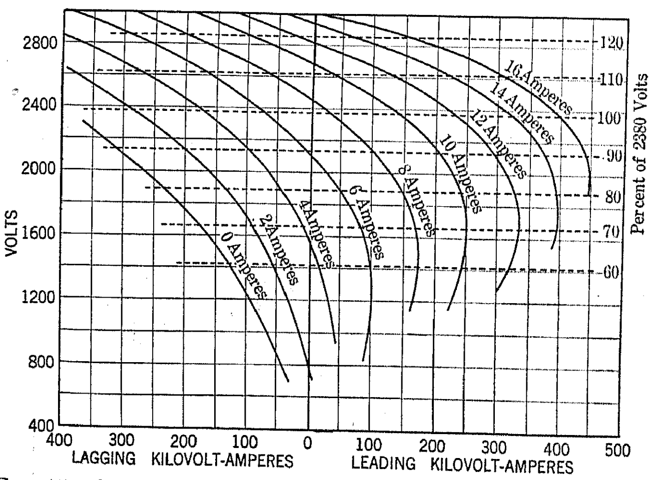

FIG. 15—CONSTANT FIELD CURRENT CURVES OF SYNCHRONOUS CONDENSERS USED IN TESTS

Curves show reactive kv-a. delivered by synchronous condenser when field current is held constant and terminal voltage is varied. These curves calculated from the saturation curves on Fig. 14.

ampere curve $e'\ b'$ for the condenser operating under-excited or delivering lagging kilovolt-amperes may be obtained. The saturation curves for ¼, ½, and ¾ full-load currents at zero per cent leading and lagging power factor may then be drawn by spacing them at equal intervals along lines parallel to $b\ b'$.

At a constant field current of 4 amperes the condenser will deliver 26.5 amperes leading at 950 volts which corresponds to 44 kv-a. leading. At 1600 volts the current is zero and the reactive kv-a. is therefore zero. At 2140 volts the current is 26.5 amperes lagging or the condenser is delivering 98 kv-a. lagging. The curves shown in Fig. 15 give the relation between condenser voltage and reactive kilovolt-amperes delivered, at a number of field currents.

Measurements of the power and reactive kilovolt-amperes being transmitted over the line were made at a and b in Fig. 13. The losses in the synchronous condenser are therefore included with the kilowatts transmitted

and the reactive kilovolt-ampere measurements include that supplied by the synchronous motors as well as the synchronous condenser.

Test No. A—1. In this test the power limit was determined for a transmission system having line characteristics similar to those of an actual 250-mile transmission line. The schematic diagram of the connections used in the test is shown in Fig. 13. To simulate a high-voltage transmission line the resistance was made small compared with the reactance.

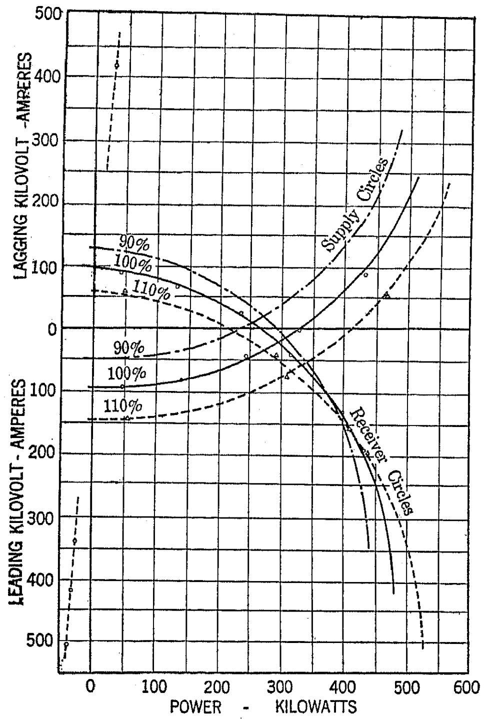

FIG. 16—TEST LINE SIMILAR TO AN ACTUAL 250-MILE LINE
Refer to Fig. 13 for connections.
$Z = 0.80 + j\,12.12$ ohms.
$Y = +j\,0.032$ mhos.
Supply voltage maintained constant at 2380 volts = 100 per cent.
Circles show relation between power and reactive kv-a. for 90 per cent, 100 per cent, 110 per cent receiver voltages.

Referring to Fig. 13 the impedance and admittance of the line to neutral were as follows:

$Z = 0.80 + j\,12.12$ ohms.

$Y = +j\,0.0302$ mhos.

The receiver and supply circle diagrams of the line calculated from these constants are shown in Fig. 16. In Fig. 17 the curves drawn in full show the reactive kilovolt-amperes which must be drawn over the line to maintain various receiver voltages at a number of kilowatt loads transmitted over the line. These curves were derived from Fig. 16. Superposed on these curves are the chain dotted curves which show the relation between voltage and reactive kilovolt-amperes delivered by the *load and synchronous condenser* at a number of condenser field currents.

The voltage at the receiver end of the line was controlled by the synchronous condenser voltage regulator. The two 200 kw. synchronous motor generator sets were used as load.

Readings were taken to check points on the calculated circle diagrams (Fig. 16) and to determine the pull-out points:

7	" (100%)	Pulled out at 450 kw. which was the average of a number of tests made under the same conditions. In these tests the pull-out point ranged from 445 to 455 kw.		

The above points have been plotted on the calculated 100 per cent receiver and supply circle diagrams in Fig. 16.

Until the load was increased to slightly more than 432 kw. at the receiver, all conditions were very stable

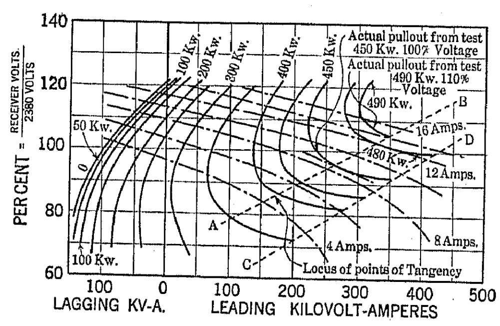

FIG. 17

——— Curves show relation between receiver volts and reactive kv-a. for different loads. These curves obtained from receiver circles on Fig. 16.

–·–·– Curves show relation between load voltages and reactive kv-a. delivered by *load and synchronous condenser* for different condenser field currents. Reactive kv-a. supplied by M. G. sets based on field excitation used in test and a constant load of 450 kw. with variable voltage.

and accurate meter readings could be made. Near the point where pull-out occurred the kilowatts and voltages were very constant but the reactive kilovolt-amperes fluctuated considerably as would be expected, because the line and synchronous condenser characteristic curves were approaching tangency as shown in Fig. 17.

When the load was gradually increased to about 450 kw. the synchronous machines at the load suddenly pulled out of step and slowed down rapidly. While slowing down the synchronous condenser and the motor generator sets remained in step with each other. When

pull-out occurred the polyphase wattmeter used for reading the kilowatts at the receiver end of the line dropped back without taking an upward swing. The voltmeter appeared to drift back and forth for an instant before dropping back. The instrument reading leading kilovolt-amperes made a sudden upward swing.

The oscillogram shown in Fig. 18 was taken at the pull-out point. The load was brought as near as possible to the pull-out point, and the oscillograph started. The load was then suddenly increased to slightly more than 450 kw. causing pull-out to occur.

The following series of points were taken on the 110 per cent receiver circles.

The above points have been plotted on the calculated 110 per cent receiver and supply circles shown in Fig. 16.

Referring to Fig. 17 it may be noted that pull-out occurred slightly before reaching the point of tangency

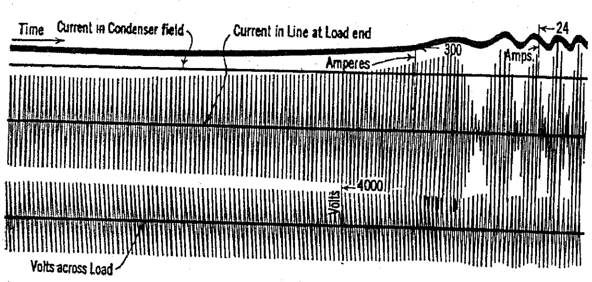

FIG. 18—PULL-OUT AT POWER LIMIT

between the line and synchronous condenser characteristic curves, both for 100 per cent and for 110 per cent receiver voltage. This can be accounted for by slight voltage fluctuations, since the operation of the voltage regulator is not instantaneous.

During the preceding part of the test when the receiver and supply voltages both were 100 per cent (2380 volts), an investigation of hunting due to faulty adjustment of the voltage regulator at the generator was made. The dash pot on the voltage regulator was loosened so that the regulator was not "dead beat" and the resulting voltage fluctuations caused hunting to take place. The load consisted of synchronous motors, which took a constant kilowatt load at all voltages; therefore, as the voltage changed the power component of current also changed. The power component of current drawn through the reactance of the line produced a shaft in phase between the supply and receiver voltages.

The synchronous motors hunted in attempting to follow the continual shift in phase of the receiver voltage. With proper damping of the voltage regulator there was no difficulty from hunting.

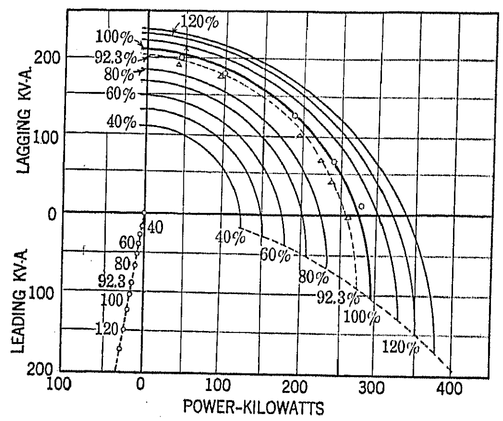

FIG. 19—RECEIVER CIRCLE DIAGRAM OF TEST LINE SIMILAR TO AN ACTUAL 500-MILE LINE

Two lines same as the one covered by the circle diagram on Fig. 16 connected in series. Connections identical with Fig. 22, except synchronous condenser No. 1 was disconnected.

$Z = Z = 0.80 + j\,12.12$ ohms. $Y_1 = Y_2 = j\,0.0302$ mhos.

See Fig. 20 for supply circles.

Supply voltage kept constant at 2380 volts equals 100 per cent. Circles show relation between power and reactive kv-a. at receiver for various receiver voltages.

Test No. A—2. This test was made on a transmission system having line characteristics similar to those of an actual 500-mile line, as may be seen by comparing Figs. 4 and 19.

The test line was built up by connecting in series two sections, each identical with the transmission line used in Test *A—1*. Referring to Fig. 22:

$$Z_1 = Z_2 = 0.80 + j\,12.12 \text{ ohms}$$

$$Y_1 = Y_2 = +\,j\,0.0302 \text{ mhos.}$$

During this test the synchronous condenser No. 1 shown in Fig. 22 at the middle of the line was disconnected.

The receiver circle diagrams calculated from these constants are shown in Fig. 19 and the supply circle diagrams in Fig. 20. The curves drawn in full in Fig. 21 show the relation between voltage and reactive kilovolt-amperes at the receiver end of the line for a number of different kilowatt loads transmitted. These curves were derived from the receiver circles in Fig. 19. It should be noted that with the power transmitted remaining constant, an *increase* in lagging kilovolt-amperes drawn over the line will *increase* the receiver voltage.

By referring to Fig. 31 it may be noted that an

increase in excitation of the synchronous condenser will always be accompanied by a rise in the receiver voltage when operating above the line $A-B$, which is the locus of the points of tangency between the two families of curves.

The voltage regulator at the supply end was set to maintain 2380 volts and the following points were taken with 100 per cent (2380) receiver voltage:

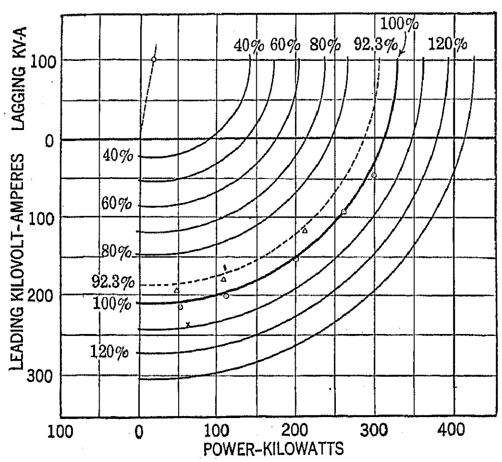

Fig. 20—Supply Circle Diagram of Test Line Similar to an Actual 500-Mile Line

For line constants, see the receiver circle diagram on Fig. 19. The supply voltage is constant at 2380 volts = 100 per cent. The circles show relation between power and reactive kv-a. at the supply end for various receiver voltages.

Within the above range of load the voltage regulator functioned perfectly, even though an increase in receiver voltage required an increase in the lagging kilovolt-amperes drawn over the line, because an increase in condenser excitation always produced a rise in receiver voltage. This can be determined by referring to Fig. 21.

The test points have been plotted on the circle diagrams in Figs. 19 and 20. Pull-out occurred at 302 kw., which corresponds quite closely with the maximum power point of the line alone as determined from the 100 per cent circle in Fig. 19. By referring to Fig. 21, it may be noted that the characteristic curves of the line and synchronous apparatus become tangent close to the maximum power point of the line alone, as determined from the circle diagrams.

Another series of tests was made to take points on the 92.3 per cent circle and one point was taken on the 110 per cent circle to show that an increase in lagging kilovolt-ampere drawn over the line actually increased the voltage, as would be expected from the circle diagram.

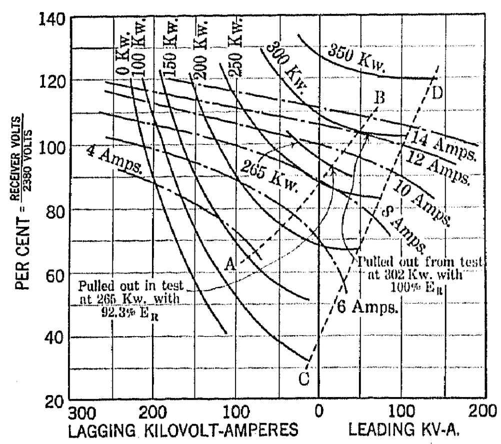

Fig. 21—Test Line Similar to an Actual 500-Mile Line

8	2620 (110%)	52	+208	

These points have been plotted on the receiver and supply circle diagrams shown in Figs. 19 and 20. The

pull-out point of the line alone with 92.3 per cent voltage corresponds very closely to the point of tangency between the two families of curves shown in Fig. 21.

During the above tests the load was suddenly varied by changing the amount of resistance used as load for the motor generator sets. The system stabilized after

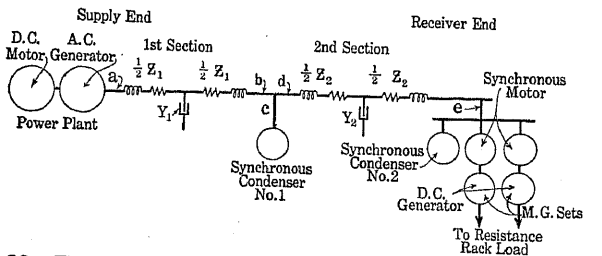

FIG. 22—TRANSMISSION LINE WITH SYNCHRONOUS CONDENSER AT MID-POINT

Y_2 = Admittance to neutral of static condenser on 2nd section.
Measurements made at *a-b-c-d-e*.

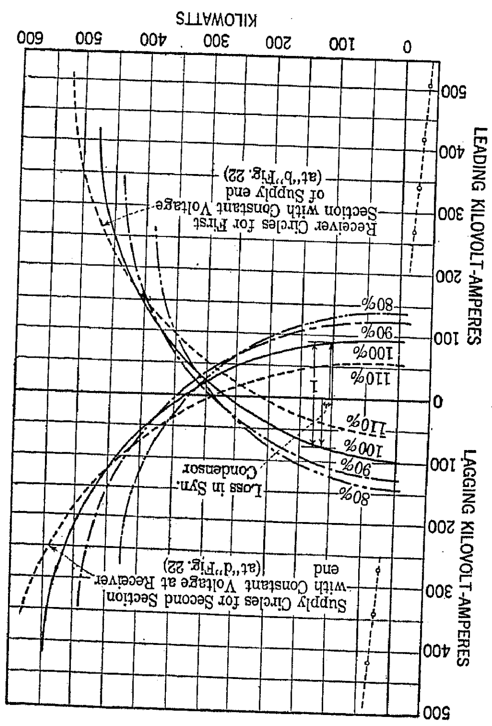

FIG. 23—MID-POINT OF TEST LINE WHICH IS SIMILAR TO AN ACTUAL 500-MILE LINE

2380 volts = 100 per cent maintained at supply end of first section and receiver end of second section. Each section identical with Fig. 16. Referring to Fig. 22 the line constants to neutral are: $Z_1 = Z_2 = 0.80 + j\,12.12$ ohms.
$Y_1 + Y_2 = j\,0.0302$ mhos.

1 = lagging kv-a. which must be supplied at mid-point to maintain 100 per cent voltage when the load at the receiver end of first section is 117 kw. To obtain the lead at the end of the line subtract losses in synchronous condenser and the second section. By continuing this process curves showing relations between volts and reactive kv-a. at different loads as in Fig. 24 were obtained.

a few oscillations and pull-out did not occur unless sufficient change in load was made to swing below the Line "A—B" in Fig. 21.

Test No. A—3. This test was made to check the operation of a loaded transmission line. Conditions were identical with those in Test *A—2* except that synchronous condenser No. 1 was connected at the mid-point of the line, as is shown in Fig. 22. The voltage regulators were set to maintain 100 per cent voltage (2380 volts) at the mid-point of the line, as well as at the supply and receiver ends.

The curves drawn in full lines in Fig. 24 show the reactive kilovolt-amperes which must be supplied by the synchronous condenser at the mid-point to maintain any desired voltage, at a number of different loads. The kilowatts shown refer to the power delivered at the end of the first section and measured at point *b* in Fig. 22. The corresponding amounts of power delivered at the receiver end of the line (at *e*), may be obtained by subtracting the losses in synchronous condenser No. 1 and in the second section. These curves were obtained from Fig. 23 in the same manner that the curves for the 500 mile line shown by Fig. 8 were obtained from Fig. 7, except that the losses in synchronous condenser No. 1 were included in the manner indicated in Fig. 23. This method may be extended to take into account loads at the mid-point.

The load was gradually increased, and the following readings taken:

6	2380 (100%)	..	384	Pulled out

Considering the two sections independently the kilowatts and reactive kilovolt-amperes at their supply and receiver ends may be checked against the 100 per cent circles shown in Fig. 23, which are the same as those in Fig. 16 used with Test *A—1*.

For loads above 330 kw. at the receiver end of the line (at *e* Fig. 22), which corresponds to 370 kw. at *b*, the reactive kilovolt-amperes fluctuated to a limited extent although the voltage and power remained steady. At a load of 340 kw. at *e* (380 kw. at *b*), the system showed signs of becoming unstable, although pull-out did not actually occur until the load was increased to 384 kw. (410 kw. at *b'*). This point was checked by several trials.

The addition of the synchronous condenser at the mid-point of the line used in Test *A—2* increased the load that could be delivered over the line from 304 kw. to 384 kw., an increase of 26 per cent.

An investigation at a number of different loads was made of the effect of suddenly throwing on about 25 per cent additional load. The figures given refer to kilowatts at the receiver end of the line, and for convenience in referring to Fig. 24, the corresponding kilowatts at *b* are given in brackets.

Trial No.	Kw. at "e"			Remarks
	On	Off	On	
1	293 (321)	243 (263)	293 (321)	Stabilized rapidly
2	320 (360)	283 (308)	320 (360)	Voltage oscillated ± 10 per cent at first, but settled down after a few oscillations.
3	344 (384)	300 (330)		Pulled out when load was thrown back.

Test No. A—4. This test is identical with Test *A—3*, except that one motor generator set was moved from the receiver end of the line to the mid-point of the line and operated in parallel with synchronous condenser No. 1. The loads were adjusted so that about one-half of the load was delivered at the mid-point, and the other half transmitted to the end of the line.

When pull-out occurred, 440 kw. (measured at *b*) were being transmitted over the first section. This is very close to the pull-out point of the first section when tested alone, which was 450 kw. in Test *A—1*. Up to 400 kw. (at *b*), the system would stabilize quickly after a sudden change in load.

In Test *A—3* with the synchronous condenser No. 1 alone at the mid-point, pull-out occurred at 410 kw. at *b*, while in this test with the motor-generator set operating in parallel with the condenser, pull-out occurred at 440 kw. This was because the additional synchronous capacity at the mid-point changed the slope of the chain dotted curves in Fig. 24 in such a manner as to increase the power limit; in other words, it gave the effect of a larger synchronous condenser at the mid-point.

Test No. B—1. The preceding series of tests was made on a transmission line having low resistance, high reactance and capacity to simulate a high-voltage transmission line.

This test was made on a transmission line having an impedance to neutral of:

$Z = 3.84 + j\ 8.08$ ohms

$Y = 0$

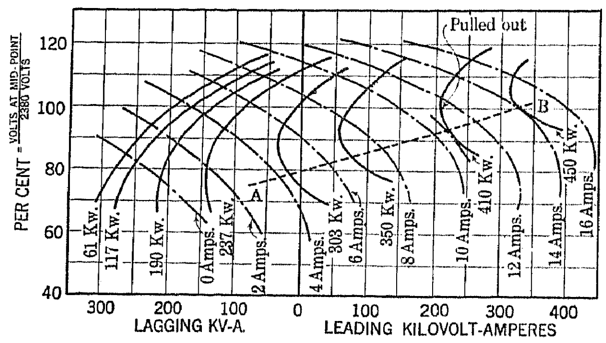

Fig. 24—Mid-Point of Test Line Similar to an Actual 500-Mile Line

Constant voltage = 2380 volts = 100 per cent *E* maintained at receiver and supply ends of the line.

———— Curves show relation between volts at mid-point and reactive kv-a. which must be supplied by the synchronous condenser for kw. measured at "*B*" on Fig. 22. The load actually delivered at receiver end of the line can be obtained by substracting the losses in the synchronous condenser and 2nd section.

- — - — Curves show relation between synchronous condenser voltage and reactive kv-a. delivered for particular values of field current. Data for curves giving relation between volts and reactive kv-a. at mid-point obtained from Fig. 23.

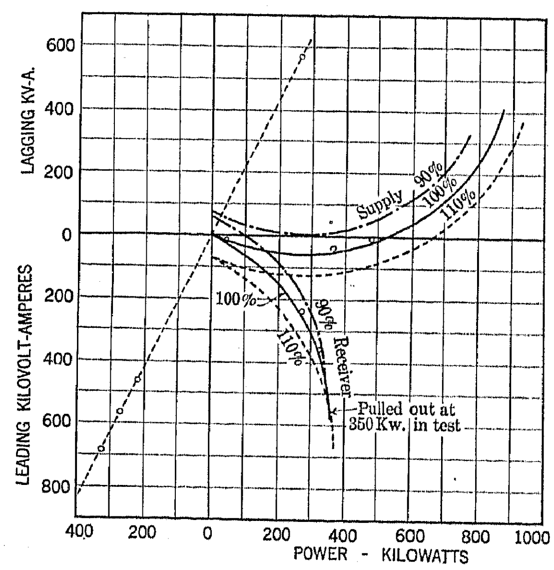

Fig. 25—Test Line Receiver and Supply Circles

Refer to Fig. 13 for connections.

$Z = 3.84 + j\ 8.08.$

$Y = 0$

Supply voltage maintained constant at 2380 volts = 100 per cent.

Circles show relation between power and reactive kv-a. for 90 per cent, 100 per cent, 110 per cent receiver voltages.

This relation between resistance and reactance is typical of a low-voltage transmission line. The circle diagrams calculated from the above constants are shown in Fig. 25. Fig. 26 shows the characteristic curves of the line and synchronous load superposed upon each other.

At 100 per cent voltage, the points of tangency between the two families of curves are almost identical with the power limits of the line considered by itself.

The connections and apparatus employed are shown in Fig. 13. The voltage regulators were set to maintain constant voltage at both the receiver and supply ends of the line. The load was gradually increased with the following results:

SUPPLY END

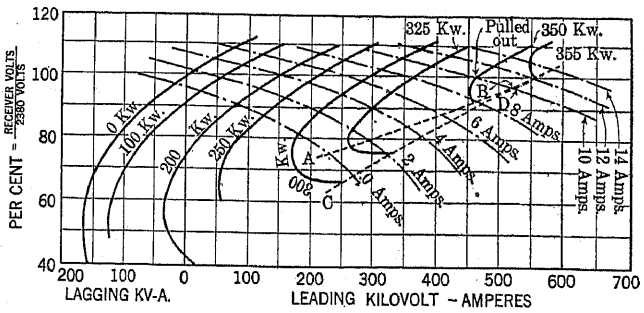

FIG. 26—RECEIVER END OF LINE IN TEST B-1

2380 volts = 100 per cent voltages.

———Curves show relation between receiver volts and reactive kv-a. at different loads. These curves obtained from receiver circles on Fig. 25. The supply voltage was constant at 2380 volts = 100 percent.

- — - —Curves show relation between load voltages and reactive kv-a. delivered by *load and synchronous condenser* for different condenser field currents. Reactive kv-a. supplied by *M. G.* sets based on field excitations used in test and a constant load of 350 kw. with variable voltage.

The test results have been plotted in Fig. 25. The points checked the calculated circle diagrams very closely, particularly the higher readings, because the circle diagrams were based on the resistance of the grids at the higher loads.

Pull-out occurred very sharply at 350 kw. without much sign of instability below this load, as would be expected by referring to Fig. 26, since the two families of curves approach tangency abruptly very close to the maximum power point of the line.

Test No. B—2. This test was made to determine whether an individual part of the system could be pulled out of synchronism without causing the entire system to pull out.

The same transmission line and apparatus were used as in Test *B*—1. The entire load was carried by motor generator set No. 2.

M. G. set No. 1 was running idle to assist the synchronous condenser.

The load transmitted was kept constant at 200 kw. The receiver voltage was gradually reduced by decreasing the excitation of the synchronous machines at the load. At 50 per cent voltage M. G. set No. 2, which was carrying the load, pulled out of step and slowed down, while M. G. set No. 1 and the synchronous condenser remained in synchronism with the generator.

The system as a whole did not pull out of step because its power limit was not exceeded when 200 kw. at 50 per cent voltage were being transmitted. The pull-out point of M. G. set No. 2 considered by itself was exceeded and it pulled out of step.

Test No. B—3. Two transmission lines each identical with the line used in Test *B—1*, were connected in series as shown on Fig. 22, except that synchronous condenser No. 1 was disconnected. The line constants were:

$$Z_1 = Z_2 = 3.84 + j\,8.08 \text{ ohms}$$
$$Y_1 = Y_2 = 0$$

The total impedance of the line was $7.68 + j\,16.16$ ohms.

A test run was made with the voltage held constant at 2380 volts at both ends of the line. Pull-out took place at 190 kw. which corresponded closely to the pull-out point of the line alone as determined from the calculated circle diagram. The characteristic curves of the line and synchronous apparatus become tangent to each other practically at the pull-out point of the line. These courses are not shown.

Test No. B—4. To determine the power limit of a "loaded" transmission line synchronous condenser No. 1 was connected at the middle of the line used in test *B—3*. The connections were then exactly in accordance with Fig. 22.

The load was gradually increased with the voltage regulators set to maintain constant voltage at *a-b-e*, and the following readings taken:

SUPPLY END OF 1ST SECTION
(At "*a*" Fig. 22)

Reading No.	Volts	Line Amps.	Kw.	Reactive Kv-a.
1	2380 (100%)	14	61	−10
1	" (100%)	50	208	−31
3	" (100%)	82	345	−32
4	" (100%)	134	550	..

MID-POINT OF LINE

RECEIVER END OF 2ND SECTION
(At "*e*" Fig. 22)

Reading No.	Volts	Line Amps.	Kw.	Reactive Kv-a.
1	2380 (100%)	14	48	− 34
2	" (100%)	41	148	− 92
3	" (100%)	62	208	−156
4	" (100%)	84	268	−229

Immediately after reading No. 4 was taken the system pulled out of step of its own accord without any further increase in power having been made. This indicated that reading No. 4 was very close to the pull-out point. The system was very stable when this reading was taken and all the meters could be read accurately.

The conditions at the middle of the line were as shown in Fig. 27. The curves were derived in the same manner as the corresponding curves used with Test *A-3*. The family of receiver and supply circles from which these curves were derived are not shown. From Fig. 27 it can be seen that the transmission line and the condenser characteristic curves become tangent to each other practically at the pull-out point for the first section, that is, slightly above 350 kw. as measured at point *b* (Fig. 22). Since the curves became tangent very suddenly it was to be expected that the voltage

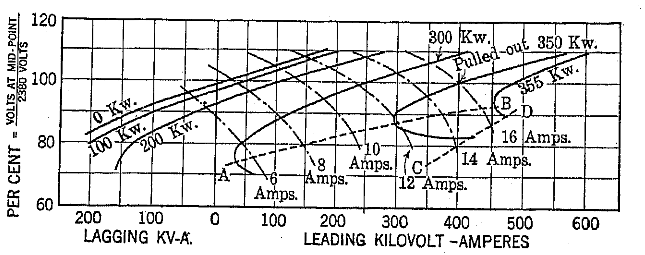

FIG. 27—MID-POINT OF TEST LINE USED IN TEST B-4

Refer to Fig. 22 for connections. $Z_1 = Z_2 = 3.84 + j\,8.08$ ohms. $Y_1 = Y_2 = 0$.

Constant voltage = 2380 volts = 100 per cent maintained at receiver and supply ends of the line (*i. e.* at "*A*" Fig. 22).

———— Curves show reactive kv-a. which the synchronous condenser at the mid-point must supply, to maintain various voltages at a number of different loads in kw. measured at receiver end of 1st section (at "B" on Fig. 22). The load actually delivered at the receiver end of the line (at "*E*" Fig. 22) can be obtained by subtracting the losses in the synchronous condenser and second section.

- — - — Curves show relation between synchronous condenser voltage and reactive kv-a. delivered for particular values of field currents (from Fig. 15). Note the large increase in reactive kv-a. between 350 and 355 kw.

regulator would operate satisfactorily almost up to the point where pull-out occurred.

At reading No. 4 with 134 amperes in the first section and 84 amperes in the second section, the per cent resistance and reactance voltages in each section were as follows:

1st Section $I R + j I X = 37$ per cent $+ j$ 79 per cent

2nd section $I R + j I X = 22$ per cent $+ j$ 49 per cent

There was no tendency toward hunting even with such high percentage resistance and reactance drops. The system stabilized after a few oscillations following a sudden change in load, provided the maximum swing did not exceed the pull-out point of the system.

As determined from Test *B—1*, 350 kw. was the maximum power which could be transmitted over the first section. In Test *B—3*, two such lines were connected in series without a synchronous condenser at the mid-point, and pull-out occurred at 190 kw. With the circuits arranged as in Test *B—3*, but with a synchronous condenser at the mid-point, 268 kw. could be transmitted. The addition of the synchronous condenser at the mid-point raised the power limit 40 per cent.

Test No. B—5. This test was made to determine the effect of damper windings on the stability of the system, particularly at times when sudden changes in load occur. The conditions were identical with Test *B—4*, except that the damper windings were removed from synchronous condenser No. 1 located at the mid-point, and from one of the motor generator sets.

The load was gradually increased and points were taken on the circle diagrams for the first and second sections in the same manner as in Test *B—4*. Pull-out occurred when the load transmitted over the first section (measured at *b*) was 356 kw., which checks closely with 350 kw. obtained in the preceding tests.

The load on the motor generator set without damper windings was changed suddenly. The tabulation below shows the fluctuation in load at the end of the second section. For convenience the corresponding loads at "*b*" (Fig 22) are given in brackets.

Trial No.	Kw. at "*c*" Fig. 22			Remarks
	On	Off	On	
1	232 (293)	160 (192)	232 (293)	Oscillations of considerable amplitude but short duration.
2	240 (301)	170 (205)		Pulled out at once. Evidently oscillated beyond "*A-B*" on Fig. 27.

The above tests show that the damper windings on synchronous condensers do not contribute materially to the stability of the system either during normal operation or with sudden changes in load.

Test No. B—6. This test was made to investigate the effect of damper windings in reducing hunting produced by forced oscillations on a system, such as would be caused by a reciprocating engine or a faulty prime mover governor. The forced oscillations were produced by cutting a block or resistance in and out of the circuit supplying the d-c. motor driving the generator used as a source of power. The severity of the hunting was gaged by the fluctuation in power as indicated by the polyphase wattmeters.

The transmission line and connected equipment were the same as used in Test *B—1*. The synchronous condenser was equipped with copper damper windings and the motor generator sets with standard brass damper windings. The voltage regulators of the generator and synchronous condensers were set to maintain 2380 volts each of the line. The load at the receiver was kept constant at 180 kw. and the frequency of the applied pulsations varied. The accompanying table shows the fluctuations in power at the receiver end of the line as indicated by the polyphase wattmeter:

LOAD AT RECEIVER END ABOUT 180 KW.

Impulses per Minute	Kw. Swing at Receiver
60	16 = 164 to 180
70	20 = 168 to 188
75	4 = 168 to 172
80	36 = 164 to 200
85	120 = 120 to 240
90	28 = 176 to 204
100	4 = 168 to 172

The hunting covered a range of 120 kw. at 85 impulses per minute which corresponds to the natural frequency. At 10 impulses per minute above or below this point the hunting was small. From these tests it can be seen that the resonant point is sharply defined and that no difficulty need be anticipated from hunting due to forced pulsations unless they are quite close to the natural frequency.

The damper windings were then removed from the synchronous condenser and one of the motor generator sets, and the test repeated. Except in the immediate vicinity of the resonant point no great change in the amount of hunting from that shown above, took place. In the vicinity of the resonant point the hunting was somewhat more severe than with damper windings. Even with damper windings the hunting at the resonant point rendered the system inoperative for practical purposes.

A similar group of tests was made with the two sections in series and a synchronous condenser at the mid-point, as in tests *B—4* and *B—5*. The results obtained were the same as in the test described above except that hunting took place at a frequency of 55 impulses per minute.

Test No. C—14. These tests were made to investigate hunting caused by the inherent characteristics of the transmission line. No external periodic pulsations were used to start hunting as was done in the preceding tests. When rotary converters first came into use considerable difficulty was experienced with hunting and investigations made at that time indicated that hunting usually occurred when the line resistance exceeded 25 per cent.

Synchronous condenser No. 1 (425 kv-a.) with copper damper windings was placed at the end of a transmission line and the line resistance and reactance were varied to investigate the effect on hunting. Power was obtained from the 2300-volt shop system to eliminate the effect of generator reactance. Hunting would not take place below the field excitations given in the table.

Condition No.	Line Impedance to neutral in ohms	Syn. Cond. excitation when hunting began
(a)	$6.66 + j\,0$	7.0
(b)	$6.66 + j\,2.02$	12.5
(c)	$6.66 + j\,4.04$	No hunting at maximum excitation = 18 amps.
(d)	$4.8 + j\,0$	9.0
(e)	$3.33 + j\,0$	No hunting at maximum excitation = 18 amperes

On the high-resistance line in (a) hunting began approximately when the excitation of the synchronous condenser was increased above that to give normal voltage on open circuit. Refer to Fig. 14 for the saturation curve.

Reactance added to the high resistance line reduced the tendency toward hunting and in (c) it was not possible to cause hunting.

When the damper windings were removed from the synchronous condenser hunting started at 4.0 amperes with the line condition at (a), instead of at 7.0 amperes with copper dampers. This shows that damper windings have some tendency to reduce hunting.

Another test was made with the set up shown in Fig. 13 and a line impedance $Z = 6.66 + j\,0$ as in (a). Power was obtained from the 625-kv-a. motor generator set. When the excitation of all synchronous machines was brought up to the value corresponding to normal voltage at no-load, vigorous hunting would occur. When hunting occurred the periodic pulsations of the synchronous machines could be heard plainly.

When the excitation was removed from any one of

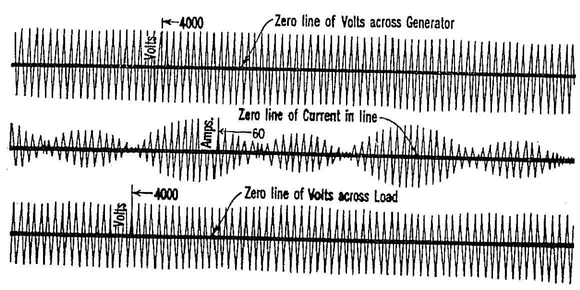

FIG. 28—HUNTING WITH HIGH RESISTANCE LINE

the synchronous machines hunting could not be started by over exciting the other two machines.

The oscillogram in Fig. 28 shows the pulsations in line current when hunting was taking place.

The foregoing tests show that a line having a large resistance as compared to reactance is likely to cause synchronous machinery to hunt. The addition of reactance to a resistance line tends to stabilize the system. On a high-resistance line, hunting is more likely to occur at high field excitation than at low field excitation of synchronous apparatus.

Test No. D—1. A number of tests were made to determine the severity of short circuits that could be applied to a system carrying load without causing pull-out to occur. The short circuit was applied through reactors to produce the effect on the main transmission system of a short circuit on a distribution circuit.

A single section of transmission line identical with that in Test B—*1* was used. The line constants were $Z = 3.84 + j\,8.08$ and the circle diagram is shown in Fig. 25. Power was obtained from the 625 kv-a. generator and the load consisted of a synchronous condenser with copper damper windings and the two

motor generator sets, all connected in accordance with Fig. 13.

When 256 kw. were being transmitted over the line (about 75 per cent of the power limit), a three-phase short circuit was applied at the receiver end, as is shown in Fig. 29. The line was short circuited through reactors having an impedance of $0.27 + j\,4.04$ to neutral. The system pulled out of step about $1\frac{1}{2}$ seconds, as measured by a stop watch, after the short circuit was applied. The oscillogram in Fig. 30 shows the reactions taking place at the time of the short circuit. The voltage regulators increased the condenser

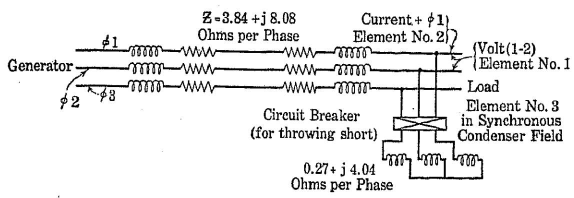

Fig. 29—Short-Circuit Test D-1

Three-phase short circuit in Fig. 30 shown. For the single-phase short circuit in Fig. 31 the oscillograph elements were connected as shown and a single-phase short circuit of $0.27 + j\,4.04$ ohms applied across phases 1 and 2.

field current to the maximum value determined by the setting of the voltage limiting rheostat in an effort to maintain the voltage.

The conditions under which pull-out will occur may be calculated by the general method previously described for determining the power limits of a transmission system, the circle diagrams of the transmission line being modified to include the reactance in the applied short circuit as a part of the line. The characteristic curves of the line (with shunt reactance)

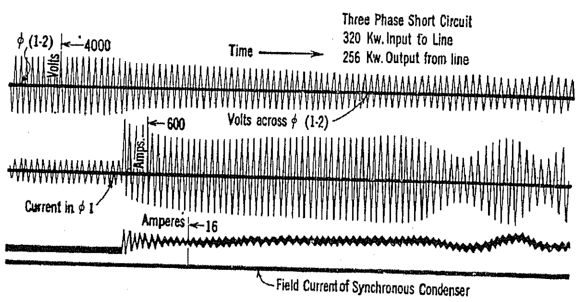

Fig. 30

and the synchronous apparatus at the load can then be obtained and superposed. If the synchronous condenser is controlled by hand the field excitation will remain constant and the maximum amount of power, which can be transmitted without pull-out taking place, can be determined from the power limit corresponding to this field excitation. If the voltage regulator is in the use it will boost the synchronous condenser excitation to the maximum value determined by the voltage-limiting rheostat and thereby increases the amount of power which may be transmitted without pull-out being caused by the short circuit.

As shown by the oscillogram in Fig. 30 pull-out did not occur until the voltage had been reduced sufficiently for the power limit of the system to be exceeded. The voltage at the receiver does not drop instantaneously because of the time required to demagnetize the synchronous condenser.

This test was repeated by applying the short circuit for only one second. The system remained in synchronism because the receiver voltage did not have time to fall until the power limit was exceeded.

Calculations made in the manner outlined above indicate that pull-out will take place with a 256-kw. load when the voltage has been reduced to about 50 per cent of normal, which checks quite closely with the oscillogram.

Fig. 31 shows the effect of a single-phase short circuit through an impedance of $0.27 + j\,4.04$ ohms applied between phases 1 and 2 at the receiver end. The other conditions were identical with those in the foregoing test. Pull-out took place in about 1-1/2 seconds as determined by a stop watch. From the oscillogram it appears that with a phase-to-phase short

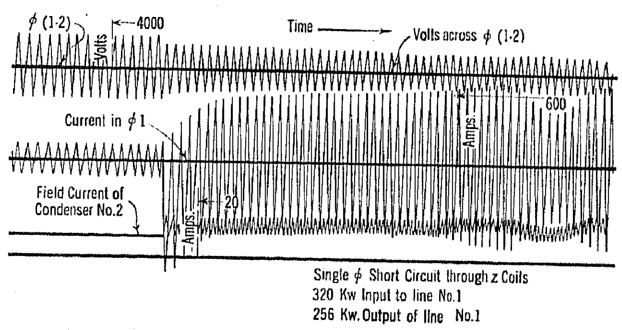

Fig. 31

circuit pull-out occurs when the voltage across the short-circuited phase has been reduced to about the same value as required to cause pull-out with a three-phase short circuit. The double frequency pulsations in the sychronous condenser field current due to the single-phase load can be seen on the oscillogram.

Conclusion

It is of fundamental importance to maintain stable operating conditions on power systems particularly for long distance transmission and interconnected power networks, not only for normal operating conditions, but also at times of short circuits on secondary systems. The method for determining the limits of stable operation presented in the paper and substantiated by tests also have application to the problem of interconnection and station tie-lines.

Power Limit of Transmission System. The method of determining the power limits of a transmission system described in this paper takes into consideration the characteristics of the load and synchronous condensers as well as those of the line with transformers.

The importance of considering the nature of the

load and characteristics of the sychronous condensers in combination with those of the transmission line is illustrated by the conditions existing on the 500-mile line.

It is reassuring to know that in the majority of the cases investigated, the power limit of the entire transmission system, when equipped with present commercial apparatus, approaches very closely the power limit of the transmission line considered by itself. As transmission distances are increased and high voltages employed, it becomes more important to consider the effect of load and synchronous condenser characteristics in combination with those of the transmission line.

Power Limits of Loaded Line. The theoretical investigations and tests show that the amount of power transmitted over a circuit may be appreciably increased by "loading the line" with synchronous condensers at intermediate points. Particular attention was given to the case where the synchronous condenser was located at the mid-point of the line. When synchronous condensers are applied at the mid-point, the power limit of the loaded line approaches that of the first section. The investigation shows that with the loaded line the power limit is to a large extent determined by the capacity of the condenser at the mid-point.

Hunting. Hunting of synchronous apparatus may be due to periodic pulsations applied to the system, or to the transmission line characteristics, when the resistance is large as compared to the reactance. In high-voltage transmission neither of these factors is of great importance. In this connection it is to be pointed out that improper adjustment of the voltage regulators may cause hunting.

The tests show that very little reduction in hunting results from operating with low-resistance copper damper windings as compared to operating without damper windings. The standard high-resistance brass damper windings commonly used for starting purposes are therefore adequate.

Pull-out Caused by Short Circuit. On a loaded line where power is distributed from loading points, there should be sufficient reactance between the transmission and distribution lines to prevent a short circuit on the distribution system from causing the entire transmission system to pull out of step.

Short circuits on a power system cause it to pull out of step as soon as the power limit at the reduced voltage is exceeded. The tests indicate that the time interval between the occurrence of a short circuit and pull-out is determined largely by the time required to reduce the line voltage.

Discussion

For discussion of this paper see page 71.

The Limitations of Output of a Power System
Involving Long Transmission Lines

BY E. B. SHAND

Associate, A. I. E. E.
Engineer, Westinghouse Electric & Mfg. Co.

***Review of the Subject.**—The conditions of stability of a system are discussed and it is pointed out that while the various transmission line diagrams as used at present implicitly assume the terminal voltage at the two ends to be constant the degree of voltage regulation as determined by load conditions is an important factor in the determination of the limit of output. A type of combined diagram is proposed whereby this factor and other characteristics of the load may be included. The effect of the inherent regulation of synchronous condensers is taken up particularly with respect to compound transmission lines.*

A numerical example of a 300-mile line is considered and various characteristic curves are drawn. The relation between the maximum output and the capacity of condensers installed at the mid-point shows the benefit obtained by increasing the condenser capacity—within certain economic limits.

Mathematical analyses are presented to cover a number of different conditions.

General Considerations and Theory

THE transmission of electric power over the long distances now considered practicable presents to the engineer a wide variety of problems for solution, some of which must be primarily economic, while others will be more strictly confined within the limits of the art. Even these purely technical problems are of radically different kinds; for instance, the necessity of the use of higher voltages results in questions of insulation and corona protection, the design of switching equipment, transformers, etc. The particular problem here considered, however, is of the capability of electric circuits of high relative impedance to deliver large quantities of power. This limitation due to impedance, becomes more prominent as the length of the lines increases and it is pertinent that methods of calculation be devised to represent as nearly as practicable the actual conditions under which a line may be expected to operate. This is the object of the present paper.

If the power demanded from a transmission system be in excess of its capability to supply, the connected apparatus at the receiving end will drop out of step and the system become inoperative. This limitation may be called the limit of output, the limit of stability or the point of pull-out. Methods of calculation of this condition based on transmission line constants and assumed voltages, or the diagrams usually substituted for these calculations, would give true results if the transmission line were the only link for the supply of power, but the electrical circuit of a transmission system comprises generators, transformers, transmission lines, synchronous condensers and the load circuit, and the limit of output will be determined by the combined effect of all of these. It may be said, therefore, that while the various transmission line diagrams as ordinarily employed give correct results as far as the definite inter-relations of power, voltage and current are concerned, the limits of output are only conventional values greater than the actual limits, and should be used only for comparative results in the case of important lines. It is possible, however, to combine the characteristics of the component parts of a power system to form a single diagram for the whole system. To make such a diagram complete becomes a much too complicated process, but it is believed that by including some of the more important factors, particularly the characteristics of synchronous condensers and of the load, a fair approximation may be made with only a justifiable amount of extra labor.

The methods presented in this paper are particularly applicable in determining the limit of output for "compound transmission lines"[1] by which is meant those lines employing synchronous condensers at intermediate stations for the purpose of voltage regulation. This type of line, recommended by Frank G. Baum,[2] promises to become of increasing importance due to the present tendency toward the development of the more distant sources of waterpower and the inter-connection of separated systems.

Before making a detailed study of the limits of output of power systems a general conception of stability of operation may be outlined. The principles involved are not advanced entirely as assumptions nor as hypotheses, but by presenting the phenomenon in this way the purpose of the various diagrams may be rendered clearer.

The characteristics of a transmission line as an electric circuit are closely similar to those of a synchronous machine, the main differences being the effect of magnetic saturation in the latter, and the much greater magnitude of the distributed capacity effect in the former. It will be found, in fact, that the various transmission line diagrams may be derived directly from the classic synchronous motor diagrams of Blondel. That the limit of stability of a line is physically re-

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

1. The term "compound transmission line" has been introduced as conveying most nearly the conception of this type of line as given in the following discussion.

2. Voltage Regulation and Insulation for Large Power, Long Distance Transmission Systems, Frank G. Baum, JOURNAL A. I. E. E., August, 1921.

lated to the pull-out of a synchronous motor is shown by the sudden and complete stalling of connected apparatus when this point is exceeded. When a synchronous motor is loaded, its rotor drops back in phase position by an angle governed by the synchronous impedance of the machine, the condition of stability being represented by the fact that an increase in angle results in an increase of torque. When the limit of stability is passed, the torque decreases with an increase in the phase angle so that this represents an impossible condition of operation. The point of transition between the two conditions occurs when the phase angle is approximately 90 electrical degrees, or more strictly, $\theta = \tan^{-1} x/r$ which may be referred to as the angle of pull-out. Similarly, the conventional limit of stable operation of a transmission line is reached when the phase angle between the sending and receiving ends has reached the corresponding value ($\tan^{-1} x/r$). This angle it will be noted is a "line constant" in both cases and is entirely independent of the values of voltage assumed.

While the angle of pull-out may be used as the fundamental expression of stability some of its accompanying relations are found to form a more convenient means of investigation in more complicated circuits. Thus in studying a simple reactive tie line with constant voltages at either end, it is found that the voltage as measured at any intermediate point will drop as the phase angle between the two extremities increases. When the pull-out angle is reached the rate of voltage change with load must be infinite. Expressing this in mathematical terms; when $\theta = \tan^{-1} x/r$, then $\dfrac{\delta \text{ voltage}}{\delta \text{ load}} = -\infty$ at any intermediate point. This has assumed that the terminal voltages do not change with load; if this condition does not exist the rate of voltage decrease will be greater over the whole line and pull-out will occur at an angle less than $\tan^{-1} x/r$ and at a correspondingly smaller load. In other words, the output limit is determined not only by the actual voltage values at the line terminals at the instant of pull-out, but also by the degree of their regulation. With this idea in mind the difference between the conventional and actual output limitations may be more definitely explained. Transmission line diagrams assume constant voltages at the sending and receiving ends so that the output limit or maximum power so derived will represent only this ideal condition. Actually, the voltage regulation is not perfect at either end of the line, and the conventional value will not be realized.

This naturally brings up the question of the effect of automatic voltage regulators as used on generators and synchronous condensers to maintain constant voltage at both ends of the line. The response of voltage to the action of regulator contacts is much too sluggish when compared with changes of phase displacement due to load to allow the vibrating regulator to be considered in a different sense from a rheostatic regulator operating with occasional adjustment and therefore their use will not modify appreciably the analysis of stability as given above. If a vibrating regulator of a much quicker degree of response were devised an entirely different state of stability might be reached. This may be considered as follows,— when the actual limit of stability is reached a condenser at the end of the line will commence to drift out of step at a rate determined by the excess load, and the voltage will drop correspondingly. A sudden increase in field excitation materially increasing the voltage would bring the rotor and voltage phase angle back again tending to cause an overshoot in the forward direction and consequent high voltage. A reduction of field current will result in the initial condition being regained, followed by the repetition of the cycle. This represents a state of artificial stability in which, with a quick enough response, it would be possible to reach the conventional output limit, or the equivalent of perfect voltage regulation would be obtained. This theory of artificial stability, although perhaps not a practical possibility, is here outlined mainly for the purpose of preventing any misconception regarding the capabilities and limitations of the commercial vibrating regulator in connection with the present subject. Moreover, if the state of artificial stability were attainable it is very doubtful that it would be desirable to depend on this apparatus as the main link in maintaining the operation of the system. In deriving the limit of output for power systems it may be considered that the condensers are operating under a definite value of excitation for each value of load, this value being adjusted by the regulator as the load conditions change.

The general conception of stability may be considered in connection with the theory of compound lines. It has been stated that if the voltages at two points in a circuit are perfectly regulated the limit of stability occurs when the phase angle between the two points equals $\tan^{-1} x/r$, this being independent of the remainder of the circuit. Applying this to the compound line it will be seen that if the voltage regulation at every condenser station be considered perfect the limit of stability is that of the individual sections of line. Adding sections of line will not reduce the output except by the losses in the sections themselves. Actually, of course, the inherent regulation characteristics of the condensers used are finite and the actual output limit of a compound line must be somewhere between the value of the "weakest" section as referred to above and that of the complete line neglecting the intermediate condensers. To accurately evaluate such a line the actual regulation characteristics of the condensers used must be combined with the line diagram.

The synchronous condenser has inherently very desirable characteristics from the standpoint of voltage regulation; it forms a kind of reservoir of magnetization by delivering magnetizing current to the line in in-

creased amounts as the voltage falls. The rough mathemtaical expression for the characteristic of a condenser with constant excitation is as follows:

$$I_o = \frac{E_c - E_r}{X_c}$$

I_o = magnetizing current.

E_c = open-circuit voltage of condenser.

E_r = applied terminal voltage.

X_c = synchronous impedance of condenser.

If a condenser be small, the regulation will be poor and its effect towards increasing the capabilities of the compound line will be limited. Considering, on the other hand, the hypothetical case of a condenser of infinite capacity, X_c will equal zero and the inherent regulation must be perfect, and in the case of the compound line the limit of stability would be truly that of the "weakest" section alone. This comparison demonstrates clearly the importance attached to the choice of condensers for such applications.

In the above connection it may be noted that static condensers are inherently unsuitable for the regulation of long lines. Their inherent characteristics may be expressed thus,

$$I_o' = E_r / X_c'$$

which signifies that the magnetizing current decreases with the voltage, the effect on regulation being therefore negative. This same argument applies to the distributed capacity of the line itself.

The subject of stability might be examined from one other angle. In a paper before this Institute[3] it has been inferred that if the load on a transmission line could be maintained at a certain critical value, the distance to which the power might be transmitted is limited only by the line losses. On examining the examples given from the standpoint of stability it was found that the conventional limit of stability occurred at the distance of one quarter wave length. It may be stated then that even for the restricted conditions considered the use of synchronous condensers at intervals of a few hundred miles would be a necessity, not to change the voltage conditions, for they might be merely floating on the line without carrying reactive current, but to reduce the relation $\frac{\delta \text{ voltage}}{\delta \text{ load}}$ along the line and thus maintain the stability of the system.

LINE DIAGRAM

In dealing with long distance transmission lines it has become the recognized practise to treat the effects of distributed capacity by means of hyperbolic functions. The conventional vector equations may be written.[4]

$$E_s = E_r \cosh \sqrt{Z\,Y} + I_r\, Z \frac{\sinh \sqrt{Z\,Y}}{\sqrt{Z\,Y}} \qquad (1)$$

$$I_s = E_r\, Y \frac{\sinh \sqrt{Z\,Y}}{\sqrt{Z\,Y}} + I_r \cosh \sqrt{Z\,Y} \qquad (2)$$

E_s and E_r are respectively the voltages at the sending and receiving ends, and I_s and I_r the corresponding values of current. Z is the total line impedance, and Y the admittance. All quantities are complex.

These expressions may be abbreviated to the form[5]

$$E_s = A\, E_r + B\, I_r \qquad (1a)$$

$$I_s = C\, E_r + A\, I_r \qquad (2a)$$

and rearranging—

$$E_r = A\, E_s - B\, I_s \qquad (3a)$$

$$I_r = -\, C\, E_s + A\, I_s \qquad (4a)$$

where

$$A = \cosh \sqrt{Z\,Y}$$

$$B = Z \frac{\sinh \sqrt{Z\,Y}}{\sqrt{Z\,Y}}$$

$$C = Y \frac{\sinh \sqrt{Z\,Y}}{\sqrt{Z\,Y}}.$$

The relation of the above formulas to those for the simpler short lines may be noted by assuming the distributed capacity Y negligible. Under this condition $\cosh \sqrt{Z\,Y}$ and $\frac{\sinh \sqrt{Z\,Y}}{\sqrt{Z\,Y}}$ both become equal to unity. Then $I_s = I_r$ and $E_s = E_r + I_r\, Z$ which is the familiar expression for the simple circuit.

A simple voltage vector diagram may be drawn, very convenient for the purpose in hand, directly from equation (1) — or (1a). This diagram has already been published several times and in some cases expanded in an elaborate manner.[6]

For convenience in graphical construction and algebraic analysis the line constants may be written in form

$$A = A_1 + j\, A_2$$

$$B = B_1 + j\, B_2$$

$$C = C_1 + j\, C_2$$

while as a scalar quantity—

$$B = \sqrt{B_1^2 + B_2^2}$$

Similarly I_r and I_s may be resolved into their power and wattless components

$$I_r = I_{rw} + j\,I_{ro}$$

$$I_s = I_{sw} + j\,I_{so}$$

I_{rw} and I_{sw} being in phase with E_r and E_s respectively.

The general construction of the voltage diagram using E_r as a datum of reference is shown in Fig. 1.

From the geometrical construction it is evident that with E_r assumed constant and considering only the power component of current, ($I_{ro} = 0$), the locus of E_s must lie on the line $T\,S$, while for any given power component of current, varying the wattless component will merely move the locus of E_s along a line perpendicular to $T\,S$,—the line $G\,H$, for instance. With these relations in mind it may be seen that the lines $T\,S$ and $T\,K$ may be utilized as the axes of the two components of current, or if preferred, of kilowatts and reactive kv-a. The former is utilized mainly in the following discussion.

Considering further the geometrical relations of Fig. 1 it is obvious that E_s' is the minimum value of voltage at the sending end which will sustain a load at the receiving end corresponding to the point S, and conversely that with the voltage E_s' this load represents the maximum value, or remembering that the voltages are taken as constant this will represent the conventional limit of stable operation of the transmission line. E_s' is parallel with $T\,S$ so that this point will occur when the phase angle between the voltages at the two ends of the line is equal to $\tan^{-1} B_2/B_1$ which is the equivalent of $\tan^{-1} x/r$ of either the simple circuit or of the synchronous machine. This angle as mentioned before is purely a line constant.

From Fig. 1 can be obtained E_r, E_s, I_r, the power factor at the receiving end, and the voltage phase angle θ. With a slight complication I_s and its phase angle with E_s may be included as well. Thus, from equation (3a)

$$B\,I_s = A\,E_s - E_r \tag{5}$$

In Fig. 2 $O\,L = (A_1 + j\,A_2)\,E_s$ and $L\,V = (B_1 + j\,B_2)\,I_s$. By using the same reasoning as for Fig. 1, I_{sw} is found to be along the axis $L\,W$ and I_{so} at right angles to it. The current values can be measured on the same scale as I_{rw} and I_{ro}. If kw. and reactive kv-a. are desired, the scale will differ from the corresponding one at the receiver end by the ratio E_s/E_r. The value of power-factor at the two ends of the line may be taken as $\cos\phi_r$ and $\cos\phi_s$ respectively. The line efficiency may be obtained from the quantities given by a short numerical calculation.

Although usually more convenient, it is not necessary to resort to graphical methods to determine certain conditions of operation. Certain expressions which are particularly convenient as occasional checks on graphical results are given below. Their derivation will be found in the Appendix.

For the conventional point of pull-out, $\theta = \tan^{-1} x/r$

$$I_{rw}\ \text{(pull-out)} = E_s/B - M\,E_r \tag{6}$$

$$P_r\ \text{(pull-out)} = E_r\,(E_s/B - M\,E_r) \tag{7}$$

where P_r is power at the receiving end in watts per phase assuming E_r to be the voltage to neutral.

$$M = \frac{A_1\,B_1 + A_2\,B_2}{B^2}\ \text{(a line constant)} \tag{8}$$

These quantities are all scalar. With the same conventional assumptions of perfectly constant terminal voltages it is possible to derive additional relations. In the case of a direct-current circuit it will be remembered that the power flow into any part of the circuit is a maximum when the voltage across this part is equal to one-half the total voltage or $E_r = E_s/2$. For a transmission line the equivalent condition is found to be represented by the expression

$$E_r = \frac{E_s}{2\,M\,B} \tag{9}$$

for which condition

$$I_{rw}\ \text{(maximum pull-out)} = \frac{E_s}{2\,B} \tag{10}$$

$$P_r\ \text{(maximum pull-out)} = \left(\frac{E_s}{2\,B}\right)^2 1/M \tag{11}$$

In investigating the significance of these equations it will be found that the limit of output is a maximum in the case of a normal 60-cycle line when the receiver voltage is considerably higher than the sending, although it is true that on account of the large condenser capacities required for such voltage relations this will not represent an economical condition of operation. For lines of 25 cycles and less it will probably be found that the maximum output of the line will be obtained when E_s is raised appreciably higher than E_r. In the case of the higher frequency lines more accruate assumptions as regard voltage regulation will naturally tend to change these relations somewhat, particularly when the condenser is such a large factor in the result. When lines are operated so that E_r is greater than the critical value $\frac{E_s}{2\,M\,B}$ it is found, as expressed in some of the following diagrams, that the actual and conventional limits of stability coincide; that is, the line actually pulls out with the angular displacement equal to $\tan^{-1} B_2/B_1$

The reactive component of current at the receiver end, I_{ro} may also be expressed in mathematical form.

$$I_{ro} = E_r\,K \pm \sqrt{(E_s/B)^2 - (P_r/E_r + E_r\,M)^2} \tag{12}$$

K being an additional line constant of the value

$$K = \frac{A_1\,B_2 - A_2\,B_1}{B^2} \tag{13}$$

The quadratic equation (**12**) will have two real solutions, a singular solution, and imaginary solutions. These may be interpreted from Fig. 1 as follows,—the smaller real solution (that of minus sign) will represent the condition of stable operation, ($\theta < \tan^{-1} B_2/B_1$), and the greater solution (that with plus sign) will represent the unstable zone where $\theta > \tan^{-1} B_2/B_1$. The singular solution corresponds to the point of pull-out, $\theta = \tan^{-1} B_2/B_1$. The imaginary solutions are for conditions where the conventional pull-out load is exceeded. For the singular solution equation (**12**) may be expressed.

$$I_{ro} = K\,E_r \qquad \textbf{(14)}$$

which shows that the value of reactive current at the conventional point of pull-out is a direct function of the receiver voltage and independent of the other conditions of operation.

Equations (**12**) and (**14**) represent only the reactive current in the line itself; to obtain the total condenser current there must be added to I_{ro} the magnetizing current required by the load as estimated at this same point. A synchronous condenser must be chosen on the basis of the algebraic sum of the two.

The System Diagram

The preceding diagram may be properly applied only to the transmission line. To define the limiting conditions of operation of a transmission system the characteristics of the line must be combined with those of the rest of the circuit. In this respect, the line transformers represent no particular difficulty, their concentrated

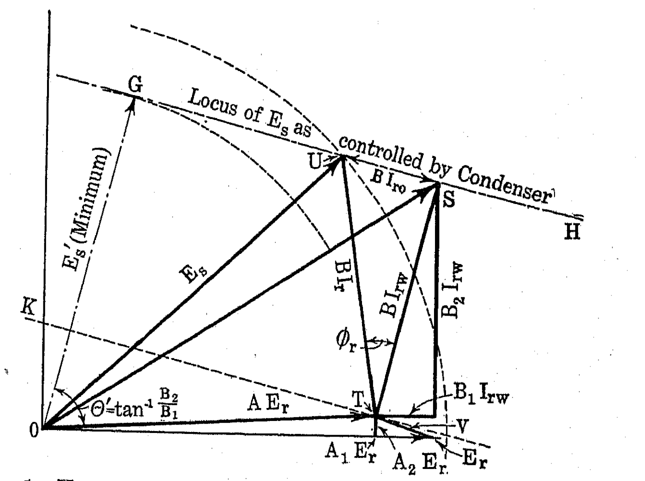

Fig. 1—Voltage Vector Diagram of a Transmission Line

impedances may be included with that of the line and a set of line constants derived by the method already referred to. The diagram of Fig. 1 will then represent the line with transformers. Due to the fact that many of the assumptions made in transmission line calculations must necessarily be rather broad approximations it may not be entirely necessary to take into account the magnetizing current of the transformers. If the necessary data for this is available, however, it should be combined with the characteristics of the adjacent synchronous condenser. The magnetizing current and the condenser currents result from shunt admittances at the same point of the circuit so that the above suggestion is technically correct. The magnetizing current decreases at a considerably faster rate than the transformer voltage so that it will add very slightly to the stabilizing effect of the condenser station. In the case of the transformers at the sending end the main effect of the magnetizing current is a very slight increase in the

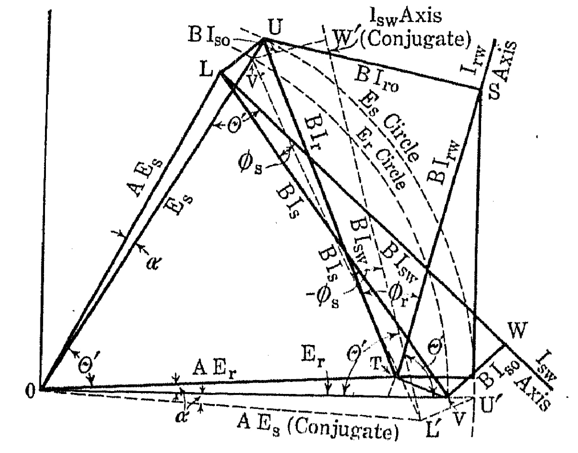

Fig. 2—Diagram Including Current Relations at Sending End

field current of the generators and may be otherwise neglected.

In the following discussion the effect of the inherent voltage regulation of the main generators has been neglected. This is justified on the grounds that the error is slight while the labor involved would increase greatly. Two methods, almost equally laborious may be used in taking this factor into account; one is the ordinary method for the compound line, while the other is an extension of the method used for transformers. The synchronous impedance of the generator may be added to that of the transformer at the sending end and a diagram used for the line transformers and generator. The "sending voltage," *i. e.*, the internal voltage of the generator, becomes a variable and a separate diagram must be worked out for each value of excitation while in addition these diagrams must be correlated with the conditions at the actual sending terminal of the line. Both of the above methods become somewhat complicated.

The effect of the load on the limits of a transmission line is important and its characteristics should be approximated with a fair degree of accuracy. For this purpose two general classes of loads may be considered; first where the power required is independent of voltage, and second, where the power required decreases with voltage. The rotating machine where the output is determined by frequency is typical of the first class, while a lighting or heating load where the power varies with the square of the voltage is typical of the second. The actual load of a system is a combination of a large number of units of both of these classes, with possibly

other classes less clearly defined in addition. The rotating load is usually of preponderant value although the component of lighting load will produce some tendency for a decrease with voltage which may be estimated when the relative proportions have been determined.

Due to the importance of the constant power type of load its characteristics may be studied in some detail. It may be noted then, in Fig. 1, that if the power com-

Constants $A_1 = 0.85$
$A_2 = 0.075$
$B_1 = 168$
$B = 183$

Fig. 3A—Reactive Current Curves Derived from Voltage Diagrams

ponent of current I_{rw} be varied inversely with E_r the locus of the point S, $(O S = A E_r + B I_{rw})$, will be a hyperbola with the lines $O T$ and $O G$ as asympotes. The hyperbolas for various values of P_r are shown in Fig. 3, the various vectors corresponding with those of Fig. 1. The reactive components of current are indicated by the intervals measured parallel to the line $N S$ and between the hyperbolas and the circular locus of E_s. The zone of stable operation considered on the conventional basis is then represented by the triangle $N O S$, $N S$ being designated as the "pull-out line." One hyperbola may be drawn which will just become tangent to the pull-out line; this represents the condition of maximum output expressed by equation (**11**). It may be observed that in consequence of the locus E_s becoming tangent to the line $N S$ the rate of change of reactive current, $\frac{\delta I_{ro}}{\delta E_r}$, is infinite for the condition of pull-out.

Although the conditions of stability may be readily visualized from Fig. 3, it will be found much more convenient for actual calculations to replot the data as in Fig. 3A. These curves show the relation between power, voltage, and reactive current at the receiving end. The characteristic curves are slightly similar in form to the V-curves of a synchronous motor although plotted on a somewhat different basis. The curves represent the requirements of reactive current for the different conditions of operation, so if the regulation curves of the synchronous condenser, representing the reactive current capable of being furnished under various conditions of voltage and excitation, be plotted with reference to the same axes, the intersections of the two sets of curves gives resultant points of operation of the combination. An additional assumption is made that the load is of unity power-factor.

Assuming the condenser to be operating with constant excitation the limit of output occurs where the two sets of curves would become mutually tangent. Thus, it is noted that the $P r = 30$ curve becomes tangent to one of the condenser regulation curves at 90 kilovolts. According to the theory already advanced, if the condenser were furnished with a vibrating regulator set to maintain 90 kilovolts on the line the limit of output would be identical with the above, even assuming the load to be free from fluctuations. The conventional limit, where the various P_r curves cross the pull-out line would indicate this load to be stable until the voltage decreased to 86 kilovolts. These curves show definitely how the actual limitations of a line depend upon the condenser characteristics, and furthermore that the static condenser does not have the proper inherent characteristics for transmission line regulation. These relations may be better appreciated by referring to Fig. 4 which is derived from Fig. 3A. Here a comparison is presented between the conventional limit, the limit with a condenser of finite characteristics, and the limit with a static condenser for line regulation. It will be noted that the various limits converge to the critical point where $E_r = \frac{E_s}{2 M B}$ (**9**). At this point and above, pull-out must occur where $\theta = \tan^{-1} B_2/B_1$ so that it may be deduced that in the case of low-frequency lines where the normal voltage relations will approach those of equation (**9**) the conventional line diagram will give reasonably accurate results for steady

loads, although such will not be the case for lines of higher frequency as is shown in the later examples.

In combining the line and condenser characteristics in Fig. 3A the reactive component of the load has been neglected; Fig. 5, however, shows the combination of

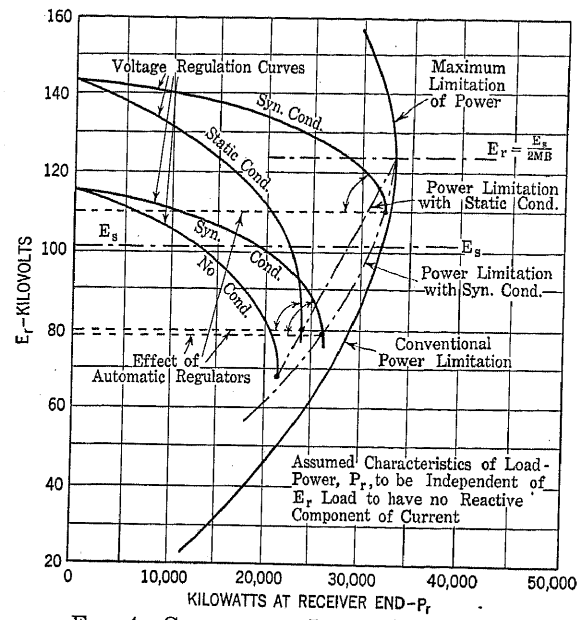

Fig. 4—Comparative Limits of Output

the line characteristics with those of a synchronous motor at constant excitation. The intersections of corresponding curves giving the points of operation, the limiting condition being as before the point of mutual tangency of the two sets of curves. To indicate the effect of a synchronous condenser on the above com-

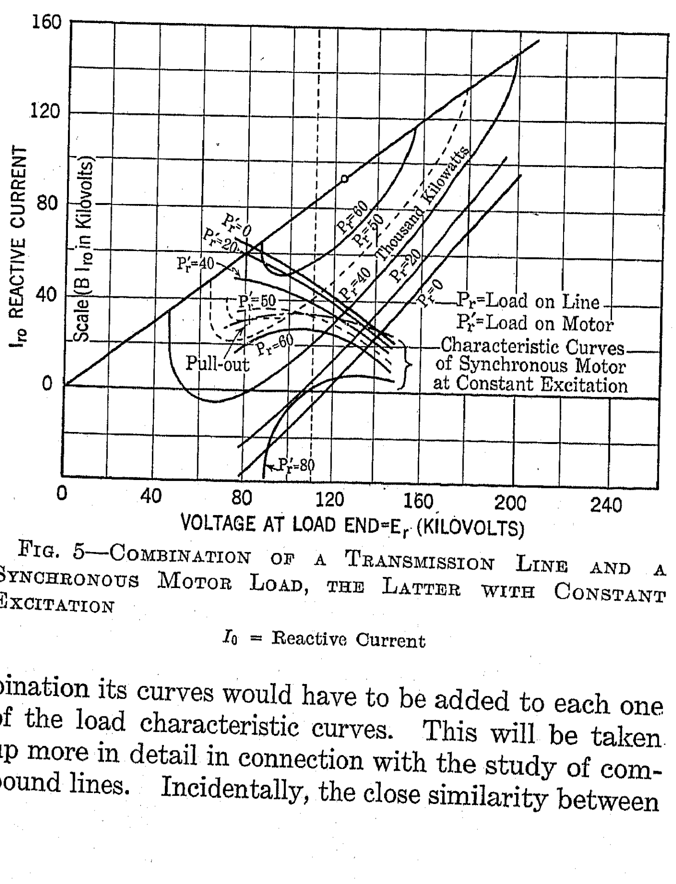

Fig. 5—Combination of a Transmission Line and a Synchronous Motor Load, the Latter with Constant Excitation

I_0 = Reactive Current

bination its curves would have to be added to each one of the load characteristic curves. This will be taken up more in detail in connection with the study of compound lines. Incidentally, the close similarity between the characteristics of the synchronous motor and those of the transmission line may be noted in Fig. 5.

To pass now from the constant power type of load, Fig. 6 has been drawn to represent a load of constant current, a state somewhere between a motor load and a lighting load. Fig. 6A shows that the actual limit of output will always coincide with the conventional value just as in the case of the constant power load when E_r is greater than $\frac{E_s}{2\,M\,B}$. The above condition, it should be noted, will not hold necessarily in the case

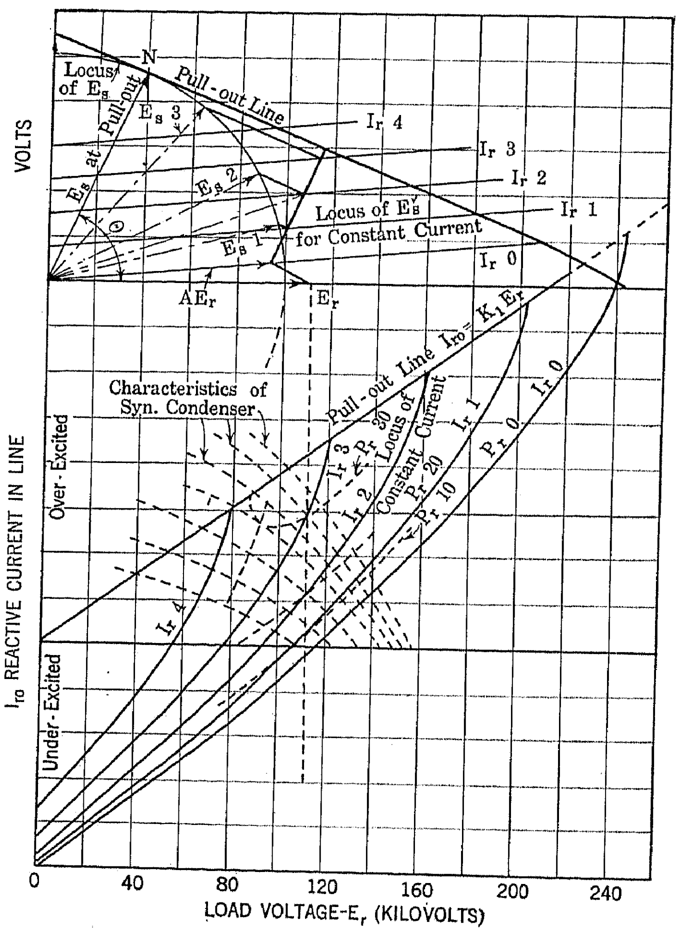

Fig. 6—Transmission Line Diagram. Diagram of Voltage Vectors

Constants A_1 = 0.85

Fig. 6A—Reactive Current Diagram Derived from Fig. 6

of a compound line for the inherent characteristics of the load are masked to some extent by the effect of the condenser at the receiving end. In general, such a load is very favorable from the standpoint of stability.

The regulation curves of the synchronous condenser depend upon the rated capacity of the machine and upon the various design features involved. The curves may be obtained in the ordinary way from the load saturation curves at zero power factor[7] with the excep-

7. See Section 4394 of A. I. E. E. Standards, 1922, etc.

tion that the condensers will always be connected to the transmission lines through transformers, the impedance of which will modify their characteristics as considered with respect to the line. This effect is equivalent to an increase in the armature reactance of the condenser, so that corrected load saturation curves may be drawn by increasing the reactance component of voltage drop by the reactance drop in the transformer. This method was employed in obtaining the data for Fig. 7. When the relation between magnetizing current and voltage is known for the transformer this current can be subtracted from the corrected condenser current at corresponding voltages, the result being a complete regulation curve for the condenser and transformer.

It may be remarked that the increased impedance due to the transformer has a material effect on the regulating action of the condenser and that it should be reduced as low as is practicable. The operating experience obtained with such transformers of high impedance fully verifies this conclusion.

In connection with the operation of automatic voltage regulation one further limitation may be mentioned. The operation of the regulator is only possible up to the point where the full exciting voltage is impressed across the condenser field winding, at which point the regulator contacts become blocked in the closed position. If the requirements from the condenser are still increased the machine operates with constant maximum excitation, the voltage dropping as the load increases. On account of economic considerations involved in the application of condensers this point of maximum current will usually be reached considerably before the limit of output. Therefore pull-out should occur with constant excitation on the condenser.

Compound Transmission Lines

The compound transmission line can probably be studied best by means of an actual example where the quantitative factors are directly involved. Consider then a 300-mile transmission line with a condenser station at the mid-point. Actually the condenser would be somewhat more beneficial if placed slightly closer to the sending end.

The following are the data on the assumed line:

Complete line

Length of line, 300 miles.

Conductors, 500,000 cir. mil aluminum cable.

Spacing—15 ft. effective spacing 18.9 ft.

Voltage between conductors 150,000 volts (86,600 volts to neutral).

Derived constants for 300 mile line.

$A = 0.807 + j\,0.043$	$A_1 = 0.807$
$B = 48.7 + j\,229$	$A_2 = 0.043$
$C = (-\,0.0228 + j\,1.52)\,10^{-3}$	$B_1 = 48.7$
$K = 3.33 \times 10^{-3}$	$B_2 = 229$
$M = 0.913 \times 10^{-3}$	$B = 234$

Derived costants for each 150 mile section.

$A = 0.9507 + j\,.0112$	$A_1 = 0.9507$
$B = 27 + j\,120.6$	$A_2 = 0.0112$
$C = (-\,0.0036 + j\,0.80)\,10^{-3}$	$B_1 = 27$
$K = 7.51 \times 10^{-3}$	$B_2 = 120.6$
$M = 1.78 \times 10^{-3}$	$B = 123.5$

For the purposes of the present discussion the impedance of the line transformers has been neglected, mainly so that the two line sections may be considered to be identical. When this factor is included the above constants will merely suffer some modification. For accurate line calculation it should be included.

The characteristics of a 25,000-kv-a. synchronous condenser combined with a transformer of 8 per cent reactances is shown in Fig. 7. The effect of the magnetizing current of the transformers has been neglected, although if desired this can be taken into account by the method already referred to. Although condensers of various ratings are introduced into the discussion the regulation characteristics of all are assumed to vary

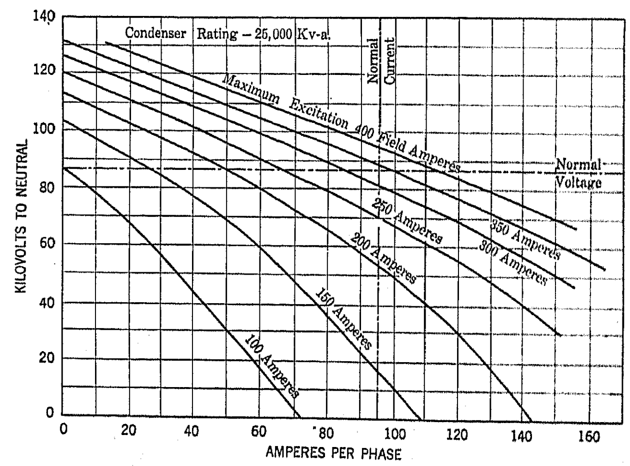

Fig. 7—Voltage Regulation Curves of Synchronous Condenser and 8 Per Cent Reactance Transformer

with these curves proportional to the rating assumed for the condenser.

For the first set of data discussed the voltages at both the sending and receiving ends of the line have been assumed constant. For the receiver voltage this means that it is unnecessary to make any assumptions regarding the change of load with voltage. The limit of output may then be obtained from equation (7), or

$$P_r = 86{,}600\,(86{,}600/234 - 0.913 \times 86.6) \qquad \textbf{(15)}$$
$$= 25{,}200 \text{ kw. per phase or } 75{,}600 \text{ kw. total.}$$

This is the conventional limit of the 300-mile line without intervening condensers. When a condenser of finite capacity is placed at the middle point of the line, a type of diagram similar to Fig. 5 must be employed. Assuming various values of voltage at the middle condenser A, from a diagram similar to Fig. 1 there may be worked out for each value of load at the receiver end, the power and reactive current at A. Also with a diagram such as Fig. 3 the conditions of voltage, power and reactance current may be worked out for the sending

section of the line. Due to the discrepancy between the power at the point A and the point B these two sets of data may, for conveneince be plotted up together in the form of Fig. 8. Here the full line and dot-dash curves represent the receiver section of the line and the dotted curves represent the sending section. With a load at the receiver end corresponding to $o\ m$ the line loss in the receiver section will be $n\ p$. The reactive current furnished to the station A will be $r\ p$ while that required for the sending section will be $-\ r\ q$, the net result being that there is an excess of magnetizing current at A of the amount $p\ q$. These data may then

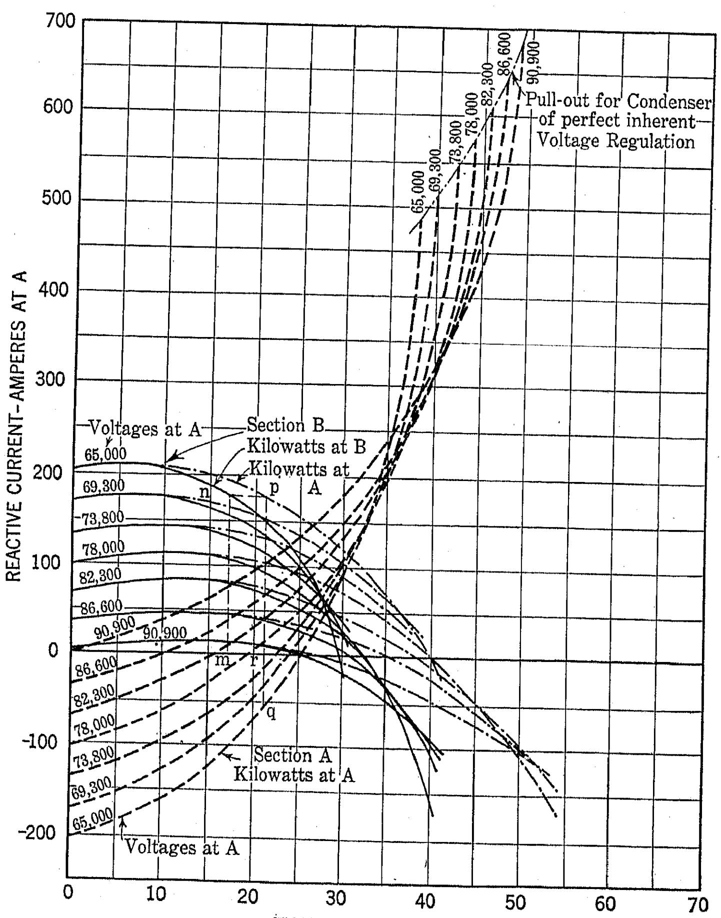

FIG. 8—CONDITIONS AT MID-SECTION OF LINE FOR DETERMINING CONDENSER CAPACITY REQUIRED

be plotted as shown in Fig. 9, the full lines representing the characteristics at the point A for the whole line. The intersections of these curves with the condenser regulation curves give the points of operation of the combination of line and condensers. By employing different condenser curves the effect of the choice of condenser is readily apparent. Fig. 10 gives the voltage regulation curves at the station A assuming condensers of various sizes to be employed. The point at which the voltage regulators become blocked is shown as well as the load and voltage at which pull-out occurs.

In connection with Fig. 10 it may be interesting to note that although the 175,000-kv-a. condenser is sufficiently great in capacity to allow the regulator to operate completely up to the pull-out line at 86,600

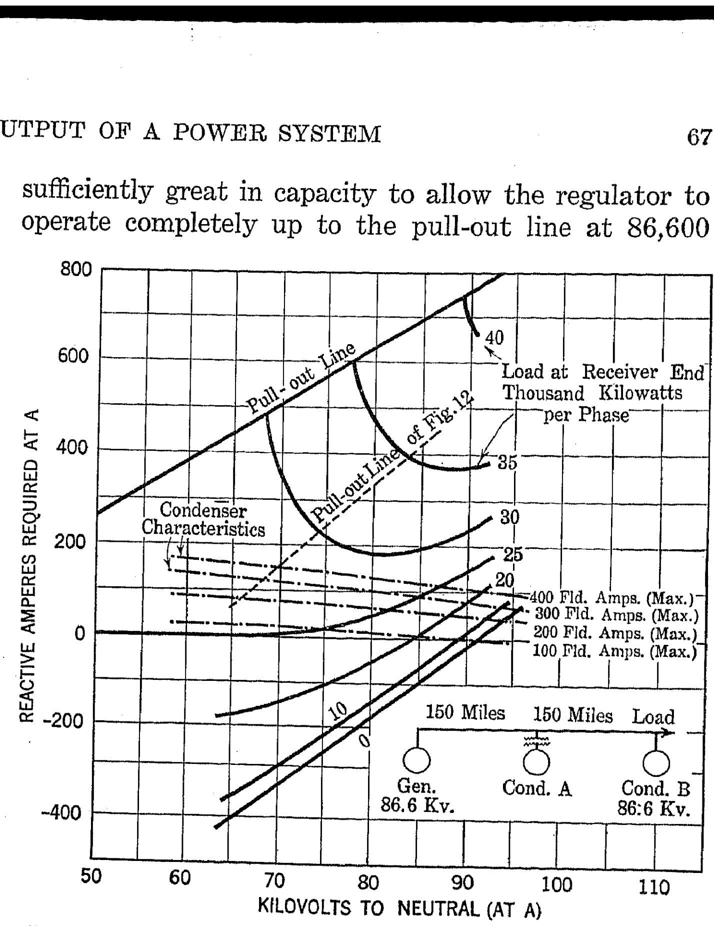

FIG. 9—RELATIONS BETWEEN CURRENT AND VOLTAGE OF THE MID-POINT OF A 300-MILE TRANSMISSION LINE RECEIVER VOLTAGE CONSTANT

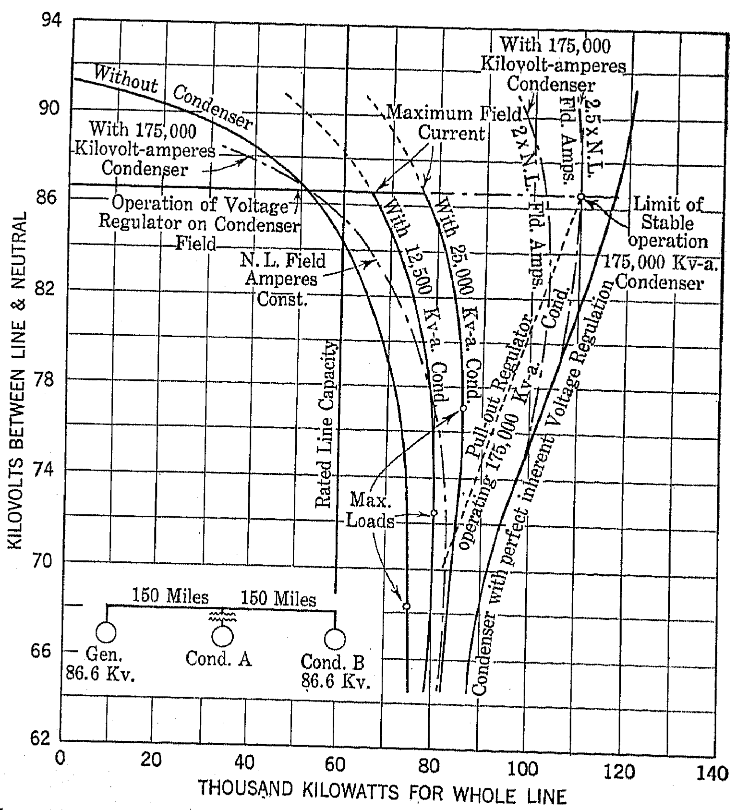

FIG. 10—CHARACTERISTICS OF VOLTAGE AND LOAD AT MIDDLE POINT OF 300-MILE TRANSMISSION LINE

volts, the inherent characteristics of the machine result in the limit of stability occurring at 110,000 kw. instead of the conventional 117,000 kw. Fig. 10 is of the same type as Fig. 4.

Fig. 11 has been plotted to show the relationship existing between the limit of output of a compound line and the size of the condenser used. It will be noted that to transmit the maximum amount of power over a line must become very uneconomical even if examined no farther than from the standpoint of the capital cost of synchronous condensers.

A final and rather elaborate study was made of this compound transmission line on the assumption that the condenser at the point B was finite in its characteristics. Two condensers, (a total of 50,000 kv-a.), each with characteristics represented by Fig. 7 were placed at this point while the load was assumed to be independent of voltage and at a constant power-factor of 90 per cent. The amount of labor resulting from this change was several times greater than before, the line being equivalent of a compound line of three sections. It is believed, however, that it may be possible to reduce this labor very considerably by using kinematic devices to represent the line characteristics. Fig. 12 is the diagram, resulting from this study, it is of the same general character as Fig. 9 although the limits are still further reduced. The above assumptions made concerning the load characteristics are only roughly approximate. If, for instance, the load is made up of 70 per cent rotating load and 30 per cent lighting load the increase of current with the decrease of voltage will be roughly half as great as in the case of constant power, which would tend to increase the stability. The assumption of the power factor being independent of load is probably not greatly in error. In a highly diversified load, where both synchronous and induction motors may be operated at various fractions of their ratings their effect on power factor with a change in voltage may be largely equalized. Where closer approximations of the load may be made the hyperbolic loci may be modified to correspond, an instance of which is given in Fig. 6.

The results of Fig. 12 have been included in Fig. 11 so that the error made in assuming a constant voltage at the receiving end is indicated as the difference between the two curves. With a 25,000-kv-a. condenser at the station A in each case the limit of output is reduced from 86,000 kw. to 75,000 kw.

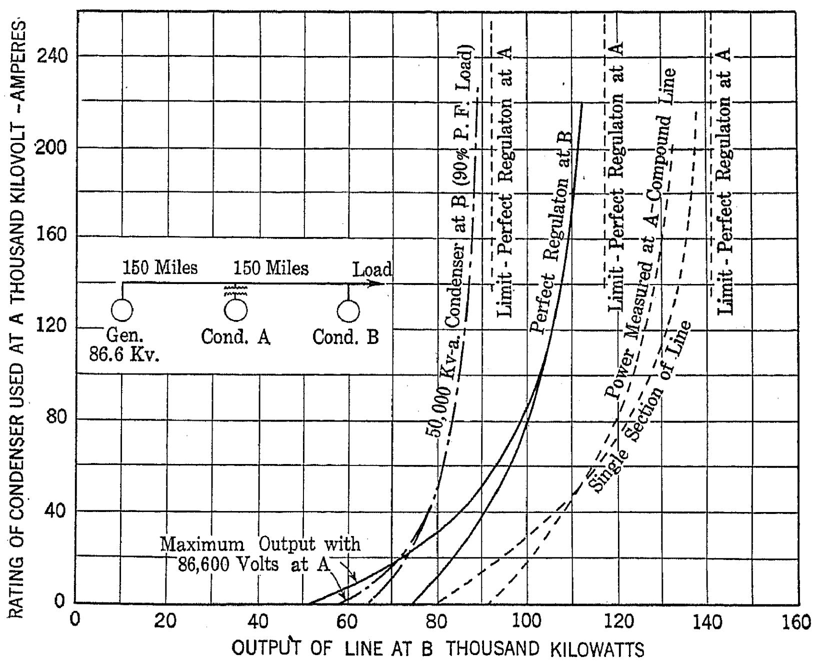

Fig. 11—Limits of Output of a Compound Transmission Line as Determined by the Condenser Characteristics

Summary

In the foregoing pages a method for determining some of the limitations of transmission systems has been developed in accordance with the conception of operation outlined, representing as nearly as practicable, it is believed, the actual conditions under which such a system will operate. In using this method it is essential that the characteristics of the apparatus connected to the transmission line, such as synchronous condensers and transformers, shall be accurately known as well as those of the line itself, and that reasonable approximations should be made regarding the characteristics of the load even when it is diversified. While this may often involve tedious complications the greatly increased accuracy of transmission line computations will much more than justify its use, if not making it almost a necessity in the case of compound lines.

The comparison of the various types of calculations given in Fig. 11 shows the importance of the more complete methods for these lines and how the maximum rating of a line may be increased by adding to the condenser capacity at the various stations. Beyond some point, however, the condenser capacity must increase rapidly for an increase of load. Such curves will furnish new data for the economic study of transmission systems.

A conclusion has been drawn that static condensers are not inherently suitable for line regulation even though their cost might compare favorably with that of the synchronous machine. The vibrating regulator in connection with the field circuit has been indicated is too sluggish to introduce a state of artificial stability

Load 90 per cent power factor

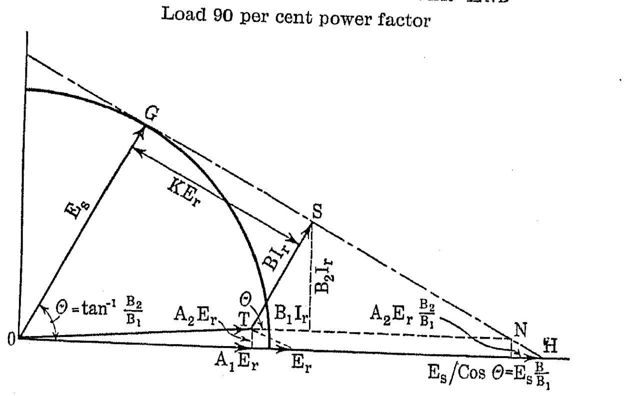

FIG. 13—VOLTAGE AND CURRENT RELATIONS FOR MAXIMUM POWER

extending beyond that produced by constant excitation even on steady loads.

The effects of fluctuating loads and load surges have not been considered. A load change of the type of a short circuit may be studied on the assumption that the field current of the condensers does not change during the period of load adjustment, but for fluctuating loads it will be practically impossible to determine the rate of increase of excitation with respect to the rate of increase of load.

Appendix

DETERMINATION OF I_s.

The construction referred to for determining the current at the sending end, I_s, has the disadvantage that a new axis of I_{sw}, ($L\,W$ in Fig. 2) must be drawn for each value of phase angle θ even although E_s is of constant magnitude. By transposing a part of Fig. 2 so that E_s falls on E_r and E_r on E_s, Q' will correspond to Q and V' to V. The triangle $L'\,V'\,W'$ corresponds to triangle $L\,V\,W$ so that $L'\,W' = B\,I_{sw}$ and $W'\,V' = B\,I_{so}$. By this modification of construction the I_{sw} axis becomed fixed for each magnitude of E_s. When obtaining series of values at different loads this will simplify greatly the graphical constructions. It should be noted, however, that the inversion of the diagram will also invert the angles of lag and lead with reference to I_{so}.

In the line diagram the values of current are expressed explicitly as voltages, $B\,I_{rw}$ for instance represents a voltage; by constructing a scale in the ratio of $1/B$ to the voltage scale whereby all currents may be read directly.

MATHEMATICAL DERIVATIONS

A number of mathematical relations may be derived as follows: Let Fig. 13 represent a transmission line operating at the conventional point of pull-out. As in Fig. 1

$$E_s^v = (A_1 + j\,A_2)\,E_r + (B_1 + j\,B_2)\,I_r \qquad (16)$$

Then as P_r is a maximum when $\theta = \tan^{-1} B_2/B_1$

$$T\,N = E_s\,B/B_1 - (A_1\,E_r + A_2\,E_r\,B_2/B_1) \qquad (17)$$

$$B\,I_{rw} = \left\{ \frac{B\,E_s - (A_1\,B_1 + A_2\,B_2)\,E_r}{B_1} \right\} \cos\theta$$

$$= \frac{B\,E_s - (A_1\,B_1 + A_2\,B_2)\,E_r}{B} \qquad (18)$$

I_{rw} (pull-out)

$$= E_s/B - \frac{(A_1\,B_1 + A_2\,B_2)\,E_r}{B^2} = E_s/B - M\,E_r \quad (6)$$

$$(P_r \text{ (pull-out)} = E_r\,I_{rw} = E_r\,(E_s/B - M\,E_r) \quad (7)$$

The value of P_r expressed by (7) will be a maximum when:

$$\frac{\delta}{\delta\,E_r} \{E_r\,(E_s/B - M\,E_r)\} = 0 \qquad (19)$$

$$E_s/B - 2\,M\,E_r = 0$$

or

$$E_r = \frac{E_s}{2\,M\,B} \qquad (9)$$

by combining (6) and (9)

$$I_{rw} \text{ (Maximum pull-out)} = \frac{E_s}{2\,B} \qquad (10)$$

the corresponding value of power is naturally

$$P_r \text{ (Maximum pull-out)} = \frac{E_r\,E_s}{2\,B} = \left(\frac{E_s}{2\,B}\right)^2 1/M \quad (11)$$

It is frequently desired to be able to determine the condenser capacity required under certain conditions of operation. To determine the reactive current in the line, but not that of the load, the following method may be used. From Fig. 1, the following relations may be derived.

$$\begin{aligned} E_s^v &= (A_1 + j\,A_2)\,E_r + (B_1 + j\,B_2)\,I_{rw} \\ &= (A_1\,E_r + B_1\,I_{rw}) + j\,(A_2\,E_r + B_2\,I_{rw}) \qquad (20) \\ E_s &= E_s^v + j\,(B_1 + j\,B_2)\,I_{ro} \\ E_s^2 &= (A_1\,E_r + B_1\,I_{rw} - B_2\,I_{ro})^2 \\ &\quad + (A_2\,E_r + B_2\,I_{rw} + B_1\,I_{ro})^2 \qquad (21) \end{aligned}$$

by substituting P_r/E_r for I_{rw} and solving for I_{ro} this becomes

$$I_{ro} = \frac{E_r\,(A_1\,B_2 - A_2\,B_1)}{B^2}$$

$$\pm \sqrt{(E_s/B)^2 - \left\{ P_r/E_r + E_r\,\frac{(A_1\,B_1 + A_2\,B_2)}{B^2} \right\}^2}$$

$$= E_r\,K \pm \sqrt{(E_s/B)^2 - (P_r/E_r + E_r\,M)^2} \qquad (12)$$

By eliminating the quantity under the radical

$$(E_s/B)^2 - (P_r/E_r + E_r\,M)^2 = 0 \qquad (22)$$

or $\qquad E_s/B = P_r/E_r + E_r\,M$

and

$$P_r = E_r\,(E_s/B - M\,E_r) \qquad (7)$$

Therefore, it is verified that the quantity under the

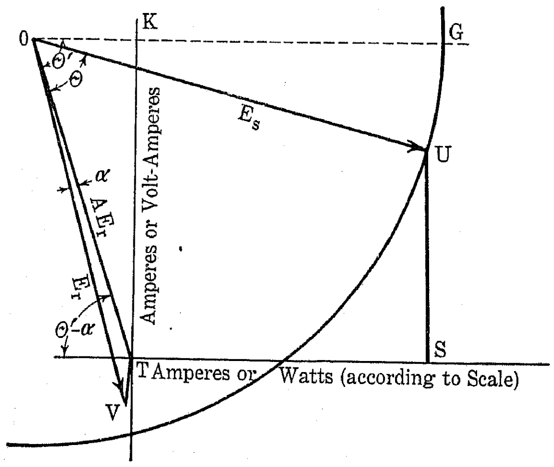

FIG. 14—POWER-CIRCLE DIAGRAM FOR RECEIVING END

radical sign in **(12)** disappears at the conventional point of pull-out, and that at this point

$$I_{ro} = K\,E_r \qquad (14)$$

POWER CIRCLE DIAGRAM.

It is of interest to show that the power circle diagram[8] is essentially the same as the diagram used in this paper.

Fig. 14, a typical power circle diagram is merely Fig. 2 rotated around the point T and using the line $T\,S$ as a longitudinal axis. The lettering is maintained to conform to that of Fig. 1. By using the scale ratio $1/B$, *i. e.* $O\,T = \dfrac{A\,E_r}{B}$ and $O\,U = E_s/B$ then $T\,S = I_{rw}$ and $S\,U = I_{ro}$, whereupon $T\,S$ and $T\,K$ become axes of in-phase and out-of-phase components of current respectively. By using the scale ratio of $\dfrac{3\,E_r}{1000\,B}$, *i. e.*

$$O\,U = \frac{E_s\,3\,E_r}{1000\,B},$$

the scales of the axes become kw. and reactive kv-a. respectively, which is the usual form of the power inch diagram. $T\,S$ is then the power output of the line and $U\,S$ the reactive kv-a. at the receiver end.

The upper part of Fig. 15 is identical with Fig. 14. The lower part is the part of Fig. 2 used to determine the conditions at the sending end of the line. The closed figure $O'\,T\,W\,V'$ of Fig. 15 corresponds to

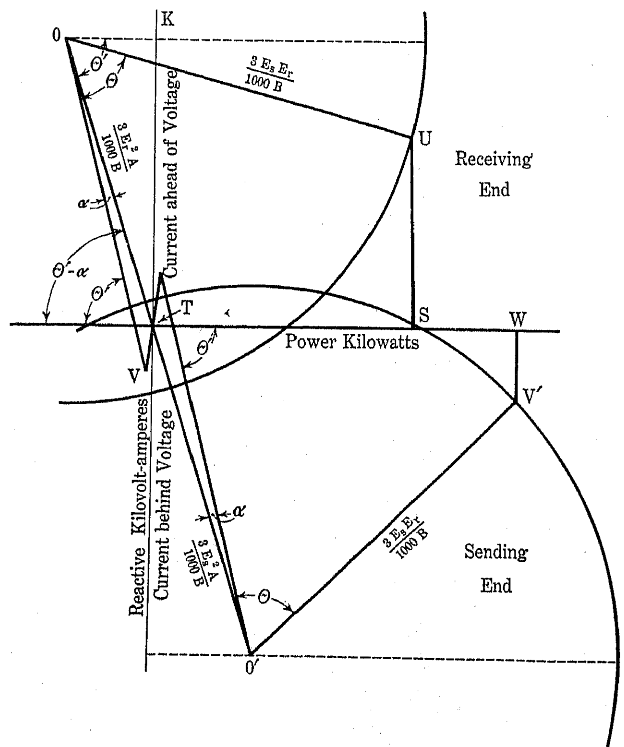

FIG. 15—POWER-CIRCLE DIAGRAM FOR BOTH ENDS OF TRANSMISSION LINE

$O\,L\,W\,V$ of Fig. 2. The corresponding scale ratio for this part of the diagram would be $1/B$ for ampere relations, or $\dfrac{3\,E_s}{1000\,B}$ for kw. and kv-a. With this latter ratio $T\,W$ will represent the power input to the line and $W\,V$ the reactive kv-a. at the sending end. The connecting link between the two parts of the diagram is that the angle $T\,O\,U$ must equal the angle $T\,O'\,V'$.

The line efficiency is $\dfrac{T_s}{T_w}$. To determine the angle $\theta' - \alpha$ for the purposes of construction.

$$\theta' = \tan^{-1} B_2/B_1$$
$$\alpha = \tan^{-1} A_2/A_1.$$

F. G. Baum: The papers that have been presented so far are based on calculations made using the hyperbolic functions. On any transmission line of considerable length in which we apply voltage at one end, we immediately get some charging current near the station. That charging current tends to raise that voltage, and as we go along the line, each increment of the current tends to raise that voltage, and we have the rising characteristic of that transmission line.

However, if we are going to have a general power system, it is necessary, as far as I can see, that we have a practically constant transmission line.

If we are going to have constant voltage transmission, then you can see at once that the charging kv-a. per mile of line or hundred miles of line will be the same. That is, it is not a quantity then that is gradually changing as you proceed out from the station to the line, but every mile of line is a repetition of every other mile, so we have a straight line of relation of the charging line, if we maintain constant potential. That makes the attack of the problem very much simpler and you can use a simpler calculating device. The paper by Mr. Shand uses the old-time method of vector equations, which is correct so long as the charging kv-a. per unit length of line is constant, and that is the assumption we are starting out with.

Edward L. Moreland: The four papers which have been presented are interesting to anyone who is working on the problem of long-distance transmission—by long distance I mean distances of from 250 miles up to 500 miles or more.

Our office has for some time been working on a specific problem of this kind,—one of our clients having asked us about a year and a half ago to study for them the electrical and mechanical feasibility of transmitting a large block of power from Canada, a distance of approximately 500 miles. We made a preliminary report in October, 1922, that such a project is feasible, and have continued our investigations of the details since that time. Mr. Booth of our office has borne the brunt of this work. Professor Bush of the Massachusetts Institute of Technology has also aided in these studies and has worked with Mr. Booth in the development of the methods of analysis which we have applied to the problem.

In the course of our studies, we have also conferred from time to time with others who might be interested in problems of this kind, particularly with the authors of some of these papers and with the engineers in the research department of the General Electric Company, but we have apparently carried our analyses further than the authors of these papers.

There is a common point of weakness in the Thomas paper, the Evans and Bergvall paper, and the Fortescue and Wagner paper, namely, that all three make their analyses on steady-state conditions, and base their conclusions as to stability of operation and limitations of power on these analyses. The limitations are, however, not imposed wholly by steady-state conditions but also by transient conditions, and consequently analyses of steady-state conditions alone do not give a proper basis for conclusions. Before accurate conclusions can be drawn, analyses must be made taking into account the transient conditions produced by sudden changes in the load, including the effects of kinetic energy of rotating equipment connected to the system and the transient effects induced in the fields of synchronous apparatus connected to the line. Fortescue and Wagner discuss the transients in a general way but make no effort to calculate the effects, and their conclusions are based on the steady-state analysis.

Steady-state analysis is interesting only as a step in the complete analysis, but does not furnish a sound basis for drawing conclusions as to stability of the line or of power limitations.

Mr. Thomas bases his design upon steady-state analysis. This takes no account of the behavior of the synchronous condensers, or of the behavior of the system during load changes. A consideration of these matters soon shows that a 500-mile unsectionalized line is unsuitable for 100,000 kw. per circuit at 220 kv. normal terminal voltage. In lines of this length steady-state analysis is not sufficient, for the instability of the system is made apparent only by transient analysis involving the electrical and mechanical constants of the connected apparatus. Mr. Thomas uses a very large conductor, but our analysis has shown that stability under switching is not greatly affected by the size of conductor, within reasonable limits. The reason for these difficulties of stability lies in the fact that 220 kv. is inherently a low voltage for 500-mile transmission at 60 cycles per second.

Messrs. Evans and Bergvall point out the limitation that at a certain load the action of the regulators becomes indeterminate and produces instability. This again is based on an analysis which considers the performance of the system to be a succession of steady states. It, hence, applies at normal operating receiver voltage, but does not apply during fluctuations; for during fluctuations various factors, such as the kinetic energy of the rotating masses and the transients in condenser fields, come into play which are not considered at all in steady-state analysis. Their analysis, therefore, shows one limit to steady operation, but it gives no information about stability during switching. There is hence here no basis for general conclusions regarding the operation of a system where sudden load changes may occur due to switching. The tests made by Messrs. Evans and Bergvall are also limited to conditions of gradually applied load, for a motor-generator set cannot transfer its load to the system until it swings back in phase. This is clearly indicated by the oscillograph record shown in one of their charts. The behavior for a suddenly applied load is very different, as will be shown.

The chart given herewith (Fig. 1) shows the power curves for a 250-mile, single-section, 220-kv., 60-cycle line, with four 20,000-kv-a. condensers at the receiving end. The locus of steady-state Tirrill instability is also shown. Considering steady-state conditions alone, the chart shows that at 100 per cent normal voltage the line can deliver 190,000 kw. This would mean that if the line were delivering 100,000 kw., the load could be increased by 90,000 kw. without pulling the line out of step. This would be true if the load were gradually increased so that the regulators had time to function and keep the voltage constant.

If, however, the load is suddenly increased, the conditions are very different due to the transient effects. The heavy wave line indicates the cycle of voltage conditions through which the

system will pass if the load is suddenly increased from 100,000 kw. to 140,000 kw. The complete cycle has not been plotted but the oscillations will center on the 140,000-kw. line and ultimately come back to it. It will be observed that the first swing carried the system into the region of apparent Tirrill instability and safely out again; this is again due to transient effects. If, however, the load is suddenly increased from 100,000 kw. to 150,000 kw., the voltage will continue to drop on the first swing and will not recover, but the line will break out of step.

The significance of this chart is that it shows that steady-state analysis alone would have made it appear that 90,000 kw. could be successfully switched onto a line already carrying 100,000 kw.; whereas, in fact, less than 50,000 kw. could be suddenly switched onto it without breaking the system apart. This clearly shows that steady-state analysis alone does not give results sufficiently accurate to warrant using such analyses as a basis for drawing conclusions.

Discussions presented by Mr. Booth and Professor Bush give some specific illustrations of complete analyses under transient conditions.

The studies made by the authors are of great interest and the data from their tests form a valuable contribution to the knowledge available on this subject, but the conclusions drawn

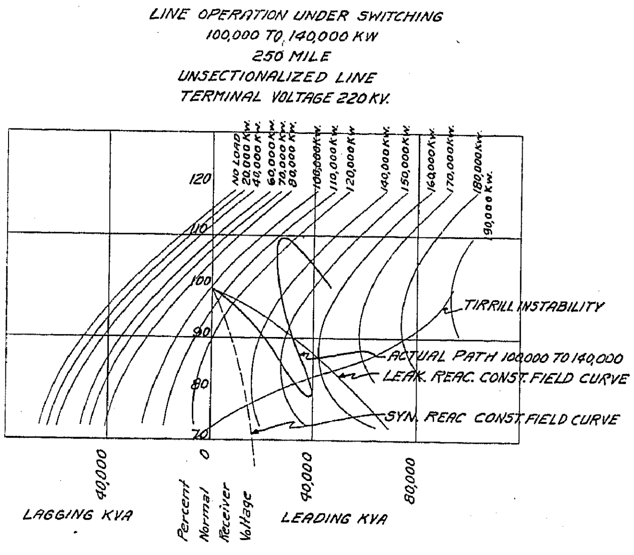

FIG. 1

should be qualified by the statement that various factors which radically affect the results have not been considered in their analyses.

PART I

R. D. Booth: Evans & Bergvall have analyzed the action of the Tirrill regulators on synchronous apparatus of the system for various steady-state voltages and found that instability occurred in the steady state at the points of tangency of the load and the field-current characteristics. However they apparently are applying this criterion to transient conditions. Mr. Moreland has, we believe, shown the fallacy of their method.

In particular we cannot agree that they have presented any substantiation for their general conclusions regarding the sectionalized line.

They have examined the load at which the regulators on the mid-point condensers become unstable in operation, and have assumed that this sets the maximum load limit for the system. Incidentally in this analysis they have assumed the receiver voltage to remain normal, and hence the only point of their curve of regulator instability which has physical significance is that corresponding to normal voltage. They have tested these conclusions by tests made with loads slowly applied through a motor-generator set. When a load is thrown on to the generator of the motor-generator set as in their tests, it does not become transferred to the system until the set falls back in phase. This occurs slowly enough so that their assumption of a succession of steady states is fairly close to being correct for this condition. But all of this leaves out of consideration what may happen in the system when a load increment is very suddenly added, as for example by the cutting out of circuit of a generating unit at the receiver end. In other words, they have examined one load limit for the system, but have drawn general conclusions which assume this to be the only limit which need be considered.

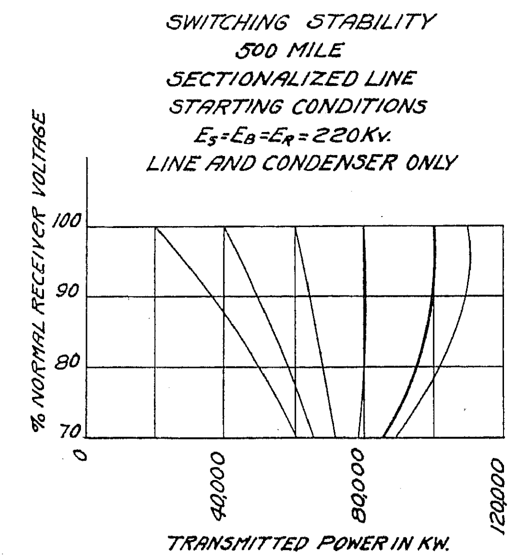

FIG. 2

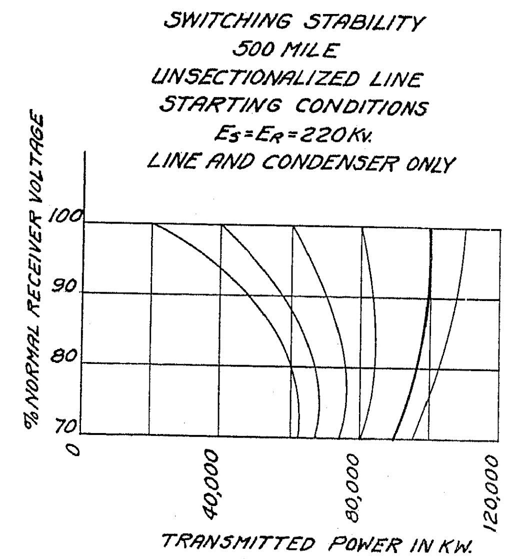

FIG. 3

In the early part of our analysis, we made for simplicity the assumption on which this paper is based, *i. e.*, neglecting the inertia of the condenser and the changes in the condenser fields. But we have examined on this bassis, in addition to regulator action in steady state, the effect of sudden switching. Even on this basis alone our conclusions as to the load limit of the sectionalized line would be very different from theirs.

We show in Fig. 2 and Fig. 3 the variation in receiver potential of the 500-mile line upon a sudden increase in load, Fig. 3 being for the unsectionalized line and Fig. 2 for the same line, with a mid-point condenser added. These curves were computed by

neglecting the inertia of the condenser as was done for the curves in the paper, but the changes of both terminal and receiver voltages in the sectionalized case were taken into account. The curves show the variation of receiver voltage upon suddenly increasing the load above that at normal voltage. The curves are here drawn for a load which is independent of the voltage, since this is the type of load considered in the Evans & Bergvall paper.

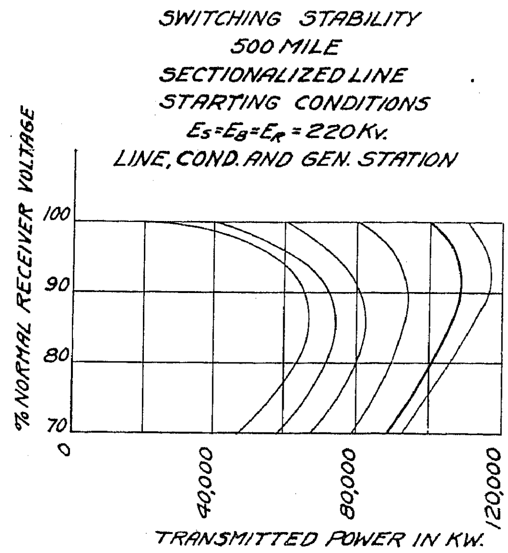

FIG. 4

It will be noted that the two curves of Fig. 2 and Fig. 3 above are not far different from one another. In each case they indicate that if the line were initially carrying 100,000 kw. a sudden increase in load of only 2 per cent, if applied before the regulators could act, would break the system apart. The curves are based, as are those of the paper under discussion, on the steady-state

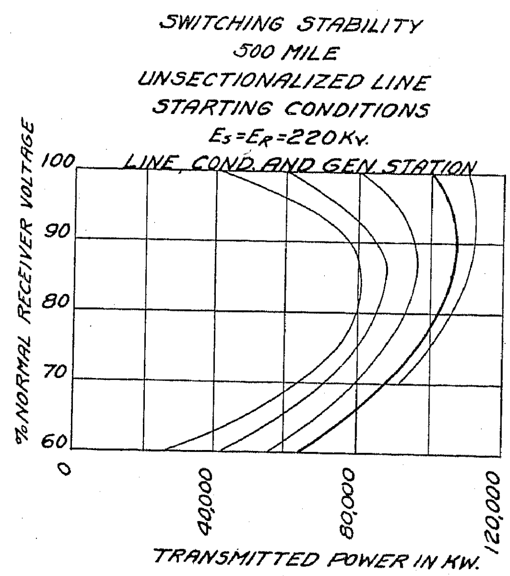

FIG. 5

characteristics of the condensers, that is, on their synchronous reactance, although, as noted, these do not strictly apply during such a transient condition.

In the statement of the methods followed in our analysis, you will note also that our studies include the coincident variation of receiver and mid-point potential for a sudden load increment, while the curves of the paper for the sectionalized line consider only the mid-point potential. It is the receiver-end potential that in this case actually sets the limit to load as far as switching is concerned, and for the sectionalized line it sets this limit far below the value found by the authors for difficulty with regulator action. Hence the premises of their paper, if applied to sudden load switching, indicate that adding a mid-point condenser with the mid-potential normally held at the same value as at the ends does not increase the capacity of the line appreciably for the type of load here considered. This is widely different from the conclusion of their paper that 40 per cent increase in capacity is obtained in this manner, and clearly indicates the need for

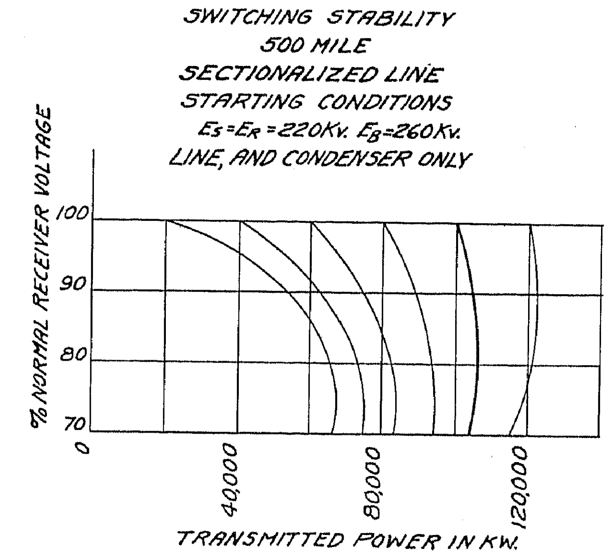

FIG. 6

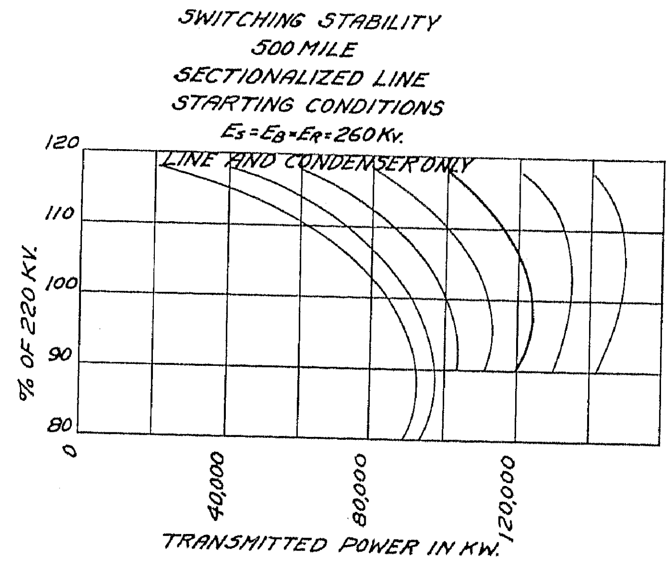

FIG. 7

complete study taking into account the factors here neglected. We have added, Fig. 4, a similar curve with the regulator at the mid-point set to maintain normally 260 kv., and Fig. 5 for line voltage of 260 kv. throughout. The installed capacity of synchronous condensers is, of course, different for these cases. This indicates that there is some benefit by this voltage increase. The stability of the line for a load which varies with the voltage may be readily obtained by plotting the characteristics of the load on the diagrams here presented.

The stability of a transmission system is of course, affected by all rotary apparatus connected to it, and therefore we have

shown the effect of the synchronous apparatus in a large generating station connected at the receiver end of the transmission line.

It must be emphasized again, however, that the analysis of the paper and of the part of our work presented above, neglects certain factors which greatly modify the action during switching.

PART II

Note on Method of Computing Stability of the Two-Section Line

(Kinetic Energy and Tirrell Transients Neglected)

The method of computing stability curves for the line with a mid-point condenser will now be outlined. This is based on the assumption of no inertia in the condenser, so that the phase of the condenser is assumed to follow that of the terminal voltage instantly. We have also used the steady-state characteristics based upon synchronous impedance. This involves the assumption of neglecting the transients produced in the condenser field current by terminal voltage variation during switching. The characteristics based upon leakage reactance may be used

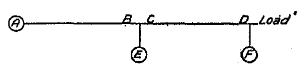

Fig. 8

instead, if desired, but this involves the assumption of neglecting the dying-out of field current transients. It is more conservative to use the synchronous reactance, so we have adhered to this assumption in our approximate analyses.

We have certain initial conditions on the system, and hence know the initial voltages, condenser fields, etc. We wish to examine the variation in voltage which will ensue if the load is suddenly increased from its initial value.

The method of analysis consists in general of finding a set of values which satisfies simultaneously the conditions at the mid point and the receiver end.

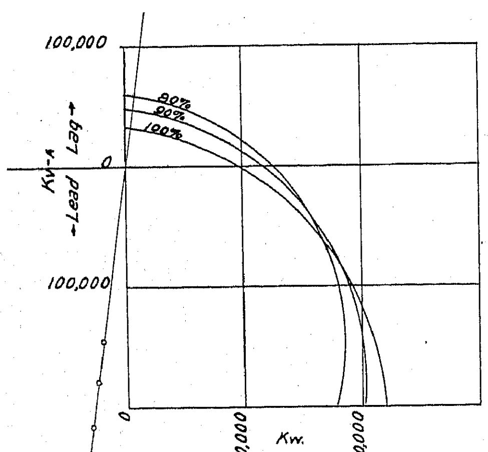

Fig. 9

The system we shall consider is as shown in Fig. 8. For the mid point we have the condition that the power at B drawn over the line must equal the input at C to the second section except for condenser losses. Also we have the fact that the difference in quadrature kv-a. at these two points must equal the kv-a. of the mid condenser. To satisfy these we will use the circle diagrams for the two sections of line, and the characteristic curves of the condensers at mid point.

Fig. 9 is the diagram for the first section based on a constant voltage at the generating station, and giving the relation between kw. and kv-a. at B for various values of mid-point voltage.

Fig. 10, drawn for the second section, is based on normal receiver voltage and similarly gives the relation between kw. and kv-a. at C for various values of mid-point voltage.

Fig. 11 gives the mid-point condenser characteristics, that is the variation of kv-a. output with terminal voltage for various values of condenser field current. The length (a) is the mid-condenser output for normal voltage at mid point and receiver,

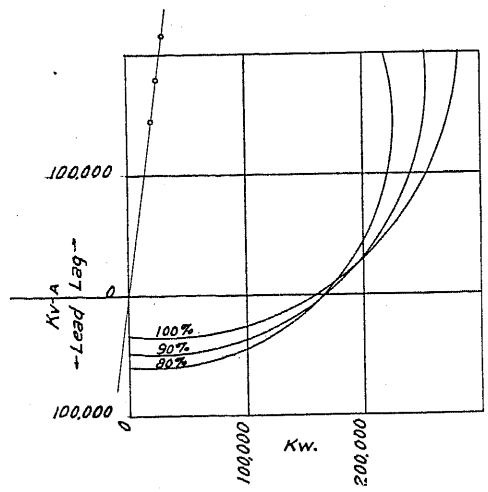

Fig. 10

and is found in the usual manner. The lengths (b), (c), (d) give the condenser output for this same field setting, and for various values of voltage at B.

Now superpose Fig. 10 on Fig. 9 as shown in Fig. 12 so that the scales coincide and pick off the values of kw. corresponding to a vertical distance between similarly labelled curves of the corresponding values (a), (b), (c), (d). Another way is to displace the curves vertically by the distances (a), (b), (c), etc.,

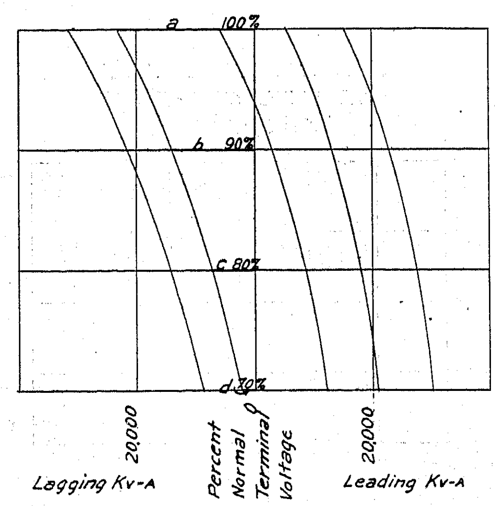

Fig. 11

in turn, as shown in Fig. 13 and read curve intersections. If the condenser output is lagging the curves will overlap. If it is desired to take into account condenser losses, the curves should simultaneously be displaced horizontally by the kw. of condenser losses corresponding to each successive value of mid-point voltage.

Now, convert the values of mid-point power to receiver end power, by means of a circle diagram. Plot the resulting values of mid-point voltage and receiver-end kw. as in Fig. 14 and label

the resulting curve 100 per cent E_r, corresponding to the normal receiver voltage which was assumed. It will be evident that points on this curve satisfy all conditions at the mid point for the assumed value of receiver voltage.

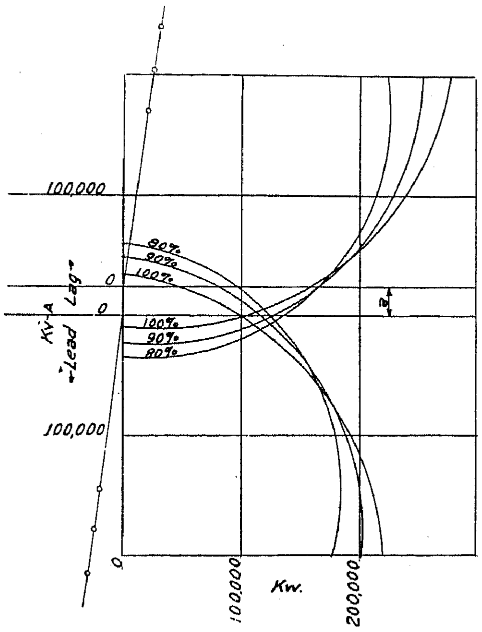

FIG. 12

Now, assume a new value of receiver voltage, for example 90 per cent of normal, use the circle diagram for the second section corresponding to this receiver voltage, and repeat this process. Plot the results as the curve 90 per cent E_r, in Fig. 14. Repeat for other values of E_r.

Turn now to conditions at the receiving end. We have here the conditions that the quadrature kv-a. of the line at D must equal the sum of the quadrature kv-a. of the condenser and the load. To satisfy these, use the circle diagram for the second

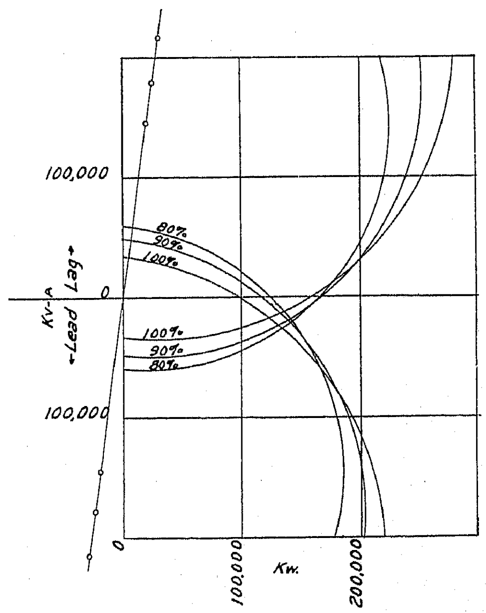

FIG. 13

section based on normal receiver voltage, Fig. 19, which shows the kw. and kv-a. over the line for various values of mid-point voltage. We make also a chart, Fig. 15, for the receiving end condenser, similar to Fig. 11, but based on a different capacity. Also we have the characteristic of the load, that is the variation in power factor of the load for different values of receiver end voltage. We can in addition take into account the characteristics of any generating station that may be connected

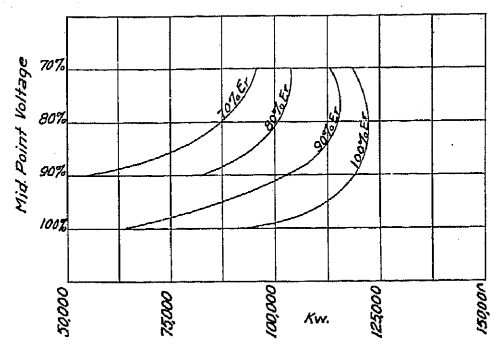

FIG. 14

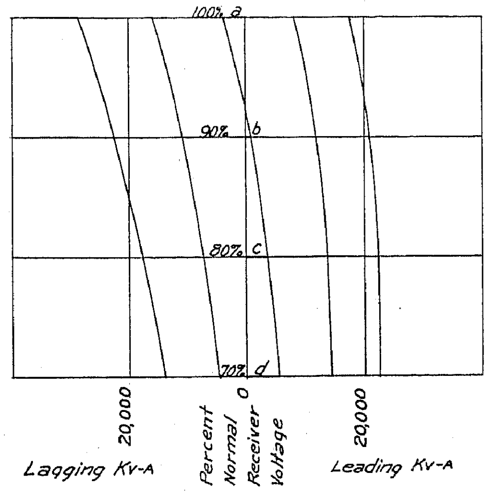

FIG. 15

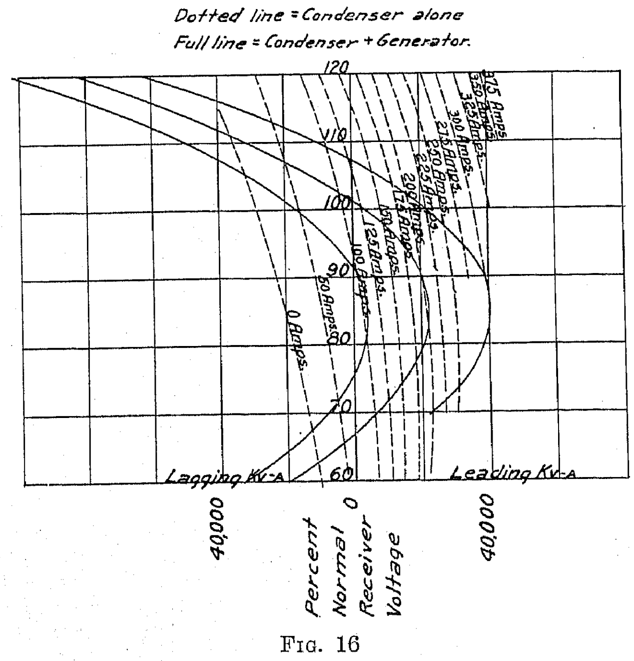

FIG. 16

to the receiver end of the line by adding them to the characteristics of the condenser station.

An operating point for the receiver end for each mid-point voltage will be at a certain load at which the kv-a. of the line is

equal to the kv-a. of the condenser plus the load. These points are shown on the above Figs. 17 and 18. For any constant E_r chart, we will have but one condenser value to consider, this may be taken in connection with the load at that particular receiver voltage.

From the intersections on each of these charts we obtain a curve of operating points which would fulfill all the operating requirements of the receiving end for the particular receiver

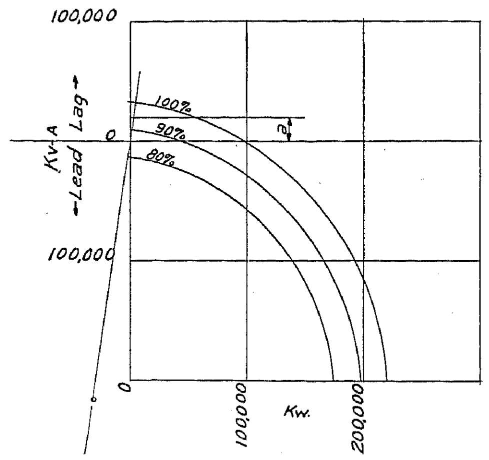

FIG. 17

voltage considered. We can then plot with voltage at the mid point against load at receiver end.

Calculations made with a number of these receiver charts for different receiver voltages will give a series of these curves for the different values of voltage at the receiver end, as shown in Fig. 19.

We now have two graphs plotted against identical functions, one of which shows the operating characteristics of the first

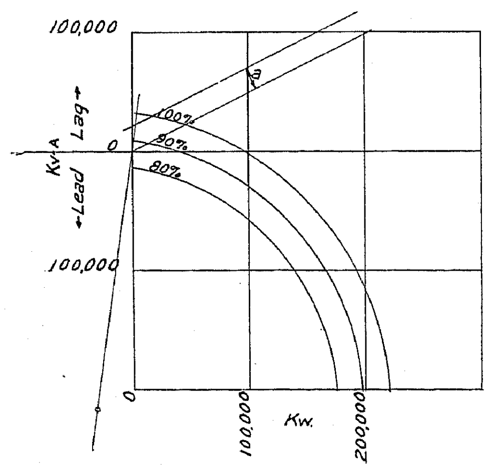

FIG. 18

section, and the other the characteristics of the second section; therefore by superimposing these as in Fig. 20, we can find the conditions which satisfy both sections. The intersections of the curves correspondingly labelled give values of receiving-end voltage and receiver-end power which satisfy all the requirements of the system. These points hence are operating points for the particular set of initial conditions considered. A group of these curves for various starting conditions shows the complete behavior of the line under sudden switching conditions with the single limitation that we have neglected inertia and condenser field changes in the computations. (Fig. 21.)

Upon this set of stability curves we can readily show the action of the line when loads of various resistance are applied. In Fig. 21 we have shown a set of stability curves with load lines representing fixed load of 85,000 kw. and another of fixed resistance of ohms.

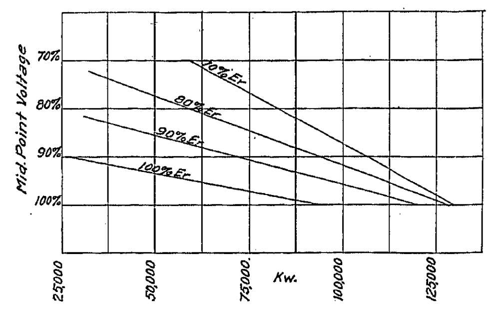

FIG. 19

With a line operating at 80,000 kw. and switching upon it a load of such character as to make the total equal to a resistance load as shown by line b we should have fallen immediately to point p and then as the regulator operated increase along line b to the operating point Q.

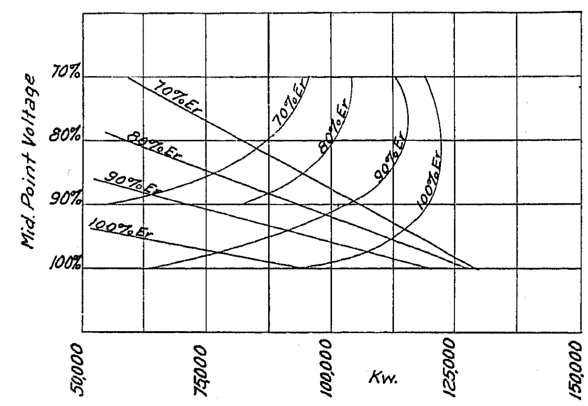

FIG. 20

It will be readily apparent that the above method can be extended to cover the case when load is drawn from or supplied to the mid point of the system. This is done by combining the station or load characteristics with those of the condenser at that

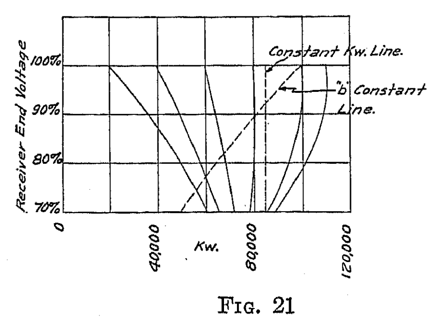

FIG. 21

point. Thus we have a method of treating a long line supplied with some power at a point along the line.

This proceedure undoubtedly appears laborious. It is really not, however, when the curves for lines and machines are once made available. Two computers can readily determine a complete sheet of stability curves in a day.

V. Bush: The criticism that has been made of Messrs. Evans and Bergvall's paper applies to the paper by Fortescue and Wagner. This paper discusses at some length the effect of kinetic energy in rotating masses, but so far as results from computations are concerned, the conclusions are based only on steady-state conditions and neglect the stored energy in rotating masses. Yet definite conclusions are again drawn in regard into consideration in the computations. We have not been willing in our work to accept conclusions obtained by neglecting condenser overswing, etc. Hence we have analyzed the behavior of a line during switching taking into account the kinetic energy of rotating masses, the transients produced in condenser fields, and the action of regulator and exciter during the transient period. We have completed this analysis for a 250-mile single-

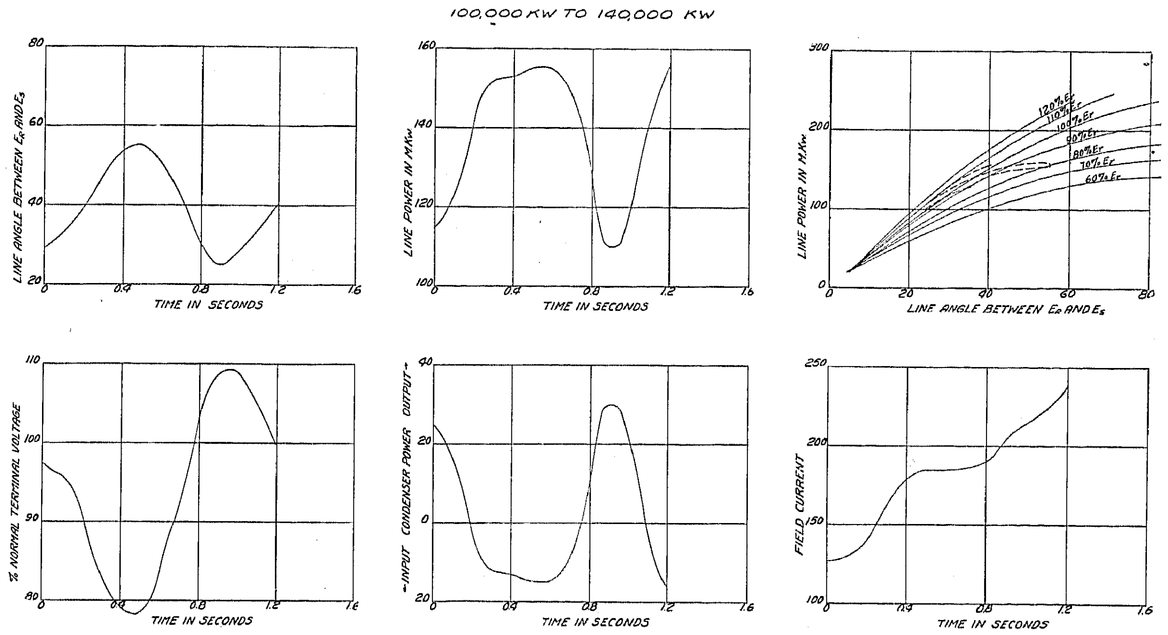

FIG. 22

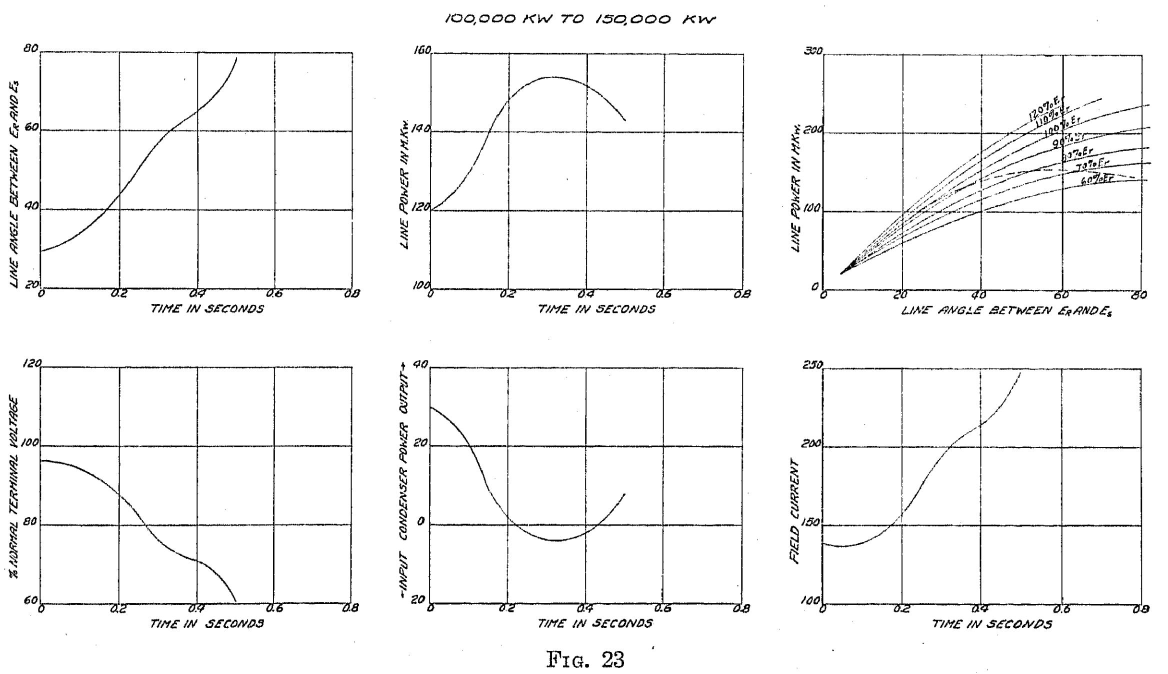

FIG. 23

to the increase in capacity of the line expected to result from adding a mid-point condenser. There is a qualitative discussion of the effect of some of the neglected factors and an arbitrary allowance of 25 per cent is made to take care of these, but this cannot be regarded as more than a guess. The authors evidently recognized that the factors neglected may be important, but they attempt no computations in which they are involved. Yet they proceed to draw general conclusions. General conclusions should not be drawn until the factors here neglected are taken

section line and now have in process the analysis for a 500-mile double-section line. The analysis of the 250-mile line was made as it forms the first step in the analysis of a two-section line. In Fig. 22 is shown the effect produced on a 250-mile line by suddenly increasing the load from 100,000 to 140,000 kw., the load in this case being assumed to have unity power factor. The variation in terminal voltage, phase angles, condenser field current and power from the condenser are shown. The field-current variation is controlled both by the terminal voltage

variation and the effect of the regulator and exciter. In this case the voltage was restored and the system did not pull out of step. In Fig. 23 the load was suddenly increased from 100,000 to 150,000 kw. and the system broke apart. Similarly in Fig. 24 the load charge was from 80,000 to 13,000 kw. and the system held together; while in Fig. 25 the charge was from 80,000 to 140,000 kw. and the system broke apart. In each of these cases the amount of load in kilowatt was assumed to be independent dict about the same load-switching limit as obtained by the complete analysis. This is, however, a coincidence. It happens that in this case the overswing of the condensers and the condenser field variation produced by voltage change and by the regulator, just about offset each other in effect. There is no basis, however, for any conclusion that this will happen generally; in fact, there is no such coincidence in certain other cases we have examined. We have presented here the curves applying to the

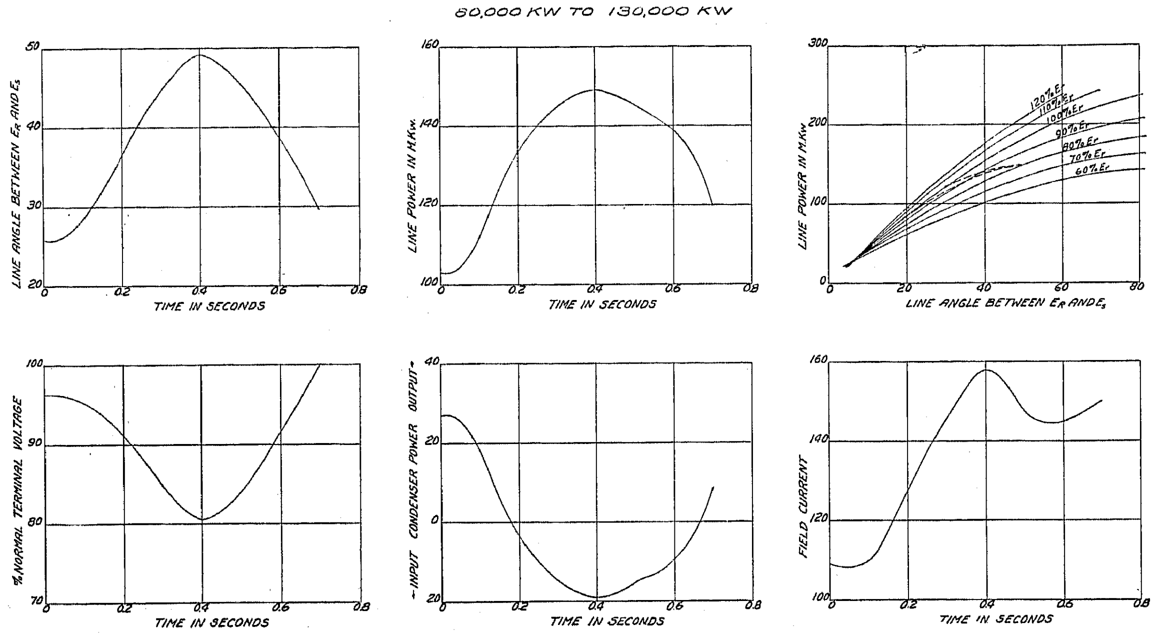

Fig. 24

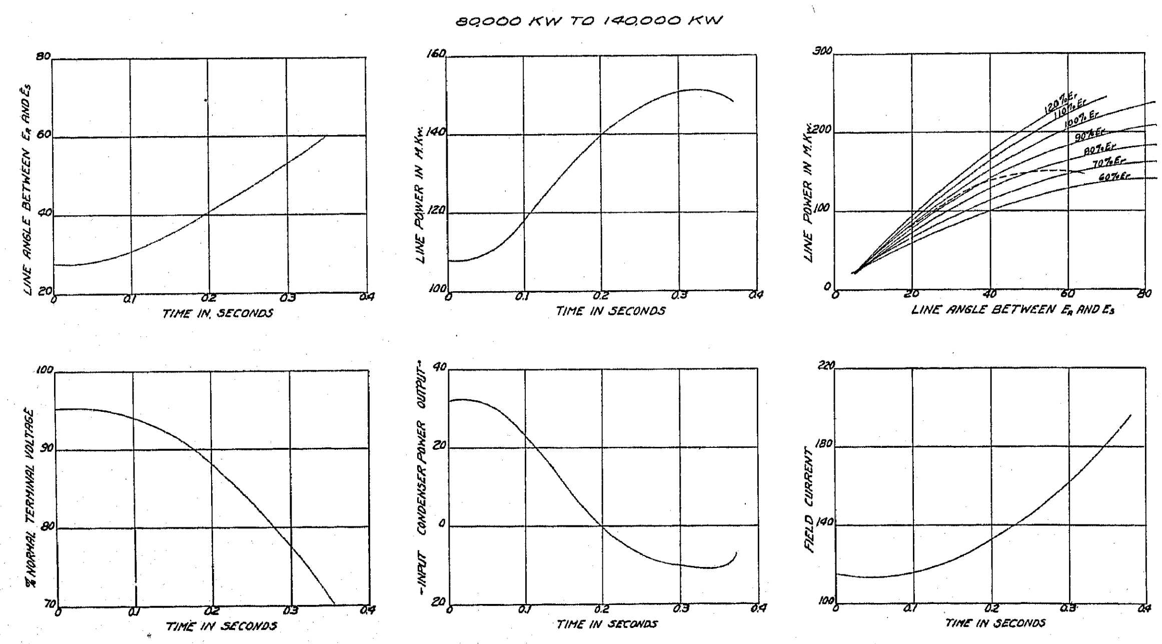

Fig. 25

of the voltage, since this is the type of load most readily considered in computation. Loads of a different character may be treated by the same analysis. The method of computing these curves and of taking into account the factors neglected in the papers presented here today, is too complicated to be explained at this time, but will be given in a subsequent paper.

In Fig. 26 are shown the stability curves of this same line neglecting the inertia of the condensers and changes in condenser field current during switching. It will be noted that they predict line and condensers only, as this is the part of the system considered as a unit in these papers. The stability of this unit will, of course, be affected by all rotary apparatus connected. Mr. Booth, in his discussion showed the effect of a generating station as determined in that approximate analysis and shown in Fig. 7.

H. Goodwin, Jr.: Under the caption "Growth of High-Voltage Networks Introduces Control Problems" the *Electrical World* on September 8, 1923, outlined very ably some problems that are confronting those interested in such development and

closed with the sentence: "Some genius has an opportunity to obtain a better solution to the general problems on such systems."

After outlining a comparatively simple network the editor asked these questions: How can the voltage regulation at each substation be controlled? How can the load division between generating stations be controlled? What are the limits of stable operation of the system if certain short circuits occur? Later the present devices and methods are referred to as unsatisfactory for "the new type of system where an immense amount of energy is to be handled and reliability of service is paramount."

In the October 20, 1923 issue of the same paper there appeared

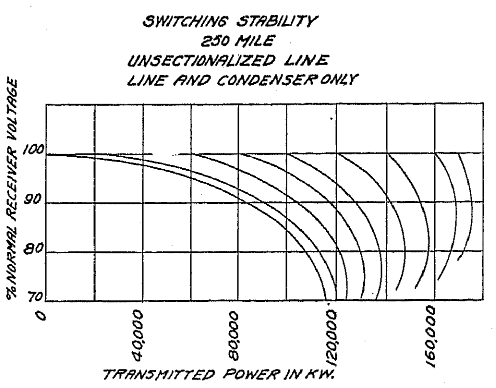

FIG. 26

a letter referring to the editorial and claiming that most of the points had already been answered.

But I and many others cannot agree with the correspondent and welcome most heartily the papers presented here today and congratulate their authors on the opportunity they have had to make the investigations and further on the simple terms to which they have reduced the problem in presentation.

Mr. Thomas' paper is a most excellent introduction to the subject (but not limited to introducing) and I should like to go into it and accentuate its many good points. But I shall have to pass on with recommending it for the study which only will give a full appreciation of its comprehensiveness. Issue might

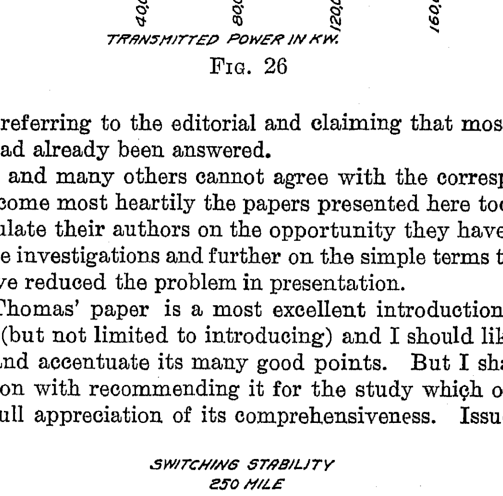

FIG. 27

be taken with his suggestion of a 400,000-kw. substation. It would, in general, be better to split it in two or three. His detail proposal of generating and substation connections at first seems out of place, but on more careful investigation it is evident that a close relation exists between the general problem and these detail connections. The exact set-up has a considerable bearing on the operation of such a system as he is considering.

It is most interesting to compare the integral operation he gives, for his system under short-circuit conditions with that proposed for a superpower system in a report of considerable authority on that subject. The latter says: "If a short circuit occurs the system will be automatically separated at selected points into several systems that are complete in themselves, in order to limit the energy interrupted to amounts that can readily be handled."

The other papers deal with the circle diagram and advocate its use. May I suggest two other things almost as potent as the circle diagram for elucidating the details of action of a transmission line: 1st.: Following Dr. Kennelly in the use of polar coordinates for vectors wherever possible instead of the rectilinear form "$a + j\,b$." 2nd.: The use of "Qualitative Analysis of Transmission Lines" as a means of forming a mental picture on which to hang and by which to understand the detail mathematics. Mr. Thomas's paper is very good in the picture it gives of the system in addition to its mathematics.

On the first page of Messrs. Evans & Bergvall's paper, reference is made to the method of calculating circle diagrams previously given by Messrs. Evans & Sels in the *Electrical Journal.* This says in one place:[1] "When such a diagram has been finished, the most desirable conditions of operation can be readily selected, and the rigid mathematical solution may be applied to the particular case with any further degree of accuracy that may be desired." Later:[1] "The loss formula may be put in the form of a circle and plotted in connection with the regular circle diagram. This seems desirable to do, as the losses *neglected* when using the general circuit constants are practically constant for different loads, so that the most economical point of operating the line can be determined from the diagram." (Italics by the speaker). Yet do we find any "rigid" check of any of the results taken from the circle diagrams? And some results are almost hair-splitting.

Perhaps the paper by Messrs. Fortescue and Wagner, giving a more vigorous proof is supposed to serve instead. But why then refer to the old articles? Also, Messrs. Fortescue and Wagner do not refer to the "Loss Circle." Can it not also be proved by rigid mathematics? These questions are not post mortems. The old articles by Messrs. Evans and Sels have been made a part of the present group by reference. The circle diagram has had a very checkered career in the past. If it is now to be used as the foundation for a great forward step in the art, as in these papers today, it must be cleared of all doubt and set forth in new clean clothes. Messrs. Fortescue and Wagner do this in part. How about the rest particularly the "Loss Circle"? Has anything been "neglected" in the use of the circle diagram in these papers?

There is apparently duplication between several of the papers. This may have the advantage of giving different points of view of the same subject. But on the whole it seems that it would have been preferable, since the authors are so closely associated, to have put all related matter together in the best form and devoted the remaining space to some phases that have not been covered, *e. g.*:

A fuller development of the problems involved with comparatively short ties of large capacity systems such as: Newark & Philadelphia; Baltimore & Washington; East Central & West Central Pennsylvania. These are of almost immediate importance.

(Messrs. Evans & Bergvall give a most encouraging point in this connection on page 15. It appears that a number of stations in parallel along a line will help to hold each other in step at times of short circuit.)

The design of synchronous condensers to meet the requirements found, instead of assuming present design as the limit of operating conditions.

In the discussion of a 750-mile line, Messrs. Evans & Sels paper there does not appear to be proof of the statement, "the receiver must operate at lagging power factors," etc. and this is apparently at variance with Messrs. Fortescue and Wagner, in regard to a 500-mile line requiring 15,000 kv-a. *leading* at the receiver. In the next paragraph the reasons for limiting to 250 miles are not at all clear.

1. ***Electrical World*, Decembe. 1921, p. 530 and p. 533.**

In the same paper the notation used in the equations is not standard or defined. It is assumed that the special symbols indicate vectors and conjugate vectors.

We meet the suggestion that "the condenser capacity Q_R may be chosen as equal to $(- m \, E_R{}^2)$." On looking for the value of m in equation (26) we find it is imaginary. Referring to Pender's Handbook page 240 we read:

"A real quantity cannot be equal to an imaginary quantity."

But even if these differences can be adjusted more detail of references are necessary to clarify the process of deduction and prove its correctness. It is not clear that the balance of equation (26) will not have an angle in it in addition to the j.

"Infinite" condenser capacity is referred to in some places while "unlimited" is used in others. Infinity is a rather dangerous toy and if the discussion could be confined to "unlimited" some will follow the deductions with greater ease and assurance.

Mr. Shand draws inferences from my paper of last year "Qualitative Analysis of Transmission Lines" and then proceeds to find fault with them. At the time the paper was presented, two of the other authors of today's papers "by inference" developed things to discuss adversely that were not in the paper. The one inference to be drawn from that paper and the whole point is that an understanding of the fundamental physics and most simple mathematics of the transmission line and the "critical load" derived therefrom are of the greatest benefit in understanding the action of a line and such detail mathematics as have been presented today.

The paper of last year showed a simple method of determining the critical load of a line and the characteristic action of loads above and below this on present commercial lines. It was then shown, by example, that if the critical load was put on an extra long line in a certain way, there would be no reactive energy drawn from synchronous condensers even if they were placed along the line. The circle diagram was then used in adverse discussion. It is most interesting to see its use here confirm the points made in last year's paper: In Mr. Shand's paper, read of operation at critical load, that the intermediate condensers "might be merely floating on the line without carrying reactive current." In Messrs. Fortescue and Wagner's paper, read the author's judgment that while with large amounts of synchronous-condenser capacity distributed on a 500-mile line, larger loads would be possible, the practical rated load would be the critical load. "The actual reactive power required at this load is zero at the midpoint and about 15,000 kv-a. leading at the receiver." In the discussion last year the circle diagram was used to prove that the most efficient operating conditions would be with reactive kv-a.

Your attention is also drawn to the many circle diagrams and the general intersection of the circles at the critical load and a slightly leading power factor which is to be expected from qualitative analysis.

Now these things are not said to continue or develop a controversy but to point out that in today's papers a difficult subject has been ably dealt with. The subject is so difficult and involved with so many practical considerations, that it is apparently impossible of general mathematical solution. The only means at hand is the working out of specific problems and generalizing from them. Generalizing is a difficult and dangerous thing without a guide. The best guide I know is qualitative Analysis, enabling one to relate the results of a specific problem to the fundamental physical conception and thereby be able better to judge the effect of change of any of the conditions or constants.

A. E. Silver: One point in Mr. Thomas' paper of particular interest is that of the avoidance of all switching on the 220-kv. side as shown in the circuit diagram, Fig. 5. This scheme is ingenious and embodies many advantageous features. However, I believe it doubtful if there can be anticipated many actual situations, when analyzed on the basis of probable conditions, in which high-tension switching can be advantageously avoided. Any 220-kv. transmission development that may at present appear to offer some probability of materialising in this country, would, I fear, prove unsuited if laid out without at least providing for later high-tension switching.

Especially at the receiving end of such a system it may be expected that interconnection between large load centers will occur hand-in-hand with, and in some cases precede, the construction of long transmission circuits of this kind coming in from distant water powers or fuel fields. It also may be expected that circuits for such interconnection must be of capacity commensurate with that of the long 220-kv. transmission circuits, otherwise full advantage cannot be taken of such factors as load diversity, reserve capacity in existing plants and load equalization over generally parallel circuits. Should several long 220-kv. lines emanate from one center of generation it is probable that, in the beginning at least, they would diverge at the receiving end so that one or perhaps a pair of circuits would deliver at each of several separated major load centers. The reserve against outage of any such 220-kv. circuit would in considerable part be provided over the interconnecting circuits between these receiving stations. Such interchange through the medium of the network on the low-voltage side of the 220-kv. transformers would, in general, appear inadequate and uneconomical because of the relatively large increase required in the transformers and lower voltage line capacity.

In other words, regardless of how simple the beginning may be, I believe the prevailing situations in laying out such a 220-kv. system will require looking ahead to a process of extension that will continue until it has developed and merged into a 220-kv. network embracing several or many major load centers and extending over a wide power consuming area. It would seem impracticable to develop such a network simply and economically and with the needed flexibility if based on other than 220-kv. switching.

At the generating end of such a group of long 220-kv. transmission circuits it occasionally may occur that the supply will be derived from a single large development so located relative to other power developments as to preclude the practicability of tying together at 220-kv. It is believed, however, that the more frequent condition will be the supplying of such a group of circuits from several moderately large plants separated by appreciable distances, as for example, a series of developments along a river. Usually, therefore, it is believed that 220-kv. switching at the generating end will be better suited for flexibility and load equalization.

As Mr. Thomas points out one definite disadvantage of the scheme of eliminating 220-kv. switching which places the transformers as an integral part of the line is the fact that the overload capacity of transmission circuits is entirely dissimilar to that of transformers. The overload characteristic of a transformer is similar to that of a generator, that is, a definite limit relatively close to normal-capacity rating beyond which the apparatus cannot be loaded without damage from heating. On the other hand, the transmission circuit has no such limitation as concerns its own safety, its practical load limit being set by voltage-regulating equipment. Economical design may permit a load, on shorter lengths of line, as great even as several hundred per cent of the load normally carried on a circuit.

It is thus evident that for utilizing the overload capacity of any of the circuits during times of maintenance or emergency, the needed flexibility can most readily be obtained by paralleling and switching on the 220-kv. side.

A system designed for 220-kv. paralleling and switching, I believe to be capable of greater simplicity than a similar system laid out for equivalent load equalization and emergency transfer of power entirely through the network on the low-tension side of the 220-kv. transformers.

It must be recognized, of course, that adoption of 220-kv.

bussing and switching for an interconnected network places the problems of circuit and apparatus arrangement, design and performance in a field of magnitude well advanced over that of the more or less conventional practise of today for lower voltages. It means that persistent attention must be given to developing and perfecting simple and dependable circuit and switching arrangements and apparatus including selective relaying and switch operation. Of particular importance is the problem of suitably dealing with short-circuit conditions. Also there will be required simple and effective devices for 220-kv. synchronizing and metering and for performing any other functions which would logically be required in the major bus of a station where the lower voltage switching facilities have been minimized. There seems no good reason to doubt that by persistent effort these devices and methods will be made available as needed.

It is, of course, not the intent of Mr. Thomas' paper to cover the situation of 220-kv. networks which I have tried to describe but rather the case of a single large generating center directly connected by high-tension lines to a single large receiving station. I am sure we would all appreciate an extension of his studies to include this companion problem of an interconnected network of large generating and receiving centers.

Mr. H. R. Summerhayes: The papers show that the transmission engineer is in the position of a navigator approaching an unfamiliar coast who pauses to take soundings, consult his charts and get bearings on a lighthouse or some established guide to navigation.

This subject of long distance transmission is of especial importance now because of the financial and economic pressure. A 500-mile line under certain conditions of cost of water power and price of coal, must transmit in the neighborhood of 100,000 kw. to justify the construction of the line from a financial and economic standpoint.

It would be easy probably to transmit 50,000 kw. over a 500-mile line, but when it comes to 100,000 kw. we are approaching the limit, as far as practical operation is concerned. A 250-mi. line is of the order of fifty or sixty per cent reactance when you are considering one hundred thousand kw. A five hundred million is over a hundred per cent reactance and it becomes a rather thin tie between generating stations of that size and larger. I think that several of the speakers discussing the papers have called attention to the fact that the transient condition should be considered and some engineers whose work I am familiar with have given special attention to these points, that is, to the sudden addition of load and what happens on the line when an increment of load is suddenly added.

To me the most significant part of these studied is the effect of the high reactance in the reduction of voltage.

Now, speaking of the charts of the navigator, the engineers have made some very creditable and thorough studies and we have been introduced to curves and whole families of curves, not simple ones but a lot of them so that one begins to think we are not only approaching the limits of transmission, but the limits of understanding the human mind. We meet so many of these curves and try to understand them that it becomes difficult.

However, this voltage question is large, and one can't put the whole subject in a nutshell, but it does seem to me that one conception of it is this: that you have to have voltage enough to transmit the power. If you suddenly increase the load so that the voltage momentarily goes down and there isn't voltage enough left to transmit the increased power, then before your voltage regulator can get busy your station will fall out of synchronism and the determination of that point of lost stability is the aim of a great deal of this work.

Edith Clarke: Messrs. Evans and Sels have explained the calculation of transmission lines by means of circle diagrams in a manner which is clear and easy to follow. I read their treatment of the subject in the *Electrical Journal* and have employed it in transmission line calculations. It is an accurate and rapid method. A complete circle diagram can be made in less than an hour and all information in regard to the transmission line is then available.

I have been accustomed however, to presenting the results of transmission line calculations in a different manner, and as this method shows clearly the variation of the receiver voltage as the load is increased or decreased, the generator voltage remaining constant, I have prepared a chart to illustrate it. (Fig. 28).

This chart illustrates a method of plotting results of calculation. The calculations themselves can be made by any method whatever. In this particular case, the calculations were made on the transmission line calculator described in the *General Electric Review* of June 1923. Such curves can be run off in a few minutes by using the calculator. They could be made as well from values taken from the circle diagram. The circle diagram could also be made from these curves.

Fig. 28 shows two families of curves, one for a 100-mile line, the operating characteristics of which are familiar to you, and the other for a 500-mile line which is the subject under discussion.

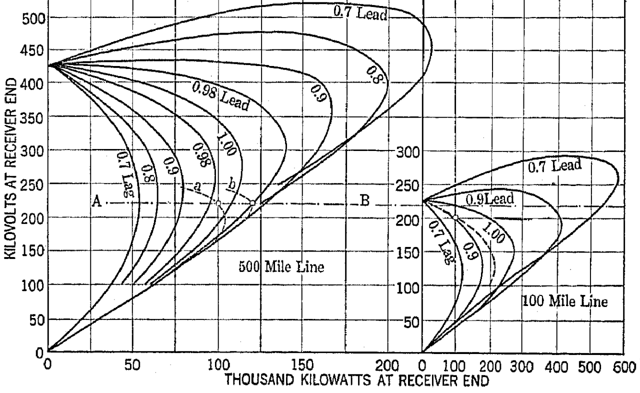

FIG. 28

You will notice in these curves kilowatts at receiver end against kilovolts at receiver end, generator voltage remaining constant for various power factors at receiver end. For each power factor at the receiver end there will be a different curve. The same conductor is used for both families of curves, the same frequency (60 cycles) and the same generator voltage (220 kv.). They have the same general shape. They are like the regulation curves of a shunt generator. With no load at the receiver end on the 100-mile line the voltage of the receiver is 225 kv., while on the 500-mile line it is 425 kv. due to the large charging current.

Let us look at the 100-mile line first. It is customary to operate such a line with the receiver voltage lower than the generator voltage and with a power factor of unity or less. If we follow the unity power factor curve, starting off with no load at the receiver and adding power, the receiver voltage continues to drop until we come to the maximum power for this power factor. This point is far below the usual operating voltage. It will be noted that as the power factor increases towards leading, the voltage at which the maximum power occurs becomes higher. Maximum power for a given line insulation is obtained by having the voltage at both ends the same, *i. e.*, with kilovolts at receiver equal to kilovolts at the generator. For the 100-mile line with kilovolts at the receiver equal to 220 kv., for maximum power we would have a power factor of about 0.7 leading and could deliver over 500,000 kw. Notice however, that we are now operating on the underside of the curve for 0.7 power factor leading and the case is comparable with the 500-mile line.

Let us pass to the 500-mile line. As we go out along the line *A*, *B*, Fig. 28, (220 kv. receiver equals 220 kv. generator), a more leading power factor shows an increase in kilowatts until we come to the limit of the line at this voltage. For the line chosen the limit is about 130,000 kw. and the power factor is 0.9 leading

while 0.8 power factor leading gives less power and 0.7 less still. This same thing has been shown on the circle diagram. With the receiver voltage equal to the generator voltage, for all constant receiver power factors we are below the maximum power points. Therefore, the 500-mile line would be unstable for a shaft load of constant power factor. Fortunately however, an induction or synchronous load does not have a constant power factor but a power factor which becomes more leading as the voltage drops and more lagging as the voltage rises. The constant power factor curves, therefore, are not the curves of receiver power against receiver voltage for induction and synchronous loads. You will notice two dotted curves. These are for induction motor loads in parallel with synchronous condensers with constant excitation on the condensers. The circles indicate the points of normal voltage operation. In Curve *a* we are delivering 100,000 kw. with normal voltage of 220 kv. An increase in load is accompanied by a drop in voltage and an improvement in power factor. Beyond a certain point, however, a drop of voltage means a more leading power factor but no more load. In Curve *b* we are delivering 120,000 kw. with normal voltage of 220 kv. We cannot get any more power with a drop of voltage although we get a more leading power factor. There is no margin. Now look at the dotted curve in the 100-mile line graph. We have the same load and the same condenser as in the dotted Curve *a* on the 500-mile line graph. We have also constant synchronous condenser excitation. A drop of voltage is accompanied by a more leading power factor and also more load, so that we can pass from 100,000 kw. to 200,000 kw. and beyond before we reach the maximum power point. The 100-mile line is stable for the load chosen, but the load is far from the maximum power the line will deliver. The 500-mile line looks dangerous for we are very near the maximum power of the line at 220 kv.

We can increase the maximum power of the 500-mile line by raising the voltage, by reducing resistance or reactance or by going to a lower frequency. A higher voltage would increase the maximum power as the square of the voltage. Decreasing the resistance when it is small in comparison with the reactance makes but little difference in the maximum power. Decreasing the reactance in the manner proposed by Mr. Percy Thomas, in a paper before the Institute in 1910, by employing split conductors, would increase the maximum power by 50 or 60 per cent. Decreasing the frequency to 25 cycles would make the 500-mile line equivalent to a 60-cycle line whose length is 500 X 25/60 = 208 miles, but whose resistance is inversely as the frequency or 60/25 as great. With 25 cycles, more than 150,000 kw. can be delivered over a 500-mile line with stability assuming constant generator terminal voltage.

The use of a synchronous condenser in the middle of the 500-mile line as suggested by the authors, will increase the maximum power that can be delivered over the line. Assuming 60,000 kv-a. in condensers at the mid point and constant voltages of 220 kv. at the generator and receiver ends but constant field on the condenser at the mid point, I find we could deliver approximately 150,000 kw. which agrees with the 152,000 kw. mentioned in Messrs. Evans and Bergvall's paper. In arriving at the 107,000 kw. mentioned in their paper for the rating of the line without condenser in the middle, constant field was assumed on the receiving end condensers but not constant field on the generators as voltage was assumed constant at the terminals of the step-up transformers. In arriving at the 150,000-kw. rating of the line with condenser at the mid point, constant field was assumed only on the condensers at the mid point. Both of these ratings would be very materially reduced if constant field were assumed at all points. Mr. Doherty discusses this phase at some length and gives some figures as to what this maximum power rating may become.

The curves in Fig. 29 are plotted as the others were, with kw. at the receiver against kv. at the receiver, (or per cent normal receiver voltage) and with constant generator voltage. I have assumed the condition shown on the graph. The upper set of curves is for the 500-mile line without condensers in the middle. The solid curves are for a constant generator voltage of 220 kv. at the terminals of the step-up transformer. A 70,000-kv-a. condenser was assumed and a load power factor of unity constant with voltage. The losses in the transformers and condensers have been neglected. The condenser field was adjusted to give the proper power factor for getting the assumed load over the line at normal receiver voltage of 220 kv. The field was then held constant on the condenser and the graph of kw. against kv. plotted. The circles indicate the points of normal voltage operation. When delivering 100,000 kw. at normal voltage we are

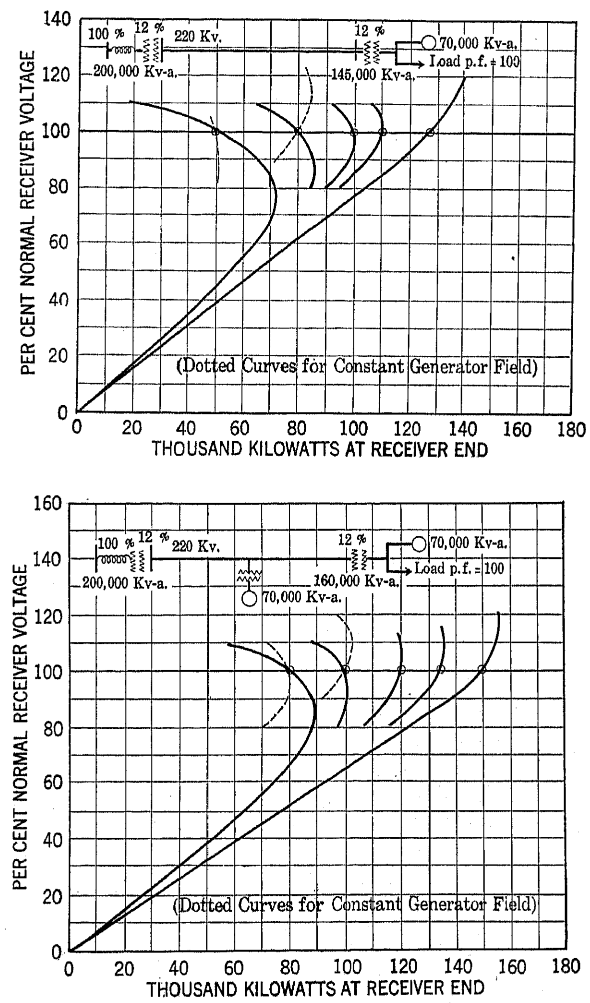

Fig. 29

above the maximum power point and when delivering 110,000 kw. we are below it. The maximum power possible over this line with constant generator voltage equal to 220 kv. and with the condenser capacity and load power factor assumed, is therefore, about 107,000 kw. as has been stated. The dotted curves are for constant field on the generator. The maximum power in this case is approximately 70,000 kw.

The lower graph of Fig. 29 is for the 500-mile line with condenser at the mid point. The solid curves are for a constant generator voltage of 220 kv. at the terminals of the step-up transformer. The receiver voltage has been allowed to vary with the addition of load as well as the mid-point voltage. Messrs. Evans and Bergvall held the receiver voltage constant and allowed the voltage at the mid point of the line only to vary with a change in load. With a 70,000-kv-a. condenser at the receiver and a 70,000-kv-a. condenser at the mid point and constant excita-

tion on these condensers, the lower graph of Fig. 29 shows how the receiver voltage varies with the load. The circles indicate the points of normal voltage operation. When delivering 100,000 kw. at normal voltage we are on the upper side of the curve, but if 2000 kw. were added suddenly, before the regulator could increase the field on the condenser the voltage would fall, and if the load were a shaft load, it would fade away. When delivering 120,000 kw. at normal voltage we are already on the underside of the curve and for a shaft load we are unstable at this point. The maximum power, therefore, with the condenser capacity assumed and constant generator terminal voltage is less than 120,000 kw., probably about 118,000 kw. The dotted curves are for constant field on the generator. The maximum power in this case, is approximately 90,000 kw. It is possible by increasing the amount of condenser capacity to get more power over this line with a condenser in the middle. However, calculations made with a 150,000-kv-a. condenser of the usual type at the end and at the middle of the line, show that it is not possible to get 150,000 kw. over the line with stability assuming constant generator terminal voltage. If the generator field instead of the generator terminal voltage is assumed constant, the case would be worse. An increase in the amount of power with stability can be obtained if a special highly saturated synchronous condenser is used at the middle of the line.

If it is necessary to transmit 150,000 kw. per circuit 500 miles, I feel sure that it will be done, if not with the equipment at present commercially available, then by means of specially designed apparatus.

R. E. Doherty: While I would not detract one iota from the many points of real value in these papers, I nevertheless believe that a wrong impression may possibly be obtained from them as to the maximum power limit of such long lines, and I therefore wish to submit for your consideration the maximum limits which, in the present state of engineering knowledge and experience, I consider to be justified.

After a careful and extended investigation, and considering the present experience and the extent to which the proposed colossal project of a 500-mile line extends beyond the bounds of experience, my conclusion is that the estimates of the maximum power given in these papers are too high. Take the case of a 500-mile straightaway transmission; where the authors proposed about 110,000 kw., we calculate about 70,000 kw. in the case of the sectionalized line with a 70,000-kv-a. condenser in the middle. Where they propose 150,000 kw. our estimate is 90,000 kw. These figures represent the maximum power which can be transmitted over the line at 220 kv. with the synchronous apparatus assumed. All assumptions are the same as those stated by the authors, excepting the generators. I have assumed a 90,000-kv-a. generator with the usual degree of saturation, and with 60 per cent synchronous reactance: which is equivalent, so far as the above results are concerned, to a 90,000-kv-a. generator with 45 per cent synchronous reactance, in which saturation is negligible. The usual value of synchronous reactance is about 100 per cent. The authors assume, in the calculations, that it is zero, when they assume constant voltage, *i. e.* $\frac{d\,E}{d\,P} = 0$.

Do not misunderstand. This difference in maximum power does not come from differences in premises, methods of calculation, or character of the synchronous apparatus considered. It is altogether a question of assumptions. Starting with the authors' assumptions, and with the same theory, long since generally accepted, we naturally arrive at the same conclusions; but the difference in assumptions is just the difference between 110,000 kw. and 70,000 kw. in the case of straightaway transmission, and between 150,000 kw. and 90,000 kw. in the case of a sectionalized line with a condenser at the mid-point.

The difference in assumptions is this: in the case of 500-mile straightaway, the authors assume a constant voltage at the generator terminals, or perhaps at the high side of the transformer; that is, they neglect the fact that the synchronous generators impose limitations upon maximum power in the same manner, and to a comparable extent, as the synchronous apparatus at the receiving end. That is, the difference in this case is altogether that they have neglected the effect of the generators, and we have included it.

In the sectionalized line with the condenser at the mid-pont, Messrs. Evans and Bergvall have not only neglected the limitations due to the synchronous generators, as all of the authors have done in the straightaway line, but have also even neglected the limitations imposed by the synchronous condenser at the receiving end—which limitations they had considered of sufficinent importance to include in calculating the straightaway transmission. In other words, in the sectionalized 500-mile line, the only limitation considered, outside of the line itself, is that imposed by the condenser at the middle of the line. That is, the difference between our conclusions regarding the sectionalized line is that the authors have neglected the limitations of the apparatus both at the sending, and at the receiving, end, and we have not.

Therefore, in comparing these conclusions, I wish to make it clear that the difference in results arises, not from any difference of opinion as to the fundamental theory of the transmission line, of the apparatus involved, or from essential difference of method, but only from a difference of opinion as to the importance of taking into account in the calculations the limitations imposed by the certain groups of the apparatus involved.

What about these assumptions? Which of them is justified? I submit that the colossal magnitude and importance of the long-distance lines now under consideration, and also the extent to which, in this study, we are projecting beyond the limits of experience, both demand that we adhere to the following principle: That we must show the system to be *inherently* stable—that is to say, we must neither gamble that a voltage regulator will be able to insert a supporting prop under an otherwise falling system, nor *depend* for stability during load transients, upon possible, momentary, favorable conditions due to momentum and field transients. These may add up in the right direction, but engineers had better keep them up their sleeves, just as they have done in the past in most other apparatus applications, particularly in generating and transmission equipments. Moreover, it should not be forgotten that the values here discussed are the ultimate maxima of power that can be transmitted at normal voltage with the apparatus considered. These are factors which must be carefully accounted for in deciding what asumptions are justified, and what are not.

The point of view which I am here outlining is presented in a masterly way in the first few pages of Mr. Shand's paper—which pages I should commend to your very careful study. After discussing generator characteristics and voltage regulators, he says, "This theory of artificial stability, although perhaps not a practical possibility, is here outlined mainly for the purpose of preventing any misconception regarding the capabilities and limitations of the commercial vibrating regulator in connection with the present subject. Moreover, if the state of artificial stability were attainable it is very doubtful that it would be desirable to depend on this apparatus as the main link in maintaining the operation of the system. In deriving the limit of output for power system it may be considered that the condensers are operating under a definite value of excitation for each value of load, this value being adjusted by the regulator as the load conditions change." Then, somewhat as a shock, he follows up with this statement: "In the following discussion the effect of the inherent voltage regulation of the main generators has been neglected. This is justified on the grounds that the error is slight while the labor involved would increase greatly." What do Evans and Bergvall say? "In this investigation the voltages at both ends of the line were assumed to be constant. Actually the voltage regulators at the generator and receiver

synchronous condenser cannot change the voltage instantaneously and some variation in voltage will occur. This does not appreciably affect the pull-out point as can be seen from the tests."

Now I think it is perfectly clear from the foregoing that there is complete agreement in fundamental theory, and in our conceptions of the general character of the behavior of all apparatus involved. But when we come to the point of making actual calculations—then, and not until then, we reach the point of disagreement. It is merely a difference of opinion as to whether the limiting effects of synchronous apparatus, which we both acknowledge, are significant or not; I am certain that they are. And inasmuch as we do agree in theory, it is only necessary for the authors to make the calculation including these effects, even if it is greater labor, and they will undoubtedly find substantially the same results. As a matter of fact, Mr. Shand has already calculated for a 300-mile line, the effect of the limited condensers at the receiver—still neglecting, however, the limitations of the generator. Why not do it for a 500-mile line, take the final step to make a complete job of it, and include the limitations of the generator. That would be more convincing than to assume that the factory test settled it. The difference is on the wrong side to let the test settle it.

I hope I have made it clear to you where the difference in results arises. The doctors do not disagree regarding diagnosis, nor as to the treatment, but merely regarding the *extent* of the treatment. And I trust that further study and calculation will bring agreement there.

T. A. Worcester: As has been brought out in some of the discussion this afternoon, the practical load limit of a 500-mile, 60-cycle line is not more than 100,000 kw., probably is in the neighborhood of 80,000 kw. If this is the case, it is well that we check up to see whether such a line would be economically practicable. The cost per kw. year of a 60-cycle transmission system to deliver 80,000 kw. per circuit is about $29. This figure includes the transmission line, step-up and step-down transformers and synchronous condensers, and to it must be added the cost of generation of power in the hydro station. It is not to be expected that power can be generated at anything less than $15 per kw-year and would likely be $20 or more. To these figures must be added the cost of transmission losses which will be approximately 25 per cent. The cost for $15 power when delivered over the 500-mile line will then be $48 per kw-year and of $20 power $54 per kw-year.

On the basis of mils per kw-hr. for 7200-hour load these figures reduce to 6.6 mils for $15 power and 7.5 mils for $20 power. To these figures must be added an amount necessary to take the power from the low side of the receiving station of the hydro system to a point where a competing steam plant might be placed, and it is very doubtful if the hydro power on this basis can compete with steam power unless the price of coal increases materially above the present-day value.

As the 80,000 kw. per circuit 60-cycle line is questionable from the economic point of view, the problem immediately arises as to how to increase the capacity of the line and lower its cost per kw.

Higher voltages have been considered but there is a strong indication that the increase in carrying capacity is about equalled by the increase in cost.

Another scheme of increasing the line carrying capacity is to divide the conductors as suggested by Mr. Percy Thomas. This will increase the capacity of the line approximately 50 per cent and may be the answer to the problem. Operating engineers, however, have shied at the difficulties involved in operating a split-conductor line as they think they have enough troubles with one wire on an insulator string.

Another alternative which involves the use only of standard equipment and methods is to use a lower frequency. A 25-cycle 500-mile line is equivalent to a 60-cycle 200-mile line and no one would worry about such a line. With slightly leading power factor 150,000 kw. can be carried over one circuit with ample margin for a sudden increase in load and there is no question of stability in the same sense as with the 60-cycle line with equivalent load. Twenty-five cycles has been avoided as the main load in the industrial districts is 60 cycles and unquestionably the growth is in that direction and should by all means be encouraged. It is necessary then to convert the 25-cycle power to 60 cycles and charge the cost of transmission with frequency changers and their losses. Assuming the losses to be 10 per cent, the useful power delivered will be 135,000 kw. per circuit instead of 150,000 just mentioned. On this basis I have figured the cost of delivering 60-cycle power into the metropolitan district and find that it can be done for 6 mils for $15 hydro power and 7 mils for $20 power. These figures include the cost of one transformation after going through the frequency changers and if it is necessary to make an additional transformation the comparison is not quite so favorable to the long line. However, they are on the same basis as the figures given above for the 60-cycle transmission and they show about 10 per cent lower cost. This percentage difference is somewhat disappointing as the margin is not sufficient to assure one that the hydro power can compete with steam. It is, however, sufficient to warrant a very close analysis for any particular undertaking, as some slight difference in assumption might throw the balance heavily on one side of the other. For instance, if any large part of the power could be used at 25 cycles, the cost and losses in the frequency changers would be reduced, with a consequent advantage for the hydro system.

Frederick E. Terman: The influence of circuit constants on the performance of the transmission line as reflected in the circle-diagram coefficients can be clearly shown by expressing these coefficients in their simplest hyperbolic form, and expanding the result into a power series. Dropping the unimportant terms, and judiciously combining the others leads to a very simple expression.

Expressed in the simplest form, the conjugate expressions of the Evans and Sels diagram coefficients become, in the case of the transmission line alone:

$$1 = \text{Real part of } (A/B) = \text{Re}\,\frac{\coth + \theta}{Z_o}$$

$$m = \text{Imag. part of } (A/B) = \text{Imag}\,\frac{\coth \theta}{Z_o}$$

$$n = \text{Modulus } (1/B) = \text{Mod}\,\frac{\operatorname{cosech} \theta}{Z_o}$$

Taking R, X, and Y as the total resistance, reactance, and admittance of the line, and remembering that a term of the character $X\,Y$ is dependent only upon the frequency and length, but is independent of the physical arrangements due to the reciprocal relation of capacity and inductance of open air lines, the following results are obtained:

$$1 = \frac{k}{(R^2 + X^2)^{\frac{1}{2}}}$$

$$m = \frac{R}{R^2 + X^2}$$

$$n = \frac{X}{R^2 + X^2} - k''\,Y$$

$k = \{ 1 + 1.133 \times 10^{-9} f^2 L^2 s \,(2 + 1.133 \times 10^{-9} f^2 L^2 s) \}^{\frac{1}{2}}$
$s = (0.1667 + 0.0221 \times 10^{-9} f^2 L^2)$
f = frequency
L = length of line in miles
$k'' = (0.333 + 0.0252 \times 10^{-9} f^2 L^2)$

For lines not exceeding 500 miles these results are accurate to within 1 per cent for open-air lines at commercial frequencies, (not over 60 cycles), and furnish an easy and yet sufficiently accurate method for the determination of the circle constants. In the ordinary line R/X is small, so we see that changing R does practically nothing to the circle diagram except alter m in pro-

portion, while a change in X affects all of the coefficients. Furthermore, it is seen that Y is only a secondary influence since the term $k'' Y$ is not of great size.

In general the characteristic one would like are: (1) A large $(n - m)$, which gives a high power limit; and (2) a small $m/1$ which gives a line requiring only a minimum of variation in synchronous capacity from no-load to full load transmission. These requirements show the desirability of first a low reactance, and next a low resistance, although the change in characteristics is not great after the conductor section increases beyond a reasonable size.

Prof. Bush has called my attention to the fact that R, X, and Y can be expressed as functions of conductor spacing and diameter, making it possible to draw a set of curves showing the relation between the physical and electrical constants of the line. This has been done in Fig. 30 for a copper conductor, and using the data for R, X, and Y taken from the Westinghouse Reprint 82.

Before the present form of the Evans and Sels circle diagram becomes too well established, it would be well to call attention to the fact that plotting leading kv-a. in the lagging position leads to several conflicts with the customary conventions.

This point becomes evident by an examination of Fig. 31, which is in general similar to the diagrams of Thielman and Holladay[2]. In the original form this diagram is suited only for constant receiver potential since it depends upon the fact that the power

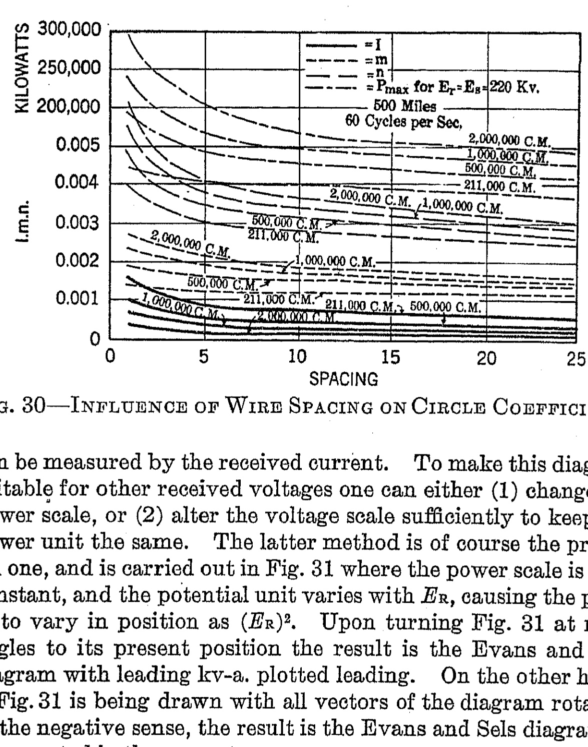

FIG. 30—INFLUENCE OF WIRE SPACING ON CIRCLE COEFFICIENTS

can be measured by the received current. To make this diagram suitable for other received voltages one can either (1) change the power scale, or (2) alter the voltage scale sufficiently to keep the power unit the same. The latter method is of course the practical one, and is carried out in Fig. 31 where the power scale is kept constant, and the potential unit varies with E_R, causing the point A to vary in position as $(E_R)^2$. Upon turning Fig. 31 at right angles to its present position the result is the Evans and Sels diagram with leading kv-a. plotted leading. On the other hand, if Fig. 31 is being drawn with all vectors of the diagram rotating in the negative sense, the result is the Evans and Sels diagram as is presented in the present paper.

This inconsistency was justified in an earlier paper[3] of the present writers by the fact that inductive impedanceis $r + j x$, but analysis shows this to be an argument on the other side. If the equation given by Evans and Sels for the circles in terms of power is divided by E_R^2 an interesting, and for some purposes, very valuable circle diagram in terms of current results, but with the $+ Q$ taken as lagging, then lagging current must be plotted leading. Again dividing by E_R^2 gives the circle diagram in terms of admittance, where with the convention adopted by the writers, $g + j b$ represents inductive admittance, clearly not in agreement with inductive impedance as $r + j x$.

Putting the center of the circles in the second quadrant as in Fig. 31, and plotting leading kv-a. leading has the great advantage of avoiding all of these inconsistencies, and conforming to the common custom.[4]

C. A. Nickle: In the following, a method is developed for calculating the maximum power under steady state for a system comprising generators, transmission line, synchronous condensers and receiving circuit. This method has been developed on the assumption that saturation in the generator does not exist to any significant degree, although it may exist to any known degree in the condensers. Saturation in the generators would increase the maximum power over the values thus calculated.

The general equations of a transmission line having distributed inductance, capacity, resistance, and leakage are:

$$E = E_R \cos\beta 1 \cosh\alpha 1 + j E_R \sin\beta 1 \sinh\alpha 1$$

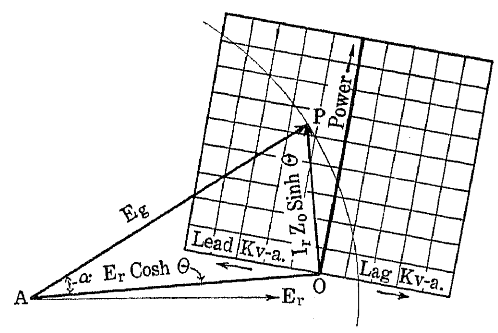

FIG. 31—VECTOR BASIS OF EVANS AND SELS CIRCLE DIAGRAM

$$+ I_R \sqrt{\frac{Z}{Y}} \cos\beta 1 \sinh\alpha 1 + j I_R \sqrt{\frac{Z}{Y}} \sin\beta 1 \cosh\alpha 1 \quad (1)$$

$$I = I_R \cos\beta 1 \cosh\alpha 1 + j I_R \sin\beta 1 \sinh\alpha 1$$

$$+ E_R \sqrt{\frac{Y}{Z}} \cos\beta 1 \sinh\alpha 1 + j E_R \sqrt{\frac{Y}{Z}} \sin\beta 1 \cosh\alpha 1 \quad (2)$$

where

E_R = receiver voltage line to neutral
I_R = receiver current per phase
Z = line impedance per phase per mile
Y = line admittance to neutral per phase per mile
α = attenuation constant $= \sqrt{\tfrac{1}{2}(z y + r g - b x)}$
β = propogation constant $= \sqrt{\tfrac{1}{2}(z y - r g + b x)}$
1 = distance to any point on the line measured from the receiver end.
E = voltage to neutral 1 mile from receiver.
I = current 1 mile from the receiver.

For the 500-mile line under discussion the line constants expressed in per cent (as a fraction) on the basis of 100,000 kv-a. at 22 kv. are:

$$\sqrt{\frac{Z}{Y}} = 0.793 - j\,0.0501$$

$$\sqrt{\frac{Y}{Z}} = 1.26 + j\,0.0796$$

$$\alpha = 0.000131$$
$$\beta = 0.00207$$
$$\alpha 1 = 0.0655$$
$$\beta 1 = 1.035$$
$$\cosh\alpha l = 1.002$$
$$\sinh\alpha l = 0.0655$$
$$\cos\beta l = 0.515$$
$$\sin\beta l = 0.86$$

2. Thielman, *Rev. Gen. d' El.* 1920-1921.
Holladay, A. I. E. E. 1922.
3. Evan & Sels in the "*Electric Journal*" 1921.

4. J. R. Dunbar in discussion on page 789 of 1922 A. I. E. E. TRANSACTIONS, on the vector representation of reactive power.

Substituting these constants in the general equations, we get the voltage and current expressed as a fraction of normal voltage and current, as follows:

$$\dot{E} = 0.516\,\dot{E}_R + j\,0.0563\,\dot{E}_R + 0.0699\,\dot{I}_R + j\,0.6813\,\dot{I}_R \quad (3)$$

$$\dot{I} = 0.516\,\dot{I}_R + j\,0.0563\,\dot{I}_R - 0.0261\,\dot{E}_R + j\,10.089\,\dot{E}_R \quad (4)$$

The receiver current expressed in terms of receiver power and receiver reactive kv-a. is

$$\dot{I}_R = \frac{P}{E_R} + j\,\frac{Pj}{E_R} \quad (5)$$

where

P = power per phase at receiver.

Pj = reactive kv-a. per phase at receiver.

E_R = receiver voltage per phase used as a reference vector.

Substituting (5) in (3) and (4)

$$\dot{E} = 0.516\,E_R + 0.0699\,\frac{P}{E_R} - 0.6813\,\frac{Pj}{E_R} + j\left(0.0563\,E_R + 0.6813\,\frac{P}{E_R} + 0.0699\,\frac{Pj}{E_R}\right) \quad (6)$$

$$\dot{I} = -\,0.0261\,E_R + 0.516\,\frac{P}{E_R} - 0.0563\,\frac{Pj}{E_R} + j\left(1.089\,E_R + 0.0563\,\frac{P}{E_R} + 0.516\,\frac{Pj}{E_R}\right) \quad (7)$$

The nominal e. m. f. of the generator is

$$\dot{E}_n = \dot{E} + j\,x_0\,\dot{I} \quad (8)$$

where x_0 is the synchronous reactance of the generator.

Substituting (6) and (7) in (8)

$$\dot{E}_n = \Bigg[(0.516 - 1.089\,x_0)\,E_R + \left(0.0699 - 0.0563\,x_0\right)\frac{P}{E_R} - \left(0.6813 + 0.0516 x_0\right)\frac{Pj}{E_R} \Bigg] + j\Bigg[(0.0563 - 0.0261\,x_0)\,E_R \left(0.6813 + 516\,x_o\right)\frac{P}{E_R} + \left(0.0699 - 0.563\,x_o\right)\frac{Pj}{E_R} \Bigg] \quad (9)$$

Expressing in absolute values, dividing through by E_R^2, completing the squares, and rearranging,

$$\left[\frac{P}{E_R^2} + \left(\frac{0\,0745 - 0.0939\,x_0 + 0.0478\,x_0^2}{0.4688 + 0.6941\,x_0 + 0.2692\,x_0^2}\right)\right]^2 + \left[\frac{Pj}{E_R^2} + \left(\frac{-\,0.3476 + 0.4706\,x_0 + 0.560\,x_0^2}{0.4688 + 0.6941\,x_0 + 0.2692\,x_0^2}\right)\right]^2 = \frac{E_n^2}{E_R^2}\left[\frac{1}{0.4688 + 0.6941\,x_0 + 0.2692\,x_0^2}\right] \quad (10)$$

Equation (10) is the equation of a family of circles having a parameter $\dfrac{E_n}{E_R}$

and coordinates $\dfrac{Pj}{E_R^2}$ and $\dfrac{P}{E_R^2}$. Thus the center of these circles is located at

$$\frac{Pj}{E_R^2} = -\left[\frac{-\,0.3476 + 0.4706 x_0 + 0.560\,x_0^2}{0.4688 + 0.6941\,x_0 + 0.2692\,x_0^2}\right] \quad (11)$$

$$\frac{P}{E_R^2} = -\left[\frac{0.0745 - 0.0939 x_0 + 0.0478\,x_0^2}{0.4688 + 0.6941 x_0 + 0.2692\,x_0^2}\right] \quad (12)$$

The radii are given by

$$R = \frac{E_n}{E_R}\sqrt{\frac{1}{0.4688 + 0.6941\,x_0 + 0.2692\,x_0^2}} \quad (13)$$

For any given generator, x_0 is known, and one set of concentric circles will give the performance of the line.

The condition $x_0 = 0$ represents an infinite generator, and a set of circles for this condition may be used for determining the voltage at the generator terminals. Fig. 32 shows a family of circles for $x_0 = 0$ and Fig. 33 for $x_0 = 0.50$, which corresponds approximately to a 200,000 kv-a. generator. The method of obtaining the maximum power which can be transmitted over a 500-mile straightaway line from these curves is as follows:

For any given receiver power, the reactive kv-a. in the line at the receiver, required to hold normal voltage at both the receiving and sending ends, is obtained from the set of curves for $x_0 = 0$. For these conditions $E_R = 1.0$ and $\dfrac{E_n}{E_R} = 1.0$.

Having found the reactive kv-a. required at the receiver, the excitation on the receiving condenser can be obtained from the condenser characteristics. A typical set of these characteristics is shown in Fig. 34.

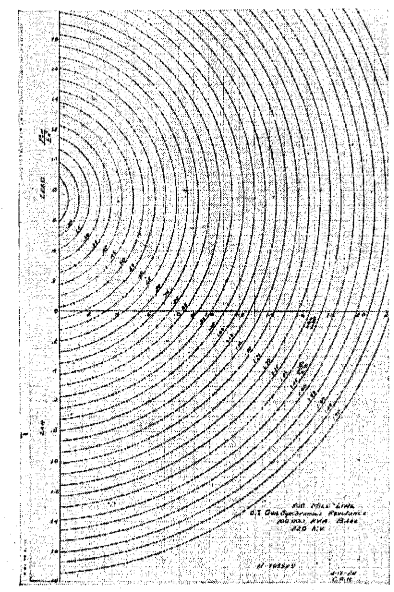

Fig. 32—500-Mile Line. 0 Per Cent Gen. Synchronous Reactance. 100,000 Kv-a. Base. 220 Kv.

Thus for any receiver power setting, the receiver reactive kv-a. and receiver power are known, and from the curves for $x_0 = 0.50$, the approximate excitation on the generator may be read directly.

The variation of receiver voltage with receiver power is then obtained under the assumption that the generator and condenser excitation remain fixed. To obtain this variation, a new receiver voltage is assumed. For this new receiver voltage, a new value of $\dfrac{Pj}{E_R^2}$ is obtained from the condenser characteristics and the new value of $\dfrac{E_n}{E_R}$ is known. Hence from the curves for $x_0 = 0.50$ the new value of $\dfrac{P}{E_R^2}$ is obtained.

Repeating this process for several assumed values of E_R, a curve may be plotted with P_R as abscissae and E_R as ordinates. The maximum power for these conditions occurs at the point where $\dfrac{d\,P}{d\,E_R} = 0$ and the maximum power of the line under

steady conditions occurs for the settings which give $\frac{d\,P}{d\,E_R} = 0$ for $E_R = 1.0$.

Fig. 35 shows a set of such curves obtained for a 500-mile line under the following assumptions:

75,000-kv-a. condenser at receiver.
Generator synchronous reactance $x_0 = 0.50$
Generator synchronous reactance $x_0 = 0$
Unity power factor motor load.

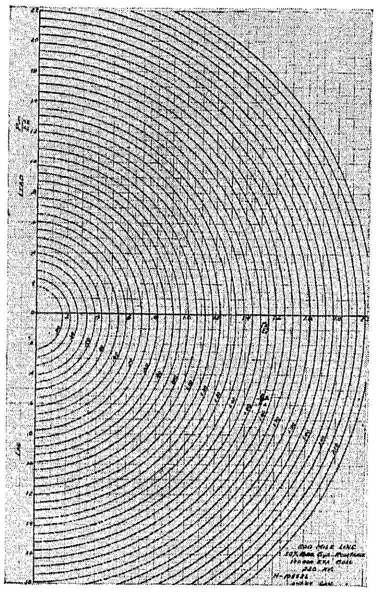

FIG. 33—500-MILE LINE. 50 PER CENT GEN. SYNCHRONOUS REACTANCE. 100,000 KV-A. BASE. 220 KV.

The solid curves are for $x_0 = 0.50$ and the dotted curves for $x_0 = 0$. For $x_0 = 0$, $\frac{d\,P}{d\,E_R}$ is zero for $E_R = 1.0$ at approximately 117,000 kw. and, for $x_0 = 0.50$, at approximately 67,000 kw. With the finite generator assumed the maximum power is thus 57 per cent of that which could be obtained with an infinite generator.

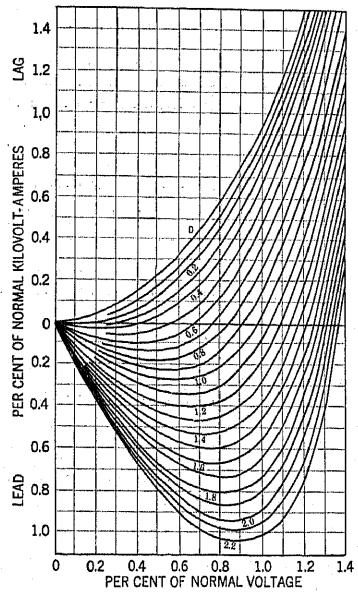

FIG. 34

SECTIONALIZED LINE

The process of obtaining these curves for a system having a condenser located at the middle of the line is considerably more difficult. For this case, separate computations are necessary for each 250-mile section. Curves, similar to those drawn for the 500-mile line, are obtained for a 250 mile line, and in addition, circles giving line loss and reactive kv-a. at the sending end are drawn for the condition $x_0 = 0$. These are shown in Figs. 36 and 37 and are derived as follows:

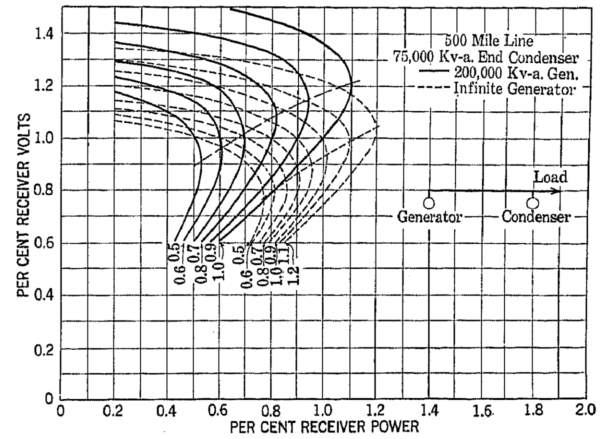

FIG. 35

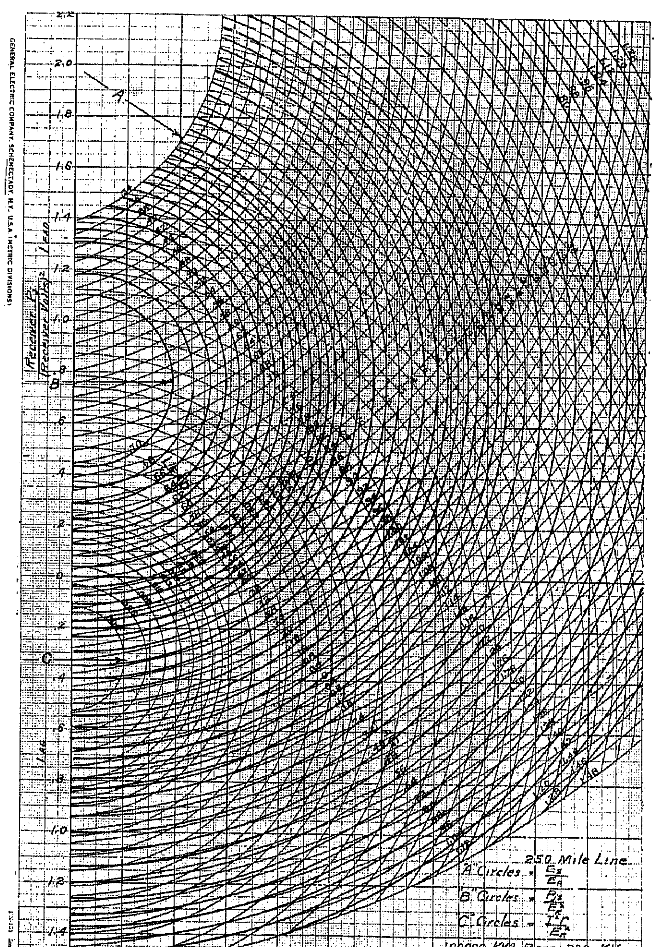

FIG. 36

For the 250 mile line, the line constants are

$$\sqrt{\frac{Z}{Y}} = 0.793 - j\,0.0501$$

$$\sqrt{\frac{Y}{Z}} = 1.26 + j\,0.0796$$

$$\begin{aligned}
\alpha &= 0.000131 \\
\beta &= 0.00207 \\
\alpha\, l &= 0.0327 \\
\beta\, l &= 0.517 \\
\cosh \alpha\, l &= 1.001 \\
\sinh \alpha\, l &= 0.0327 \\
\cos \beta\, l &= 0.87 \\
\sin \beta\, l &= 0.493
\end{aligned}$$

Substituting these constants and equation (5) in the general equations (1) and (2) we get

$$\dot{E} = 0.87\, E_R + 0.0473 \frac{P}{E_R} - 0.389 \frac{Pj}{E_R}$$

$$+ j \left(0.0161\, E_R + 0.389 \frac{P}{E_R} + 0.0473 \frac{Pj}{E_R} \right) \tag{14}$$

$$\dot{I} = -\,0.00345\, E_R + 0.87 \frac{P}{E_R} - 0.0161 \frac{Pj}{E_R}$$

$$+ j \left(0.620\, E_R + 0.0161 \frac{P}{E_R} + 0.87 \frac{Pj}{E_R} \right) \tag{15}$$

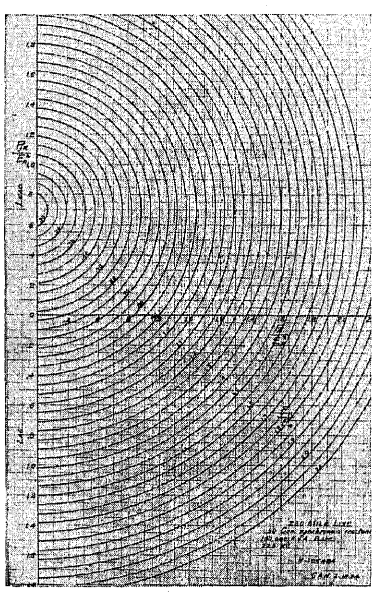

FIG. 37—250 MILE LINE 0.50 GEM SYNCHRONOUS REACTANCE, 100,000 KV-A BASE 220 KV.

Telescoping (14) and (15) for power at the sending end.

$$P_s = \dot{E}\, \dot{I}$$

$$= 0.007\, E_R^2 + P + 0.0306\, Pj + 0.0474 \frac{P^2}{E_R^2} + 0.0474 \frac{Pj}{E_R^2} \tag{16}$$

The line loss is the difference between the power at the sending end and the power at the receiving end or

$$P_L = 0.007\, E_R^2 + 0.0306\, Pj + 0.0474 \frac{P^2}{E_R^2} + 0.0474 \frac{Pj^2}{E_R^2} \tag{17}$$

Dividing through by E_R^2, completing the squares and rearranging,

$$\left(\frac{P}{E_R^2} \right)^2 + \left(\frac{Pj}{E_R^2} + 0.343 \right)^2 = \frac{21.1\, P_L}{E_R^2} - 0.0430 \tag{18}$$

This is the equation of a family of circles of radii,

$$R = \frac{21.1\, P_L}{E_R^2} - 0.0430 \tag{19}$$

and the center at

$$\frac{Pj}{E_R^2} = -\,0.343 \tag{20}$$

$$\frac{P}{E_R^2} = 0 \tag{21}$$

The reactive kv-a. at the sending end is the magnitude of the cross product of (14) and (15). Thus

$$P_{j_s} = 0.540\, E_R^2 + 0.0306\, P + 0.516\, Pj - 0.337 \frac{P^2}{E_R^2} - 0.337 \frac{Pj^2}{E_R^2} \tag{22}$$

Dividing through by E_R^2, completing the squares and rearranging,

$$\left(\frac{P}{E_R^2} - 0.0454 \right)^2 + \left(\frac{Pj}{E_R^2} - 0.765 \right)^2 = 2.193 - 2.97 \frac{P_{j_s}}{E_R^2} \tag{23}$$

This is the equation of a family of circles of radii

$$R = \sqrt{2.193 - 2.97 \frac{P_{j_s}}{E_R^2}} \tag{24}$$

and the center at

$$\frac{Pj}{E_R^2} = 0.765 \tag{25}$$

$$\frac{P}{E_R^2} = 0.0454 \tag{26}$$

The nominal e. m. f. of the generator is

$$\dot{E}_n = \dot{E} + j\, x_0 \dot{I} \tag{8}$$

Substituting (14) and (15) in (8)

$$\dot{E}_n = \Big[(0.87 - 0.62\, x_0)\, E_R + (0.0473 - 0.0161\, x_0) \frac{P}{E_R}$$

$$- (0.389 + 0.87\, x_0) \frac{Pj}{E_R} \Big]$$

$$+ j \Big[(0.0161 - 0.00345\, x_0)\, E_R + (0.389 + 0.87\, x_0) \frac{P}{E_R}$$

$$+ (0.0473 - 0.0161\, x_0) \frac{Pj}{E_R} \Big] \tag{27}$$

Expressing in absolute values, dividing through by E_R^2, completing the squares, and rearranging,

$$\left[\frac{P}{E_R^2} + \left(\frac{0.0478 - 0.0306\, x_0 + 0.007\, x_0^2}{0.1537 + 0.676\, x_0 + 0.757\, x_0^2} \right) \right]^2$$

$$+ \left[\frac{Pj}{E_R^2} + \left(\frac{-\,0.338 - 0.516\, x_0 + 0.54\, x_0^2}{0.1537 + 0.676\, x_0 + 0.757\, x_0^2} \right) \right]^2$$

$$= \frac{E_n^2}{E_R^2} \left[\frac{1}{0.1537 + 0.676\, x_0 + 0.757\, x_0^2} \right] \tag{28}$$

This is the equation of a family of circles of radii.

$$R = \frac{E_n}{E_R} \sqrt{\frac{1}{0.1537 + 0.676\, x_0 + 0.757\, x_0^2}} \tag{29}$$

and the center at

$$\frac{Pj}{E_R^2} = -\left(\frac{-\,0.338 - 0.516\, x_0 + 0.54\, x_0^2}{0.1537 + 0.676\, x_0 + 0.757\, x_0^2} \right) \tag{30}$$

$$\frac{P}{E_R^2} = -\left(\frac{0.0478 - 0.0306\, x_0 + 0.007\, x_0^2}{0.1537 + 0.676\, x_0 + 0.757\, x_0^2} \right) \tag{31}$$

In Fig. 36, circles are drawn giving reactive kv-a. at the sending end, voltage at the sending end, and line loss.

In Fig. 37, generator nominal voltage circles are given for a generator synchronous reactance $x_0 = 0.50$.

The sectionalized 500-mile line may be represented by two 250-mile sections in series as shown in Fig. 38.

The reactive kv-a. at D required to give normal voltage at C and D can be obtained from Fig. 36. From this reactive kv-a. the excitation required on the receiving condenser C_2 can be

obtained from the condenser characteristics, Fig. 34. The power and reactive kv-a. at C may also be obtained from Fig. 36. The power at B is the same as the power at C excepting the losses in the condenser C_1. If the condenser losses are significant, they should be added to the power at C to obtain the power at B. The power at B, thus obtained, is the receiver power for the section A B and from Fig. 36 we can get the reactive kv-a. required at B to hold normal voltage at A and B. The difference between the reactive kv-a. required at B and the reactive kv-a. at C, due to the load at D, gives the reactive kv-a. which the condenser C_1 must furnish.

The excitation on the condenser C_1 is then found from the condenser characteristics, Fig. 34. From the values of power and reactive kv-a. at B, the generator excitation can be obtained from Fig. 37.

Next, assume a new value of power at D. Then assume three or four different values of voltage at D, with the assumed new value of power. For each of the assumed voltage at D, the power and reactive kv-a. at D are known since the excitation on the condenser C_2 is assumed to remain fixed. From these values of power and reactive kv-a. the voltage, power, and reactive kv-a. at C can be obtained from Fig. 36. Then from the voltage at C and the known excitation on the condenser C_1 the reactive kv-a. furnished by this condenser is found from the condenser characteristics, Fig. 34. The reactive kv-a. at B is then the sum of the kv-a. at C and the condenser kv-a.

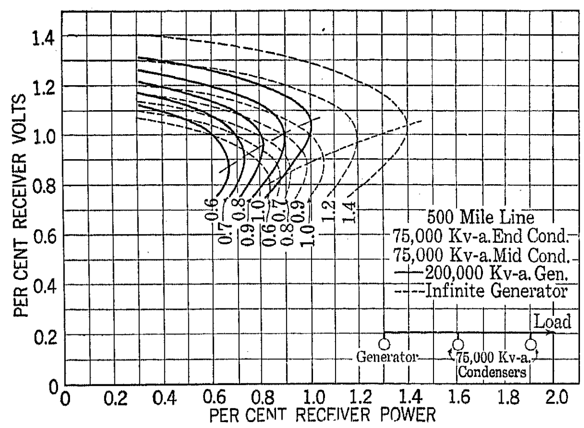

FIG. 38

Thus, for each assumed voltage at D, the power conditions at B are found, and, since these are the receiver conditions for the section A B, the excitation required on the generator G to give these conditions is found from Fig. 37.

The values of generator nominal voltage thus obtained are plotted against the assumed values of receiver voltage at D and that point on the curve, where the generator nominal voltage is the same as the value previously obtained, gives the correct value of receiver volts which correspond to the power assumed at D. This process is repeated for different assumed values of receiver power at D and a curve is plotted with receiver power as abscissae and receiver volts as ordinates. Similar curves are drawn for different power settings, and that power setting which gives

$\frac{d P}{d E_R} = 0$ for $E_R = 1.0$ is the maximum power that can be transmitted over the line at $E_s = 1.0$.

In Fig. 38 curves are shown for a sectionalized 500-mile line for the following assumptions;

75,000 kv-a. condenser at receiver.
75,000 kv-a. condenser at mid-point.
Generator synchronous reactance $x_0 = 0.50$.
Generator synchronous reactance $x_0 = 0$
Unity power factor load at receiver.

The maximum power for an infinite generator is thus 130,000 kw. and for the finite generator, 90,000 kw.

E. A. Smith: In referring to the paper on Superpower Transmission, I have noticed that Mr. Thomas has brought up some interesting points, such as I had recently figured on and by following Mr. Harold Goodwin, Jr. in his paper on Qualitative Analysis of Transmission Lines, a thorough analytical study can be made covering the general principles of very high tension transmission problems.

I doubt very much if the average engineer can solve and foresee the many difficulties encountered with 250 and 500-mile transmission systems of the 220,000 or higher voltage type.

The capacity of the transmission lines as well as the voltage regulation required for each particular system has to be taken into consideration to solve the principle factors from the performances on the systems as outlined under all conditions to operate efficiently. The different loads on a transmission system as well as the heating effects and losses have to be expounded in a way to cover the starting and stopping of the necessary apparatus at the distributing centers.

The costs of a system have to be studied in two ways, namely, construction and operation and by putting a system into operation, the best economical results are required to produce the means to cover these two principles. The period of construction being only of a short duration, it must be overlooked after completion, if the entire system is on a satisfactory operating basis.

Owing to the many theoretical assumptions for high voltages of this kind, a series of complications will arise in time, causing many difficult problems to appear on these systems at enormous expense and to keep the receiving end supplied, studies will have to be undertaken to analyze thoroughly all the principles involved in generation and transmission to bring out such points of interest which will help eliminate all unnecessary troubles and expenses.

I think Mr. Thomas is quite right in his assumption of installing a stepdown station in the center of the transmission system, by placing synchronous condensers therein, and providing for automatic means of fixing the potential which at the same time would divide the system entirely into two separate sections or lines. This would make the system more expensive as far as construction is concerned, but in the end would pay for itself.

I feel that the transmission system at 220,000 volts will not be able to stand up under all maximum load and weather conditions for any great length of time as the qualities of the conductors are not up to the point of satisfaction to withstand the continuous heat factors.

As a matter of fact the load at the receiving ends must be supplied at a fixed voltage and power factor and the synchronous condensers must be arranged to operate automatically to deliver the leading or lagging kv-a. as required, otherwise if this is not provided, the voltage will change accordingly to load conditions and losses. It will be seen by referring to Figs. 1, 2, 3 and 4, the curves will also change accordingly, owing to the fluctuating conditions of the load, voltage and losses which take place on long transmission lines, whereas on short-distance lines the losses would be considerably reduced and better operation would result. From this point it will be seen, that by introducing a central stepdown station at the middle of the transmission system, the line losses would be reduced at different loads.

According to calculations it is noted that with a maximum output of the generators, the power factor will be nearly unity, but due to many changes in the load, it will be unable to retain this value and the losses will be greater.

Assuming that all the curves in Figs. 1, 2, 3 and 4 and the values in Table A are correct, we have to compare them with actual practice, although, they appear to be fair values in connection with this superpower transmission when operating under no-load and full-load conditions.

E. A. Smith: In reference to Messrs. Evans and Sels paper although the curves represent certain conditions for a transmission system, the details are more or less based on theoretical assumptions.

It is seen that the curves are plotted according to the con-

ditions of the load and voltage of the system and depend mostly upon the resistance, reactance and impedance of the circuits described. By following the diagrams as shown it is readily seen that the synchronous condenser capacity required for any load at the receiver end, can be determined for approximate values at different power factors, but if the supply voltage varies between wide limits the radius of the receiver circle changes, which offsets the assumed fixed values and results in greater transmission losses for the length of the line.

Although the receiver load must retain a fixed power factor and is also assumed to act as an impedance across the circuit, it must have synchronous apparatus available for maintaining the voltage and controlling the power factor at the receiver end, to increase the power limit.

For any long transmission system, the most suitable arrangement would be, a synchronous condenser station at the center of the system in which the synchronous apparatus would tend to help regulate the voltage up to the maximum power limit.

As this system will include all kinds of electrical equipment as well as rotating apparatus, the system will be subjected to voltage fluctuations at different periods of the day (due to load conditions) and so will cause the rotating apparatus to fall out of step when the voltage drops below its fixed minimum value.

Professor V. Karapetoff: For the last year or so, we have been constructing at Cornell University a mechanical device to imitate the performance of a long transmission line. This device consists of pivoted weights and of springs, each weight taking the place of the inductance of a small section of the line and each spring representing the capacitance of that section. We are practically ready now to assemble this apparatus and then we shall have to provide a device for communicating to it sinusoidal vibrations to imitate the generator, and a load consisting perhaps of a friction disk, a spring, and a flywheel. Such a mechanical device is subject to the same equations of motion as a transmission line, under any desired transient conditions. Therefore, no mathematics is necessary: All you have to do is to impose a desired mechanical condition upon that model and to observe what happens. The natural frequency of vibration of each element is several seconds so that it is easy to follow a transient along such a line with a naked eye.

The authors of the papers use the method of complex quantities, and I should be the last one to deprecate it or to speak against this method, having used it so much myself. However, we now have to make another step, namely, in the direction of the so-called vector analysis. In the JOURNAL for last December I have a little article on the application of vector analysis to the circle diagrams of certain types of a-c. machines, principally commutator motors, and I urge the use of vector analysis, especially of the scalar product and of the vector product of two vectors, in the study of transmission lines under steady conditions.

In view of the importance which the circle diagram of power has acquired of late, it seems advisable to reduce its proof to the simplest possible terms, in order to make its use more general. The authors use the familiar method of complex quantities; in the case of power this necessitates a multiplication of a voltage by a current which is conjugate of the actual current. In other words, they use the relationship $P + j\,Q = (e + j\,e')\,(i - j\,i') = (e\,i + e'\,i') + j\,(e'\,i - e\,i')$ (11)

While this method is perfectly legitimate and leads to correct results[5], it is also of interest to solve the same problem using the principles of *Vector Analysis*. This branch of mathematics has not been used much as yet in electrical engineering, although its use has been found of great advantage in many branches of physics and mechanics. Since the theory of electrical engineering is largely based on these sciences, it is only a question of time when Vector Analysis will find its place in engineering investigations.[6]

Referring to Fig. 39, let vectors of voltages and currents be drawn in the $X\,Y$ plane. Let unit vectors parallel to the X and Y axis be denoted by $\mathbf{x}$ and $\mathbf{y}$ respectively. Then a current vector and a voltage vector may be written in the following form:

$$\mathbf{E} = \mathbf{x}\,e + \mathbf{y}\,e' \qquad (12)$$

$$\mathbf{I} = \mathbf{x}\,i + \mathbf{y}\,i' \qquad (13)$$

Vector quantities are denoted by bold-face letters, scalar quantities by italics.[7]

In Vector Analysis two kinds of products of two vectors $\mathbf{M}$ and $\mathbf{N}$ are distinguished: the *scalar product* (or the dot product)

$$\mathbf{M} \cdot \mathbf{N} = M\,N \operatorname{Cos} \theta \qquad (14)$$

and the *vector product* (or the cross product)

$$\mathbf{M} \times \mathbf{N} = \mathbf{q}\,M\,N \operatorname{Sin} \theta \qquad (15)$$

in these expressions θ is the angle between the vectors $\mathbf{M}$ and $\mathbf{N}$, and $\mathbf{q}$ is a unit vector in a direction normal to the $X\,Y$ plane (see figure)

From these definitions we may write

$$\mathbf{x} \cdot \mathbf{x} = \mathbf{y} \cdot \mathbf{y} = 1;\ \mathbf{x} \cdot \mathbf{y} = 0 \qquad (16)$$

$$\mathbf{x} \times \mathbf{x} = \mathbf{y} \times \mathbf{y} = 0;\ \mathbf{x} \times \mathbf{y} = -\,\mathbf{y} \times \mathbf{x} = \mathbf{q} \qquad (17)$$

These expressions follow from eqs. (14) and (15), by putting $\theta = 0$ or $\theta = 90°$, and $M = N = 1$. Forming a scalar product of eqs. (12) and (13), we get

$$\mathbf{I} \cdot \mathbf{E} = \mathbf{x} \cdot \mathbf{x}\,i\,e + \mathbf{y} \cdot \mathbf{y}\,i'\,e' + \mathbf{x} \cdot \mathbf{y}\,(e\,i' + i\,e') \qquad (18)$$

Using eqs. (16), we find that

$$P = \mathbf{I} \cdot \mathbf{E} \qquad (19)$$

In other words, the real power is equal to the scalar product of the current and voltage vectors. This also follows directly from the expression $P = I\,E \operatorname{Cos} \phi$, which is identical with the definition (14).

Similarly, forming a vector product (cross product) of eqs. (12) and (13), we obtain:

$$\mathbf{I} \times \mathbf{E} = \mathbf{q}\,(i\,e' - i'\,e) \qquad (20)$$

In other words, the reactive power

$$\mathbf{Q} = \mathbf{I} \times \mathbf{E} \qquad (21)$$

Thus $\mathbf{Q}$ may be represented by a vector normal to the $X\,Y$ plane. Since for any combination of values of $\mathbf{E}$ and $\mathbf{I}$, $\mathbf{Q}$ is always normal to the $X\,Y$ plane, this result is not objectionable on the score that reactive power cannot be a vector. It is a vector which always is in the same direction, or which for a certain range of values of angle ϕ may be negative, but which is always normal to the plane in which $\mathbf{E}$ and $\mathbf{I}$ are drawn.

It is convenient to consider P and Q as orthogonal components of a vector, say $\mathbf{U}$, so that

$$\mathbf{U} = \mathbf{p}\,P + \mathbf{q}\,Q \qquad (22)$$

where $\mathbf{p}$ and $\mathbf{q}$ are unit vectors at right angles to each other. But $\mathbf{q}$ is perpendicular to the $X\,Y$ plane; hence $\mathbf{p}$ lies in that plane, as shown in the Fig. 39. The exact position of the P axis with respect to the X axis is immaterial; in fact the $P\,Q$ diagram can be drawn entirely separate from the $X\,Y$ diagram. Thus, from the foregoing theory we have for the supply power

$$\mathbf{U}_s = \mathbf{p}\,(\mathbf{I}_s \cdot \mathbf{E}_s) + \mathbf{I}_s \times \mathbf{E}_s \qquad (23)$$

Eliminating $\mathbf{I}_r$ from eqs. (1) in the paper, we get

$$B\,\mathbf{I}_s = A\,\mathbf{E}_s - \mathbf{E}_r \qquad (24)$$

which is equivalent to the first of the eqs. (2). Multiply eq. (24) separately by $\cdot\,\mathbf{E}_s$ and by $\times\,\mathbf{E}_s$ and substitute the results in eq. (23). This will give

$$B\,\mathbf{U}_s = \mathbf{p}\,(A\,\mathbf{E}_s \cdot \mathbf{E}_s - \mathbf{E}_r \cdot \mathbf{E}_s) + (A\,\mathbf{E}_s \times \mathbf{E}_s - \mathbf{E}_r \times \mathbf{E}_s) \qquad (25)$$

But, according to eqs. (14) and (15),

$$\mathbf{E}_s \,.\, \mathbf{E}_s = E_s^2;\ \mathbf{E}_s \times \mathbf{E}_s = 0 \qquad (26)$$

Hence $\quad B\,\mathbf{U}_s = \mathbf{p}\,A\,E_s^2 - (\mathbf{p}\,\mathbf{E}_r \cdot \mathbf{E}_s + \mathbf{E}_r \times \mathbf{E}_s) \qquad (27)$

The last equation may be simplified as follows:

$$\mathbf{p}\,\mathbf{E}_r \cdot \mathbf{E}_s + \mathbf{E} \times \mathbf{E}_s = (E_r\,E_s)\,(\mathbf{p} \operatorname{Cos} \theta + \mathbf{q} \operatorname{Sin} \theta) = (E_r\,E_s)\,\mathbf{r}_\theta \qquad (28)$$

where $\mathbf{r}_\theta$ is a unit vector in the $P\,Q$ plane at an angle θ to the P

5. For a deduction of the terms on the right-hand side of this equation, see for example, V. Karapetoff, "The Electric Circuit," pp. 91 and 92.

6. As a beginning in this direction, the present writer has recently published an article entitled "The Use of the Scalar Product of Vectors in Locus Diagrams of Electrical Machinery," this JOURNAL, 1923, Vol. 842, p. 181.

7. For an elementary exposition of the general principles of the subject see, for example, J. G. Coffin's "Vector Analysis" (Wiley).

axis, and θ is the phase angle between $\mathbf{E}_r$ and $\mathbf{E}_s$. Thus, eq. (27) becomes

$$\mathbf{U}_s = \mathbf{p}\,(A/B)\,E_s^2 - (E_r\,E_s/B)\,\mathbf{r}_\theta \qquad (29)$$

Let E_s be kept constant; then the term $\mathbf{d} = \mathbf{p}\,(A/B)\,E_s^2$ is also constant. (A/B) is a complex quantity, which may be written in the form:

$$A/B = c\,\epsilon^{j\sigma}$$

Consequently, $\mathbf{d}$ is a vector of length $c\,E_s^2$, at an angle σ to the p axis.

The complex quantity B may be written in the form

$$B = b\,\epsilon^{j\tau} \qquad (31)$$

so that

$$(E_r\,E_s/B)\,\mathbf{r}_\theta = (E_r\,E_s/b)\,\mathbf{r}_{\theta-\tau} \qquad (32)$$

which is a vector of length $E_r\,E_s/b$, at an angle $\theta - \tau$ to the p axis. If E_r is also kept constant, this term represents a circle of radius

$$R = E_r\,E_s/b \qquad (33)$$

The above expressions for $\mathbf{d}$ and R are identical with the values given in the paper for the position of the circle and its radius.

While the above deduction may seem long, its length is due to the general introduction on vector analysis. The specific problem to be solved begins with eq. (23) and ends with eq. (29).

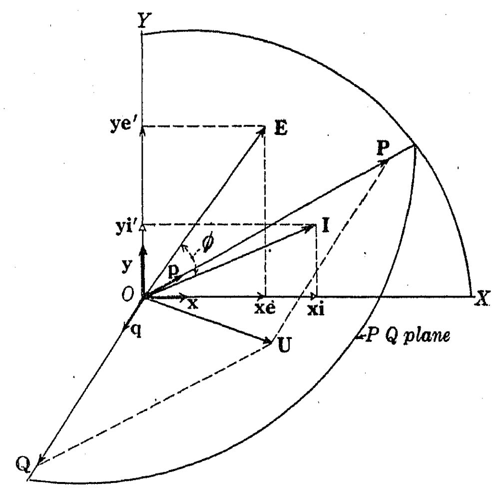

FIG. 39

which is the desired equation of the circle when E_s and E_r are constant.

By assuming E_r to be variable and differentiating eq. (29) *vectorically* (that is, with respect to both $\mathbf{r}$ and θ), a new vector equation is obtained. Eliminating E_r between this equation and eq. (29), gives a vector equation of the envelope. It is not necessary to introduce the components $\alpha, \beta, \gamma, \delta$, and the awkward square roots of the sums of the squares.

C. M. Longbottom (by letter): I propose to discuss one or two aspects of long-distance transmission which were not brought out in the papers. Reference has been made by Messrs. Evans and Bergvall to the amount of reactive kv-a. required at the mid-point of the line when a synchronous condenser is placed there to maintain constant voltage at this point. It seems very pertinent that one should carry this discussion a little further in order to examine the conditions arising from such subdivision of the line and what is more important, to determine how many subdivisions should be made in any case for the most economical arrangement of equipment.

With this object in view, I have examined four particular cases of a 500-mile transmission line operating at 220 kv. It was assumed that transformer banks of 200,000 kv-a. were situated at either end of the line. While banks of this rating would be too big in the case of an "unloaded" line as in case (1) outlined below, banks of this rating would be too small for case (4) but as this is an average value of the maximum load delivered it is not considered necessary to take different transformers in each case. This fact will not materially effect the conclusions to be drawn from this analysis.

The following four cases were considered; (1) a 500-mile transmission line with transformer banks at each end, ample synchronous-condenser capacity at the receiver and ample generator capacity at the supply end. (2) The same line as in (1) but with a synchronous condenser stationed at the mid-point thus dividing the line into two equal portions and forming what we will term "nodal" points at the generator, the mid-point and the receiver end. (3) Similar to (1) but with four nodal points equally spaced or, in other words, two intermediate condenser stations. (4) As in (1) but with five nodal points equally spaced. It will be assumed that the voltage at nodal points is kept constant at 220 kv., that the synchronous condenser

FIG. 40

losses will be neglected and that the generator characteristics will also be neglected.

Figs. 40 and 41 represent the four cases outlined. In Fig. 40 is represented the variation in the net resultant reactive kv-a. injected into the system with variations in loads for a 500-mile line with two nodal points, that is, at the receiver and supply ends. By net reactive kv-a. is meant the algebraic sum of the reactive kv-a. components delivered to the line at each nodal point. Thus in case (1) there will be delivered to the line approximately 150,000 kv-a. lagging, part of this being supplied by the generator and part by the condenser at the receiver end. At any other load the net resultant kv-a. can be read off from the cruve.

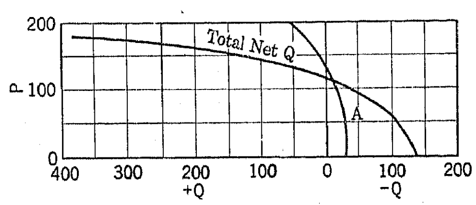

FIG. 41

Curve A, in all cases, refers to the generator characteristics and is actually the circle diagram for the supply end of the system. In Fig. 40 at no load it will be seen that there is nearly 80,000 kv-a. charging current to be supplied by the generator. This reactive kv-a. seriously effects the operation of the system since it tends to over-excite the generators so that the excitation of these machines must be very substantially reduced and this in itself presents a problem of no little difficulty. Reference to Figs. 41, 42 and 43 will show that in general the more nodal points, that is, synchronous condenser stations distributed along the system the less the generator excitation needs to be interfered with. It will be seen from Fig. 43 that with five nodal points the generator power factor differs very little from unity under any condition of load. It follows, therefore, that the best use is made of the generators when a large number of condenser stations are used. In other words, the rating of the generating equipment is higher under these conditions.

A question which is equally important with that of the generator is the amount of synchronous-condenser equipment that must be installed under the various conditions. This represents a capital cost which must be taken into account in the same way

as the cost of the conductors. In general, it might be said that a synchronous condenser placed at any point along such a line is less effective in regulating the voltage than one placed at the receiving end, due to the fact that the inductance between that station and the generator is less than that for the whole line.

The amount of reactive kv-a. supplied at the nodal points has no direct relation to the amount of plant required since leading kv-a. may be supplied at one point and lagging kv-a. at another as is shown in the accompanying tables. It must be pointed out that the total net kv-a. shown in Figs. 41 to 43 gives no indication of the power factor on the system. The curve is of more theoretical interest than practical. Fig. 44 shows this net reactive kv-a. for the four cases considered plotted for different values of kilowatts transmitted. As a matter of interest, it

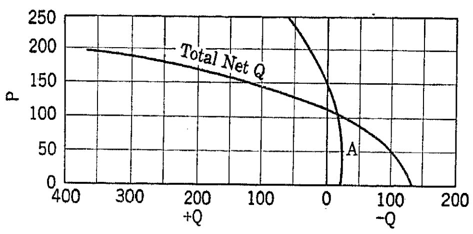

FIG. 42

might be pointed out that the load curve for zero reactive kv-a. represents approximately the conditions mentioned by Mr. Percy H. Thomas on Page 2 of his paper. If resistance were neglected there would be no reactive kv-a. injected into the line for this particular line for this particular load. Although Fig. 40 shows that there is no net reactive kv-a. injected at 125,000 kw. nevertheless Table 1 shows that the generator is actually supplying 24,000 kv-a. and the receiver condenser is drawing 24,000 kv-a. The apparent discrepancy in Fig. 44 from this purely theoretical consideration, is due to several causes among which are; first, the neglect of resistance in the theoretical case; secondly, the rise in voltage along the line in the practical case; and thirdly, possible inaccuracies in calculation as no great accuracy was aimed at in deriving these figures.

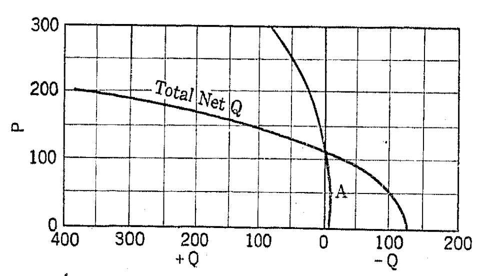

FIG. 43

Tables I to IV show the amount of plant in synchronous condensers required for any particular number of nodal points. In general it might be said that the more nodal points give the greater amount of synchronous-condenser plant required but at the same time the load which may be transmitted over the line is increased. Fig. 45 is a purely theoretical analysis of the four cases considered. The maximum load referred to is the maximum possible load which would be transmitted over the line regardless of any questions of stability. This corresponds to the power limit of the line as originally mentioned by Mr. H. B. Dwight and others some time ago. And in general will be the limiting load of the first section of the line, that is, the generator end. This maximum load has been used to derive the curve showing the ratio between the total net reactive kv-a. and maximum power.

In summarizing the above discussion the following conclusions may be drawn:

1. The effect upon the generator excitation of increasing the number of nodal points in a long transmission line is to increase the stability of the generator at light load and, general to improve the power factor and hence increase the station capacity.

2. An increase in the number of nodal points leads in general to an increase in the synchronous-condenser equipment required.

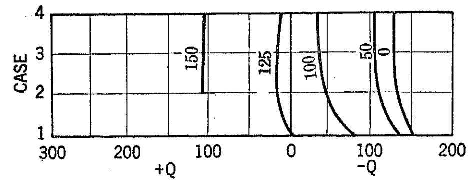

FIG. 44

At the same time the output of the line is materially increased.

I have purposely avoided discussing questions of stability as the characteristics of the load have such a direct bearing on this subject that each particular case must be considered on its merits. It is for this reason that I have chosen transformer banks of 200,000 kv-a., although actual stability limitations would call for transformer banks of approximately half this rating.

I wish to raise one point in connection with part 2 of the paper by Evans and Sels in their discussion of parallel transmission lines. It sometimes happens that two transmission lines of different voltage are working in parallel and it is necessary to determine the line constants for the combined line. This may be done in the following manner. Use one voltage as a reference voltage and determine the line constants, A_1, B_1, C_1 and D_1 of this line and also the line constants A_2, B_2, C_2 and D_2 of the other line. It is necessary now to transfer the second set of constants into new constants referred to the reference voltage. The A constant will remain the same, the B constant must be multiplied by the square of the ratio of the voltages, and the C constant must be multiplied by the reciprocal of that ratio squared, the D constant remaining the same. Equations **18** to **21** may then be applied.

The method of determining the division of load between the lines may be had by reference to Fig. 1 of the paper by C. L. Fortescue and S. C. F. Wagner, since whichever path is followed the voltage vector must turn through the same angle for equal voltage so that by plotting the circle diagram for both lines

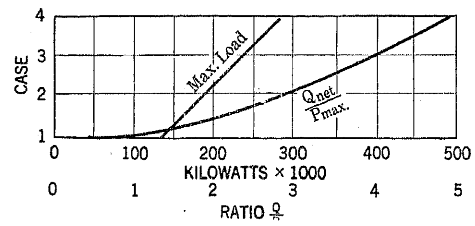

FIG. 45

separately and for the combined lines we can determine the angle θ for any given load on the combined line and by drawing this same angle on the separate line diagram, determine the amount of load on each line.

L. A. Herdt (by letter): I read with great interest the paper by Messrs. Fortescue and Wagner on "Some theoretical consideration of Power Transmission" in the February 1924 issue of the JOURNAL of the A. I. E. E.

I noted (and they are not the only writers that do so) that the term *Synchronous Condenser* is used—Leading and Lagging Condenser Fig. 2. Applied to such machines this term is a misnomer, giving the impression that the chief function of the machine is to supply leading current while this represents but one-half of its use in service. The other and fully as important function is to supply *lagging* current.

The use of the term *Synchronous Reactor* for such machines was suggested by the writer (see the *Electric Journal* September, 1915—Constant Voltage Operation of a High-Voltage Transmission System) in view of the common use of the term reactance as positive to represent inductive reactance and negative to represent condensive reactance.

A synchronous reactor is a machine having the property of reactance positive or negative, that is inductive or condensive.

A. E. Kennelly (by letter): The paper by Mr. Thomas is valuable in presenting the conditions that may be expected to occur during the steady-state, over a power-transmission line of unusual and hitherto unattained length, operated three phase at 220 kilovolts.

On three-phase power-transmission lines of the lengths that have hitherto come into service, the hyperbolic-formula corrections for the effects of distributed capacitance at the fundamental frequency of 60 cycles per second, have been small. In most cases, these corrections might be ignored in first-approximation calculations, and the lines treated on the basis of capacitance placed either in one lump at the middle of the line (for the nominal T), or in two equal lumps at the ends of the line (for the nominal π).

In the case, however, of Mr. Thomas' line, 500 miles long (804.7 km), the nominal π of any one of the three line conductors has an appreciable error at 60 cycles per second, and has to be corrected by some process which takes the uniform distribution of capacitance into account. This is done in the paper by means of the equations at the foot of its third page, and which have been shown by Mr. Thomas in an earlier paper to be suitable for the purpose. An alternative method, preferred by the writer, is to form the equivalent[8] π of one line, such that the electrical behavior of this π, according to Ohm's Law, gives the same voltages, currents and powers at its terminals under the assigned conditions of load, as the actual line with its distributed constants.

In the accompanying Fig. 46, $A\ B\ G\ G$ represents the nominal π of one of the conductors considered in Mr. Thomas' interesting paper. The line has $R = 39.6$ ohms resistance in the conductor, and also $X = 370$ ohms reactance, at the working frequency of 60 cycles per second, assuming that there are no harmonics present in the voltage or in the current. The line leakance is ignored $(G = O)$, and the total dielectric susceptance is taken as $j2.882$ millimhos, divided into two terminal condensers of $j1.441$ millimhos each.

The angle θ of the line is $\sqrt{Z\,Y} = 1.035 \angle 86°.56'.44''$ hyperbolic radians, and the correction factors, by reference to the charts prepared for that purpose,[9] are $0.832 \angle 1°.12'$ for the architrave of the π, and $1.10 \nwarrow 0°.37'$ for each pillar. Applying these factors, we obtain the equivalent π, $A'\ B'\ G'\ G'$ in the lower part of the Fig. 46. The line behaves as though it had 27.0 ohms resistance instead of 39.6, a reduction of 31.8 per

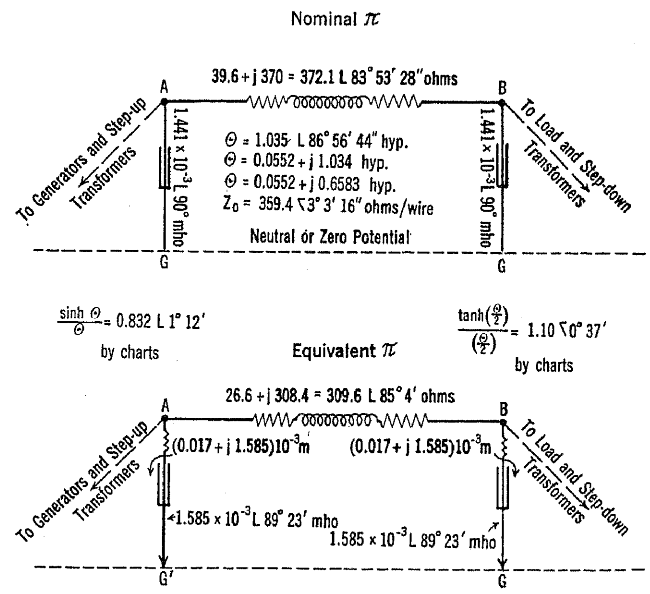

FIG. 46

Nominal and Equivalent π of one of the three-line conductors considered in the Thomas superpower transmission paper:

L = 804.7 km. = 500 mi. $f = 60\sim$ $D = 15.8' = 4.816m$ $d = 0.0278$ m.
r = 0.04921 ω/w. km. = 0.07920 ω/w. mile $R = 39.6$ ω/wire
l = 1.220×10^{-3} h/w. km = 1.963×10^{-3} h/w. mi; $j\,x = j\,0.46$ ω/w. km = $j\,0.74$ ω/w. mi; $j\,x = j\,370$ ω/wire.
L = 0.9815 h/wire; $g = 0$ $G = 0$. $c = 0.950 \times 10^{-8}$ f/w. km. = 1.529×10^{-8} f/w. mi.
C = 7.645×10^{-6} f. $j\,b = 3.581 \times 10^{-6}$ m/w. km. = $j\,5.763 \times 10^{-5}$ n/w. mi. $j\,B = j\,2.882 \times 10^{-3}$ n/wire.

cent, and $j\,312.4$ ohms reactance instead of $j\,370$, a reduction of 15.5 per cent. The effect of distributed capacity upon the π of the line $A\ B\ G\ G$, is to reduce its apparent conductor resistance by nearly one third. The admittance of each pillar is, however, increased ten per cent, to 1.585 millimhos, with a small leak element added of 0.017 millimho. If now the load to neutral be attached at B' and the generator apparatus at A', the equivalent π enables the terminal voltages, currents and

9. "Electrical Characteristics of Transmission Lines" by Wm. Nesbit, Westinghouse El. & Mfg. Co., Publication, Pittsburgh. Feb. 1922.

powers to be determined by the ordinary vector Ohm's law calculation.

It is evident that the hyperbolic correction factors for a line of this length operated at 60 cycles, are by no means negligible.

F. R. Sharpe: The mathematical results found by Fortescue and Wagner may be expressed in the following simple form.

(A) Consider the normals in Fig. 47 drawn at any point P of a parabola to meet the axis in N. A circle with its center at N and of radius $P\,N$ will touch the parabola at P and at the symmetrical point P'. The envelope of all such circles is clearly the parabola. The smallest circle has the radius $2\,p$ and is tangent to the parabola at its vertex V.

If we denote $F\,N$ by h the radius is

$$P\,N = \sqrt{P\,M^2 + M\,N^2} = \sqrt{4\,p\,V\,M + (2\,p)^2} = \sqrt{4\,p\,h}$$

Hence the envelope of the circles

$$(x - h)^2 + y^2 = 4\,p\,h \tag{1}$$

is the parabola $y^2 = 4\,p\,(x + p)$, the origin being the focus F.

In the case of the receiver circles the vectorial form of the equation (1) is

$$R = \frac{P_r + j\,Q\,v}{\alpha - j\,\beta} = E_r^2 - \frac{\gamma - j\,\delta}{\alpha - j\,\beta}\,E_s\,E_{re}{}^{-j\,\theta}$$

$$= E_r^2 - \sqrt{\frac{\gamma^2 + \delta^2}{\alpha^2 + \beta^2}}\,E_s\,E_{re}{}^{-j\,\theta'} \tag{2}$$

where $\theta' = \theta + \theta_1 - \theta_2$

so that $h = E_r^2$ and $4\,p = \dfrac{\gamma^2 + \delta^2}{\alpha^2 + \beta^2}\,E_s^2$

(B) We may also derive the same results by vector differentiation of (2): The vector to a point of intersection Q of (2) with the neighboring circle is given by (2) and by

$$R = (E_r + \delta\,E_r)^2 - \sqrt{4\,p}\,(E_r + \delta\,E_r)\,e^{-j\,(\theta' + \delta\,\theta')}$$

and is therefore determined by the vector equation

$$0 = 2\,E_r\,\delta\,E_r - \sqrt{4\,p}\,\delta\,E_r\,e^{-j\,\theta'} + \sqrt{4\,p}\,E_r\,e^{-j\,\theta'}\,j\,\delta\,\theta'$$

as in the case of ordinary differentiation. Hence taking the real and imaginary parts we have

$$(2\,E_r - \sqrt{4\,p}\cos\theta')\,\delta\,E_r - \sqrt{4\,p}\,E_r\sin\theta'\,\delta\,\theta' = 0$$

and

$$\sin\theta'\,\delta\,E_r - E_r\cos\theta'\,\delta\,\theta' = 0$$

Hence

$$\frac{2\,E_r - \sqrt{4\,p}\cos\theta'}{\sin\theta'} = \frac{\sqrt{4\,p}\sin\theta'}{\cos\theta'}$$

that is

$$E_r\cos\theta' = \sqrt{p}$$

$$E_r = \sqrt{p}\ \mathrm{sec.}\ \theta' \tag{3}$$

Hence the envelope from (2) is

$$R = p\sec^2\theta' - 2\,p\sec\theta'\,e^{-j\,\theta'}$$

$$= p\tan^2\theta' - p + 2\,p\tan\theta'\,j = x + j\,y$$

Hence $y = 2\,p\tan\theta'$; $x = p\tan^2\theta' - p$; or eliminating $\tan\theta'$, $y^2 = 4\,p\,(x + p)$.

(C) The differentiation performed graphically gives at once the result

$$\cos(\theta' + \delta\,\theta') = \frac{\sqrt{4\,p}\,\delta\,E_r}{2\,E_r\,\delta\,E_r} \text{ approximately}$$

because

$$\cos Q\,N'\,N = \frac{Q\,N' - Q\,N}{N\,N'}$$

and taking the limit, as $\delta\,E_r$ and $\delta\,\theta'$ approach 0,

$$\cos\theta' = \frac{\sqrt{4\,p}}{2\,E_r} \text{ as in (3).}$$

F. W. Peek, Jr: All of these papers refer to a specific problem,—the transmission of a large amount of power 500 miles at 220 kilovolts, sixty cycles. It happens that a 500-mile line is not economical unless power of the order of 100,000 kw. per circuit can be delivered over it. This is a rather large amount of power for 500-mile transmission at 220 kv. under the conditions fixed by the problem. Since the load must be increased to the limit for economic reasons the question of stability is an important factor. A higher voltage or lower frequency would permit greater power per circuit without approaching the instability point. The difficulties, therefore, arise to a considerable extent from the fixed conditions of the problems rather than to limitations of high-voltage transmission.

It is not the actual physical length of the line that causes limitations. Limitations are caused by certain factors that depend upon physical length, mainly inductance, but to some extent capacity and resistance. If the inductance is reduced the line has the characteristics of one of short length. Some time ago Mr. Percy Thomas suggested how this might be done by "split conductors." Split conductors are also advantageous from the corona standpoint. At 25 cycles this line would have characteristics similar to present 220-kv. lines 200 miles in length.

In considering the effects of transient load changes on stability it is not only necessary to consider how quickly the generator

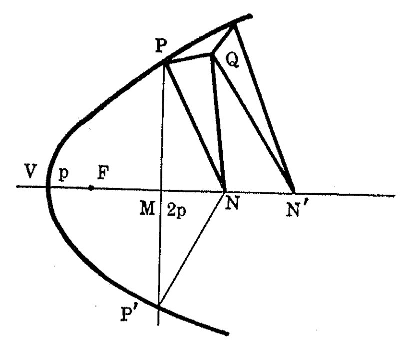

FIG. 47

can respond but also what the increments of load are and how rapidly they can be changed. The size of the system is an important factor.

It is interesting that it is not necessary to discuss insulation limitations. As the transmission voltages and distances of transmission increase the size of apparatus units increases and becomes an important problem. This introduces the question of size of material and difficulties of transporting built-up units.

Chairman Baum: I have been working, as some of you know, with quite a large transmission system for the last twenty-five years. As I say, the stability of that system has been increasing all the time and the last addition of the synchronous condensers has increased the stability so markedly that if you talk to the operators, they will tell you right away how easy it is to operate and how difficult it is to shake that system apart.

I don't think the load transients should apply to your regulation, back to include your generator reactance.

I think Mr. Thomas is too pessimistic about his system, but the only criticism I would make is this: he thinks the switching is difficult. Therefore, he eliminates the high-tension switching. As a matter of fact, the high-tension switching has been of no trouble on our system, and is one of the most satisfactory thing-we have. We laid down the rule twenty years ago that the highs tension switching must be the same as low-tension switching, and I don't believe you can have a successful transmission system without that condition being fulfilled.

If you put that condition down, that you must have switching in and out, no matter what the time of day or what the conditions are, then you must have that line cut up into sections, you can't help that, and that means of course adding some cost. People say the cost of condensers and the cost of switching is

too great. When you get through, the cost per kilowatt transmitted is the real thing you are after, and the cost per kilowatt at two hundred twenty thousand is about one-half the cost per kilo watt at one hundred ten thousand and that is the real answer to your transmission problem.

R. C. Bergvall: Our papers show a method of determining the maximum amount of power which can be transmitted with a load gradually applied. Mr. Moreland has incorrectly inferred that we propose to *rate* a transmission system as being capable of carrying this amount of power under normal operating conditions. The maximum amount of power which can be transmitted under steady state conditions can only be used as a basis for forming an engineering judgment as to the amount of power which should be transmitted over a given system. The point at which a transmission line should be worked will depend on local factors such as continuity of service requirements, a discussion of these factors being obviously outside of the scope of this paper.

During transient conditions there are so many variables, which would have to be taken into account, including the action of machine governors, which has not been considered by Mr. Moreland, that the reliability of any transient mathematical analysis is open to a great deal of question. The analysis carried out by Mr. Moreland and his associates which show that the *rate of change of load* instead of the amount of suddenly applied load is the important factor, is not borne out by practical operating experience or by our tests. There are numerous cases of two transmission lines operating in parallel where a 100 per cent increase in load results on one of the lines whenever the second line is tripped out and pull-out does not result. In one case where the load thus added to the second line approached the maximum power limit, the system occasionally pulled out of step after two or three seconds, thus indicating that the process is a slow one.

Mr. Moreland has stated that the loads in our tests were gradually applied, basing his conclusion on the oscillogram shown by Fig. 18. This oscillogram does not refer to the suddenly applied load tests as may be ascertained by reading the test data. This oscillogram shows the pull out taking place as the load is *gradually* increased. The suddenly applied load tests were made by intermittently shunting out a portion of the resistance used as load. The inductance of the armature of the direct-current generator of the motor-generator set is very low as compared to the resistance in the load so that the resulting time constant is negligible. Calculations taking into account the inertia of the motor-generator set show that the load variation would be applied to the system in from 1/20 to 1/10 of a second. The results of this test do not agree with the conclusions arrived at by Mr. Moreland and his associates, as to the effect of suddenly applied loads.

The amount of load which can be suddenly applied without causing pull-out to occur can be approximately determined by considering that the synchronous machine excitation remains constant, due to the inductance of its field, resulting in a drop in the receiver voltage. As an example, refer to Fig. 5 in our paper. Assume that the line is carrying 80,000 kw. at 100 per cent voltage, which corresponds to a synchronous condenser excitation of 155 amperes. If the load is suddenly increased to 87,500 kw. and the excitation of the synchronous condenser remains constant, the voltage would drop to point *D* or 58 per cent voltage, resulting in pull out. Mr. Moreland assumes that we would continue out at 100 per cent voltage and could therefore, stand a swing to 107,000 kw. instead of 87,500 kw. without pull out taking place.

The assumption of constant synchronous condenser excitation is, if anything, pessimistic because the armature reactance during transient conditions is in such a direction as to assist the synchronous condenser voltage regulator in increasing the field current. Mr. Evans, in his discussion of Mr. Thomas' paper, presented our ideas of a method for determining the rating of a transmission line and the results are in substantial agreement with those of the other speakers, whereas Mr. Moreland's discussion would make it appear that our results would be widely different from theirs.

Our calculations were based on a constant voltage at the generator end of the line as stated in the paper. This, of course, would only be approached for a very large generating station as compared to the transmission line connected to it. The generator used in our tests was somewhat larger than the maximum load of our transmission line and our tests indicate that for this condition the effect of generator synchronous reactance was small. However, in most practical cases it will be necessary to take into account the generator synchronous-reactance by merely adding it to the reactance of the line and considering the internal voltage of the generator instead of the supply voltage of the transmission line. Our method of calculation may readily be extended to meet such condition.

R. D. Evans: Mr. Thomas, in his paper on "Superpower Transmission" has sought to fix a rating of a 500-mile transmission line. Mr. Thomas states that the maximum permissible load on the line is 143,000 kw., and he proposes to operate the

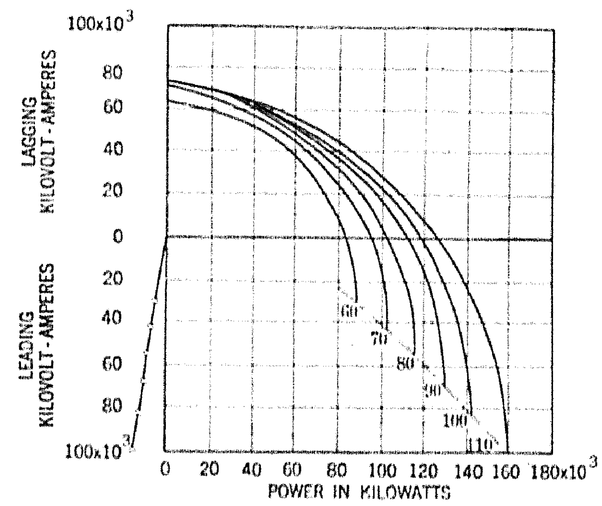

Fig. 48—Circle Diagram for 500-Mile Transmission Line

line at 120,000 kw. continuously when one of the transmission lines is out of service. We do not find that Mr. Thomas made any allowance for the characteristics of synchronous condensers and load which would reduce the maximum permissible output of the line to an amount not exceeding 100,000 kw., and, in our opinion, this amount should be considerably lower to allow a reasonable factor of safety.

We have made calculations, taking into account the characteristics of the synchronous condenser and load, using the transmission line, synchronous-condenser capacity, et cetera, as given in Mr. Thomas' paper. The performance of the transmission line is shown in the circle diagram given in Fig. 4, Condition *A* of Mr. Thomas' paper. A family of power circles derived therefrom is reproduced in Fig. 48. The synchronous-condenser capacity is based on 75,000 kv-a. in condensers per line with spares, the condensers having equal leading and lagging kv-a. range. Under emergency conditions, with one transmission line out of service, the condenser capacity per circuit with all the spare units in operation, amounts to 125,000 kv-a. per line, as indicated in Mr. Thomas' Fig. 5.

Mr. Thomas assumes the power factor of the load as 85 per cent. The characteristics of the load for changes in voltage are not indicated, but a reasonable assumption would be that 70 per cent of the load consists of rotating machines of essentially

constant power characteristics. The remainder of the load is assumed as a lighting or resistance load which varies approximately as the square of the voltage. It has been assumed that the reactive kv-a. of the load remains substantially constant, independent of the voltage. Referring to Fig. 49 the curves in solid lines show how the reactive kv-a. required by the line varies with voltage for loads corresponding to the amounts indicated, at 100 per cent voltage; that is, these curves take into account the decrease in power due to the decrease in resistance load with lower voltage. The dotted-line curves show how the reactive kv-a. of the load and synchronous condensers varies with voltage at various constant condenser field excitations. The line *A B* is the locus of points of tangency between the two families of curves. The system will pull out of step when the conditions of operation fall below the line *A B*.

In the actual operation of transmission lines, even in large systems, there are inevitably many sudden fluctuations of load due to short circuits and switching operations either on the main lines or on auxiliary lines or systems tied in therewith. When the load on a transmission line is suddenly increased, the inertia of the rotating apparatus will momentarily supply part of the

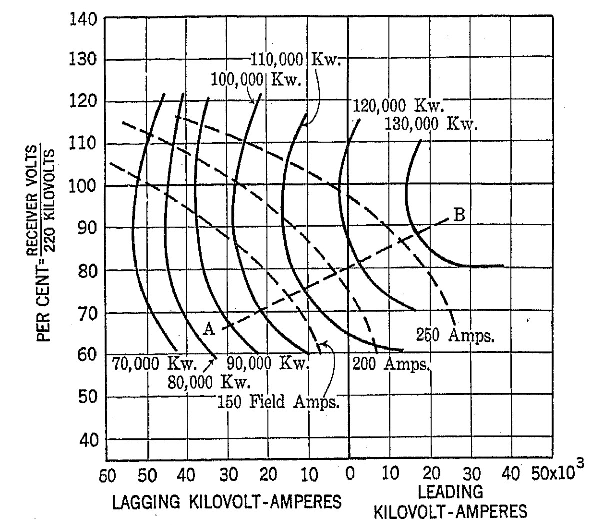

FIG. 49—500-MILE TRANSMISSION LINE WITH 125,000-KV-A. IN SYNCHRONOUS CONDENSERS

additional load requirements. Even allowing for the load increment momentarily taken by the rotating apparatus, a 15 per cent sudden increase in power which the line must supply is a small alowance to make for sudden increase of load due to loss of a transmission line or other disturbing condition. Applying this test to the curves shown in the Fig. 49, it will be noted that if the transmission line is operated at a load of about 101,000 kw., corresponding to a condenser excitation of 200 amperes, pull-out will occur with about 15 per cent increase of load.

Mr. Thomas has tacitly assumed that the line is stable up to the maximum power capacity of 143,000 kw. He has taken no account of the characteristics of the load and synchronous condensers, or of the fact that the machine excitation will not be varied as rapidly as the load can change.

The above analysis indicates a maximum permissible load of 100,000 kw. beyond which there is no certainty of securing stable operation and which must be reduced to allow for the necessary margin of safety. Assuming a 20 per cent margin, the capacity of the line would be reduced to about 80,000 kw.

It is to be pointed out that assumptions have been made which are favorable to the transmission of a large amount of power. For example, our calculations of the transmission-line constants for the particular conductor described by Mr. Thomas show a power limit of approximately 10 per cent below that stated by him and assumed in the preceding discussion. The condenser capacity assumed is very liberal, taking all the spare units in operation. The assumption that 30 per cent of the total load is lighting and resistance load varying with the square of the voltage is also liberal. Mr. Baum's survey shows that lighting load constitutes about 15 per cent of the total. The effect of generator characteristics in limiting the power output of the line has been neglected. The final assumption made in the preceding discussion was the amount of increase in load that should be provided for. The value selected appears quite small when it is pointed out that with three lines in service, the loss of one transmission line would increase the load on the remaining circuits about 50 per cent.

Our analysis indicates that it is impossible to give a rating to the circuit of 120,000 kw. for continuous operation under emergency condition with one line out of service. In our opinion, the maximum permissible amount of power would be of the order of 70,000 to 80,000 kw.

The importance of a consideration of the characteristics of the synchronous condenser and load is emphasized by the fact that the transmission line in Mr. Thomas' paper should not be expected to carry more than about 80,000 kw.

E. B. Shand: My paper on the subject of the maximum output of transmission systems has been the result of a study made several years ago on the principles of stability of synchronous generators both under the condition of constant excitation, and also when the terminal voltage is maintained constant by means of a vibrating regulator. This study gave rise to the distinctions of inherent and artificial stability as defined in the paper. No thought of applying these principles to transmission systems had occurred to me until the proposal of F. G. Baum in 1921 to use synchronous condensers to regulate the voltage at intermediate points of lines suggested itself as permitting a broad extension of the same principles.

On account of the absence of any experimental data regarding the relative speeds of regulator action and of inertia changes in regulated machines, the writer considered it probable that the maximum steady load with a vibrating regulator would be somewhat in excess of the limit determined by inherent conditions; but on account of sudden load increases, where it was appreciated that the regulator action would be too sluggish, he proposed the maximum load as determined by the excitation values of the machines preceding the load increase as the criterion of stability, that is, inherent condition of stability.

With this conception of the problem in mind, he evolved a method for the determination of the limitation of inherent stability of a system utilizing the actual characteristics of the synchronous condenser and of the load. As far as his information extends he believes that this was something entirely new in the study of transmission systems.

At the close of this work the writer came in contact with the power-circle diagram as developed by Messrs. Evans, Sels and Fortescue, and an actual system was investigated using this as a basis. Further study, however, convinced him that the voltage vector diagrams expressed the conditions of stability with greater significance so that this type of diagram was used in the presentation of the paper.

The tests described in the paper of Messrs. Evans and Bergvall, which were made some time later, were of special interest from the writer's standpoint, for they demonstrated definitely that with the vibrating regulator as now developed and with the relative magnitudes of machine inertia as used on the tests, the possible range of artificial stability was negligible. It has been noted that the criterion of stability had already been proposed on the basis of inherent stability, therefore, the result of these tests laid additional emphasis on the importance of this limitation. The co-operated endeavors of the authors of the various transmission papers, both before and after these tests,

cleared up many other questions regarding the operation of transmission systems and their limitations. This is believed to be evident from the papers themselves.

Some of the above discussion, although somewhat recapitulatory, has been included particularly with respect to the discussion by a number of the members,—Messrs. Moreland, Booth, Bush, Doherty, etc., regarding the steady-state stability and surge stability. From additional and more careful reading of this discussion, it seems that a part of their criticism at least is due to a misapprehension or perhaps a mis-application of the data given in the papers. Although the papers referred to take no definite account of transient effects such as inertia, etc., in their calculations, the writer most certainly agrees that in the case of a sudden increase of load the limit of stability will depend mainly on the excitation values of the machines considered prior to the increase of load and not the values required to maintain the proper voltage after the increase. The writer had never comprehended that this point was in question.

Referring now particularly to my own paper, the sole question discussed was that of maximum output, and neither (a) the maximum permissible load, nor (b) the maximum rated load

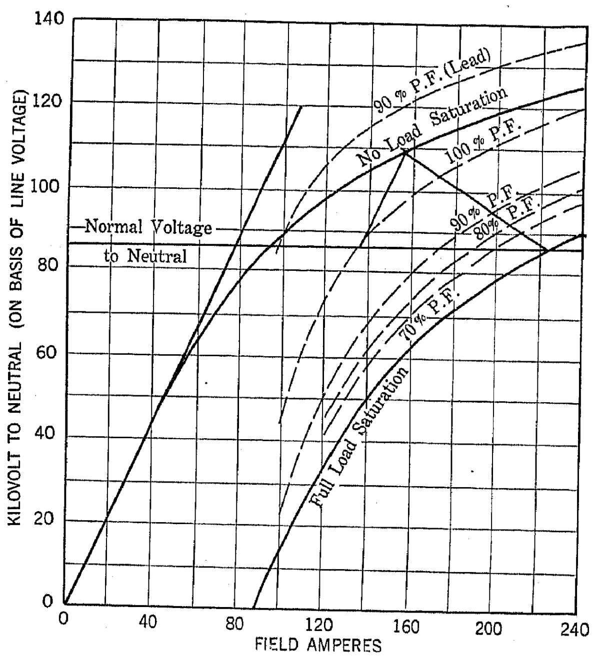

FIG. 50—CHARACTERISTIC CURVES OF AN A-C. GENERATOR CONNECTED TO A TRANSMISSION LINE

was considered, the purpose of the paper being rather to explain the one phenomenon discussed. The results of examples serve, therefore, as criteria of design, that is, they represent a definite limitation determined by the system itself and not by a combination of variable conditions of operation. The rated capacity on the other hand, is a quantity which may be chosen to give satisfactory results over a more or less restricted range which represents a balance between capital cost and reliability. It may be pointed out, therefore, that a single margin, or factor of safety, might be as judicially chosen as the amount of sudden load increase to be used in determining a new limitation to which a new factor of safety must be added to obtain either a safe maximum load or the rated capacity. Of the two methods of procedure above outlined the writer prefers the former, although to determine a suitable margin it has been his practise to determine the maximum limit of stability under reduced excitation, for instance, that corresponding to normal load on the line, which will, it is believed, check roughly with the methods referred to in the discussion. Fig. 10 of my paper represents the method referred to for the special case of maximum excitation on the synchronous condensers. It will be observed that pull-out occurs at reduced voltages.

Messrs. Moreland and Bush have strongly recommended the inclusion of inertia and field transient effects in calculations. Until these gentlemen have given us the details of their methods it is impossible to discuss them fully. While it would undoubtedly be desirable to include these factors, the writer feels that these members have over-estimated the importance of these factors, and under-estimated the difficulties of accurately taking them into account, particularly in the case of the more complicated types of systems.

Mr. Doherty has censured the writer for his neglect of the effect of generator reactance in the examples of his paper and I have already admitted culpability in the matter. It is only fair to state, however, that if Mr. Doherty had continued his quotation from my paper it would have been evident that the matter was not passed entirely by. Since the presentation of the paper,

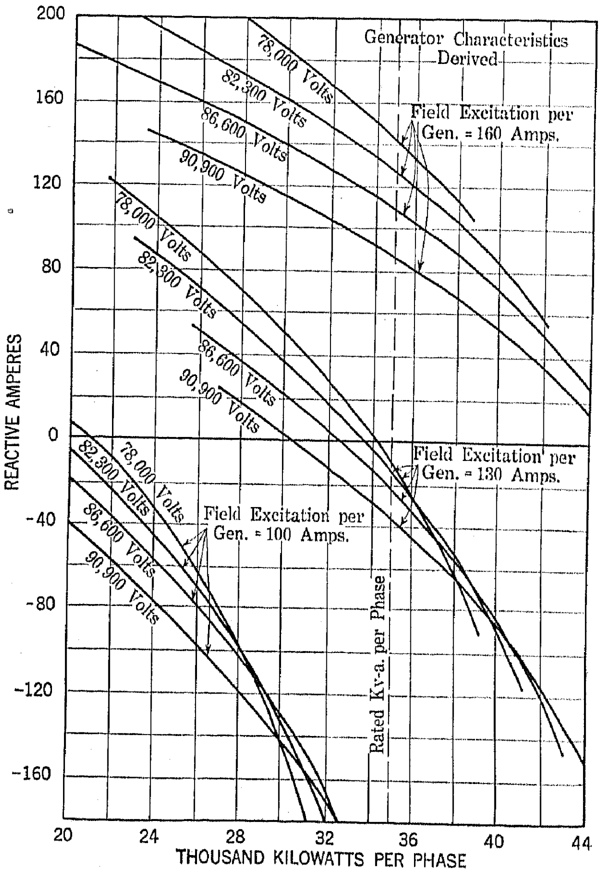

FIG. 51

however, I have extended the diagrams to which he referred, to include the effect of generator reactance. This was accomplished by the first of the two methods referred to in my paper, because the second will prove inaccurate unless great care is used in the choice of synchronous impedance to represent a given machine.

Fig. 50 represents in the conventional manner, the electrical characteristics of the generators considered. The total full-load rating of all the generators combined was assumed to be 35,000 k-va. per phase or 105,000 k-va. total. Fig. 51 gives these same characteristics replotted in accordance with the conventions used in the paper. Three separate values of field excitation are represented. The characteristics of the same compound line of Fig. 12 of my paper, represented by Fig. 52 are derived from an extension of the general method employed for compound transmission lines. All condensers are assumed to be operating under maximum excitation, which is constant regardless of the

voltage conditions at the various points regulated. As a matter of fact, the voltage at the mid-point comes out slightly above normal value which tends to increase the effect of generator impedance slightly. It also causes the generator excitation to be somewhat less than it would otherwise be.

The superposition of the generator characteristics on those of

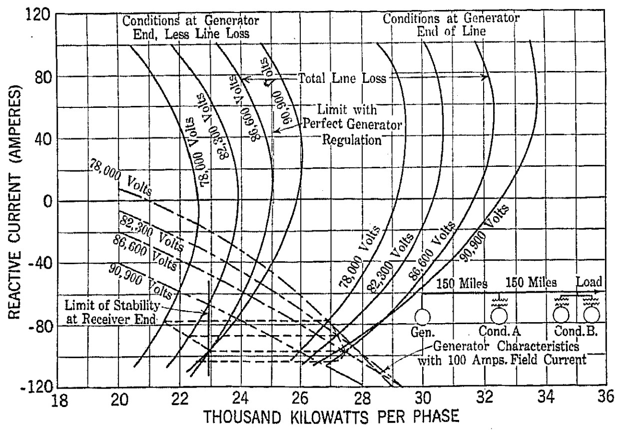

FIG. 52

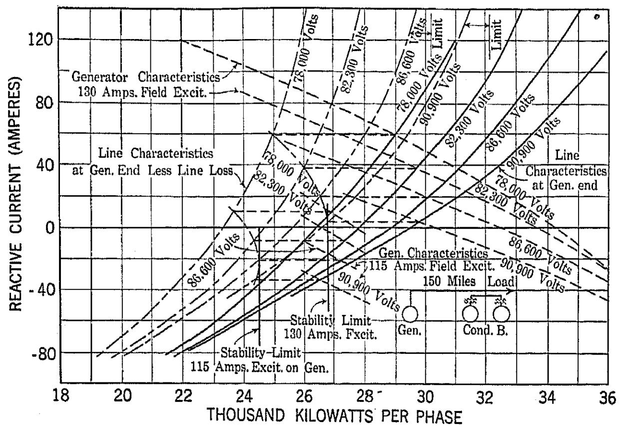

FIG. 53

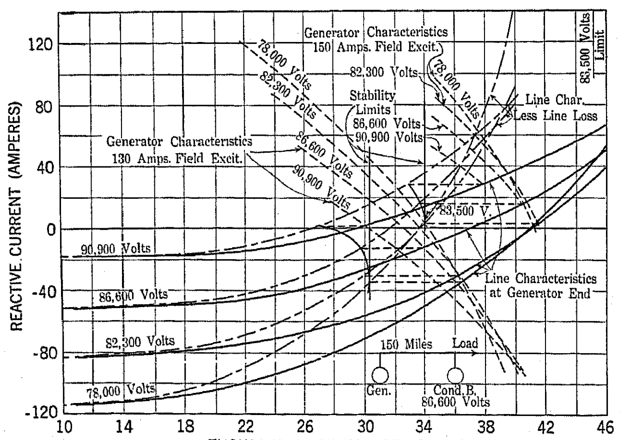

FIG. 54

the line allows the operating condition of the combination to be determined. With a generator field of 100 amperes, the point of maximum output at the receiver end occurs at approximately 86,600 volts at the generator terminals. The load value itself is 22,900 kw. per phase with a power input of 27,400 kw. per phase. The corresponding output with perfect generator regulation is 25,050 kw. which is the same value as that given in the paper. The effect of the generator impedance in this case is a reduction of output of 2150 kw. per phase or by 8.5 per cent. Considering that the generators are underloaded, this value will be slightly smaller than what might normally be expected, but in any event the effect should not be greater than 10 per cent.

Fig. 53 has been plotted to indicate the corresponding effect on a simple line of one half the length of that used above, the rated condenser capacity at the receiver end being 50,000 kv-a. as before. In this case the generator impedance reduces the maximum output from 30,200 kw. to 24,500 kw. which is a reduction of 19 per cent.

A third case, Fig. 54, assumes the conditions to be the same as in the last case except that the receiver end is perfectly regulated. The effect of generator impedance will then be approximately 33 per cent.

This successive increase in the effect of generator impedance is quite to be expected as each change is equivalent to a reduction in line impedance while the generator impedance remains practically constant.

The general conclusion from this investigation is that for transmission lines of the length of those considered in the papers and discussion the effect of generator impedance should be of the general magnitude of 10 per cent reduction of output and that this will naturally increase as the line is reduced in length.

Mr. Terman has brought up in his discussion a point of technicality regarding the conventions in plotting power-circle diagrams. While this is perhaps of minor importance it may be noted that Figs. 14 and 15 in the appendix of my paper comply with his suggestions.

C. L. Fortescue: I thought I had read my own paper over very carefully, but it appears from the remarks made by Mr. Moreland and Mr. Booth and Dr. Bush that I haven't. However, in rebuttal of their accusations I want to point out that it is an entirely different thing to make a hypothetical load in a paper as a basis for comparison and to advocate it as a proper rating.

Now, Mr. Moreland intimates that we advocated a certain rating which was an impractical rating on a transmission line. We have not done so. We have merely taken a hypothetical rating to form a basis of comparison between two different systems: one, a system of 500 miles straightaway, and the other one, 500 miles in length loaded at a middle point. That is quite an appropriate thing to do.

As regards the question of rating, I have always taken this point of view: I say, let's figure up the stability under the worst possible conditions and call these emergency conditions. Let's take a good margin of safety and then under normal operating conditions we shall be good and safe. That is the position I take.

Now, I am an optimist, and I saw a passage in a recent book by Havelock Ellis, in which he says, "The nice balance between optimism and pessimism is the best thing." I think Mr. Moreland and his associates have gone to the other extreme. They are indulging in a great deal of pessimism. They have done a lot of work and hard digging, but it is all theoretical work, and they haven't shown the way they obtained their results. They have shown us a number of curves but how did they get these curves? I hope that Mr. Moreland and his associates will sometime tell us how these curves were obtained.

We, as an actual matter of fact, made tests on a system that imitated on a small scale a 500-mile straightaway line; also a 500-mile line loaded at its middle point, and with this system we had ordinary generators of fair size. We took generators of approximately 500-kw. capacity which at that time we considered would give a fair basis of comparison with those used on large transmission lines.

Now, we supposed it fair to assume that the inertia conditions in those generators and synchronous condensers and also their

synchronous reactance were about on the same scale as these quantities for the generators and synchronous reactors used on an actual 500-mile, 220-kv. line. Under the test conditions we were able to throw off and on blocks of power, 25 per cent of the maximum power which was obtained over that line without throwing the synchronous condensers out of step. These are actual results. I feel a whole lot more optimistic about the problem than Mr. Moreland and his associates.

As regards Mr. Doherty's discussion, I think he has given us a splendid one. He has pointed out that there are other factors that enter into the problem which should be considered. I tried to present the fact that while we, so as to simplify the problem, used the usual convention of ignoring certain factors that we considered did not enter into the problem sufficiently to affect the results, properly speaking, we should have also considered these factors. In other words, I think it is important to get as complete a solution of the problem as possible, and as I pointed out, by the analytical method you can go as far as you please, provided you have sufficient perseverance.

Professor Karapetoff says that the doctors do not agree. He is wrong. The doctors do agree. The only point of difference is the extent to which we should consider all the factors that enter into this problem.

I don't disagree with Mr. Doherty and Mr. Summerhayes in the essentials of the problem. I think we ought to take all the factors into account. We ought to take them into account to see how much they influence the problem, and we shall do so as soon as we can get time.

Percy H. Thomas: All the papers except the first, and most of the discussion treat of the conditions of theoretical stability of a hypothetical *single-circuit* transmission line of *extraordinary length* taken as the *sole supply of power* for a system of distribution containing a mixed load such as is supplied by the usual public utility system.

All are agreed that such a line is capable of carrying certain large blocks of power with 220 kv. maintained at each end, provided the power factor of the passing power at each end has a suitable value. This value of power factor will be different for each value of power transmitted and the line will not transmit this amount of power with the 220 kv. at each end at any other power factor. There is no difference of opinion about this.

Now the line itself has no control over the power factor of the load which it is expected to carry, so that some means must be provided to keep the power factor of the load at the right value for the particular load passing at the moment. Furthermore, the generator must be able to accept the load at 220 kv. at the power factor at which it is brought to the generator by the line.

If either of these conditions is not met, the particular required amount of power will not be transmitted. This power of adjusting the power factor to the proper value to suit the momentary conditions is naturally the function of synchronous apparatus, the generator at one end and a synchronous condenser or another generator at the other end, which *tends* to accomplish this result automatically. So the ability of the system as a whole to carry the load depends directly on the performance of the generator and the synchronous condensers.

Now it so happens that the designers of such apparatus have for sometime been doing their best to build machines that will deliver a minimum amount of arc kv-a. on short circuit, relying on automatic voltage regulators to maintain voltage with varying load. This tendency in design is emphasized since it makes a cheaper machine. But this characteristic of a small short-circuit current is directly opposed to the ability of a generator or condenser to control power factor as required by the *long line.* Furthermore, the action of voltage regulators in readjusting voltages of the machines is too slow (as these systems now operate) to satisfy the line requirements and a second or two of hyatus occurs. Naturally, therefore, when the authors of the papers attempted to determine the performance of the long-line system as a whole, using the electrical performance of commercial machines designed to limit short circuit, the latter were found to be inadequate so that the system as a whole would refuse to transmit the full amount of power expected, at least until regulators had time to act.

These principles and methods of analysis and mathematical and graphical treatment therefore have been beautifully and thoroughly worked out in these papers and have been materially extended by the discussion. The report of tests on a model system is an addition of great value. But after all, the importance of the limitation developed in the transmission system may easily be over emphasized, and wrong impression is perhaps created by the unqualified statements frequently here made that the capacity of a 500-mile line is only so and so much, with or without the midpoint condenser station, etc. In such statements the qualification should have been added, that it is assumed that present commercial designs of machines developed for another service are used, and that a single circuit, or its equivalent is used, without other means of connecting the supply with the load network. These limitations are of the greatest importance as will be seen in a moment.

Returning now to my own paper, I would like to point out that the object of this paper was to cover in a broad way all the pertinent characteristics of an isolated 500-mile transmission feeding an extended network, taken as a whole. In such a broad consideration it would not be feasible to discuss *in detail* all the new features of design, of which there are many, besides the performance of synchronous apparatus.

In studying this subject I soon discovered the weakness of a single-circuit, heavily loaded long transmission line, which is vulnerable not only when supplied with inadequate condensers but also when *for any reason* the voltage at either one or both ends falls seriously. It will do no good to have a perfect condenser if a short circuit on the line will cause the voltage to drop and the load to be lost and the generator thus be left light-loaded to pull out of step. A broader remedy than a perfect condenser is required.

The layout described in my paper and shown as a one-line diagram in Fig. 5, is proposed as one scheme which is not subject to the limitations of the machines brought out in the papers, at least to anything like the same extent as a single circuit and which further provides for many other likely contingencies not considered by the others,—and naturally so, as they would be outside the scope of their papers. I am sorry that no consideration seems to have been given to the method of meeting the situation that I have proposed. Mr. Goodwin has rightly stated that the great detail in the connection to the network at the receiving end of the line shown in Fig. 5, is introduced because it is an essential part of the layout as a whole.

The features of the layout which give it relative immunity to the effects of limited condensers and accidental voltage disturbances are the following:

1st—Each circuit, of which there are four, with its transformers is an independent unit, electrically speaking, and electrically connected to a separate part of the general network, so that a short on one circuit will not cause a serious drop of voltage on the others and hence will not prevent them from carrying their normal load and a certain amount of overload, for a very considerable margin of overload is allowed in the system of my paper. This overload capacity together with the generators in the *receiving network* will be able to do the duty of the affected line.

2nd—After all, the effect of a drop in voltage or of an increase in load which are taken as fatal to synchronism in the limited single-circuit transmission considered in the other papers, unless very severe, is not to cause the circuit to drop all the load from the affected line, but perhaps to drop 10 or 15 or 20 per cent of the load, which can easily be taken up by the other circuits in Fig. 5, provided they all stay in synchronism.

3rd—If we assume large generating capacity in the network, this will go far to relieve the transmission line of its burdens. For example, suppose a big generator or two drops out in the network throwing an additional load on the rest of the system, which is the worst case that is assumed. This will not primarily cause a great drop in voltage per se (if unaccompanied by a short circuit) and the added load will be taken up by the other network generators. It is sufficient in preserving synchronism for the transmission line to carry the same load as before. In any case, any showing down of the system as a whole, will be slow on account of the very small excess load and the large flywheel effect and the voltage regulators will have time to act to restore any drop in voltage.

4th—The condensers of Fig. 5 cannot fall out of step readily because they are all on the same bus bar—similarly with the auxiliary bus at the generator station. This keeps all generators in synchronous operation through any disturbance on any one line.

5th—Four generators or four condensers are available to support any one circuit in case of need, instead of only one condenser per circuit as is considered for single-circuit operation.

Finally, it may be pointed out that much may be expected from efforts to design machines to give a favorable performance for *long-line service.* A comparatively small improvement in the behavior of the machines will greatly better the performance of the system and largely eliminate the machines as a limitation.

I would like to say that I entirely agree with much that Mr. Silver says to the effect that in most actual situations, long transmissions without intermediate stations will not occur, but in this paper I have set myself this particular problem—I have considered the broad network in a second paper, presented at the Birmingham Convention entitled "New Type of High-Tenion Network." In this Birmingham paper I have made free use of high-tension switching.

With regard to high-tension switching, the essential thing in the layout of Fig. 5, is not the elimination of high-tension breakers so much as keeping the high-tension circuits electrically independent. Until some other means is shown of meeting high-tension short circuits without loss of synchronism, this high-tension separation stands as the most feasible proposal for a *heavily loaded isolated long line.*

Mr. Moreland, Mr. Booth and Mr. Bush have greatly emphasized what might be called the pendulum effect of the revolving parts of machines resulting from sudden changes in load. It is certainly true that the effects of such action must be considered. As these gentlemen do not tell by what method their curves are derived, no intelligent analysis of them can be made. If they are based on theoretically perfect pendulum action it is not likely that they represent the actual practical case on a large scale. If they take into account all the pertinent factors in the case, I do not see how they can have any general application, since these factors will vary greatly in different cases and are many of them subject to design.

They state that I have ignored such pendulum-action transients in my paper, but I would point out that this subject is treated on page 13 and in Fig. 6. It is true that it is not gone into at great length, but the system of my Fig. 5 is such as to largely eliminate any noticeable effect from this phenomenon.

I will close with calling attention to the fact that all the limitations of condensers, generators and pendulum action are of an exceedingly transient nature perhaps of the order of one or two seconds and that all that would be required to eliminate their effect is to speed up the automatic voltage regulator and exciter system to meet the actual speed of change in phase position of rotors, sufficiently so that machines do not have time to pull out of step. This is by no means a hopeless remedy. In this I assume that no sudden increases of load can occur in any big system able to cause more than a very moderate per cent increase of the load on any one generator, when divided pro rata over the system.

H. K. Sels: In regard to Mr. Goodwin's comments on our reference to the articles brought out in the *Electrical Journal* some time ago, our reference is not made to bring in the loss diagram in our present paper but merely the matter of general calculations of power diagrams. The two statements that he brings up were, first, the application of the mathematical solution for purposes of checking the power diagram and second, the "losses neglected" in the loss diagram. The point that we meant to bring out in the first statement was that analytical methods would only be applied when the scale on the power diagram came out, say, 5000 kw. in dealing with loads of 10,000 kw. In this case you would have to go to analytical methods to determine what you were doing. As none of the examples we have ever selected come in this class, we have never shown a parallel mathematical solution but considered the diagram sufficiently accurate. In regard to the loss diagram there are no losses neglected in the derivation of the loss formula or diagram. What we did have in mind when we said "the losses neglected when using the general circuit constants are practically constant," were the ordinary assumptions every transmission engineer makes for transformer exciting current, line leakage or corona losses. In other words one rarely includes these factors in a practical problem and furthermore being practically constant, "the most economical point of operating the line can be determined from the diagram" without including them.

Mr. Goodwin also refers to Equation 26 as being imaginary. He will see when he multiplies out the vector quantities, he gets another j term which makes a j^2 or -1, giving the m term a real value.

In regard to the remarks of Mr. Moreland, Mr. Booth and Mr. Bush on throwing sudden loads on lines producing heavy transient conditions, I wonder where that sudden load will come from. About the only way that you will get it would be to have one line drop out due to short circuit and the others assume that sudden load. It would never be obtained in the normal load curve of a system.

I want to agree heartily with Mr. Silver's remarks on high-tension switches. That is, these super-power systems are going to grow by connecting up nearby load centers, which may be done before you connect these to some outside power supply, so that you again come back to short sections. That means that sudden loads on long lines will not be obtained when these short sections drop out.

In regard to the statements of Mr. Moreland and Mr. Peek about getting increased power limits by raising the voltage, I want to point out that raising the voltage does not change the general shape of what we call the voltage power surface. When we use up the additional power that an increase in voltage gives us, we still have the problem of the general shape of this voltage power surface.

In regard to Mr. Worcester's remarks on the 25-cycle system with frequency changers as against the 60-cycle system, I might say that calculations made on 350-mile lines show them about equal, and I would suspect that his conclusions of slight reduction in cost would be correct for a 500-mile line.

H. K. Sels (Communicated after adjournment): In the discussion of the 750-mile line, Fig. 8 of our paper is sufficient proof that "the receiver must operate at lagging power factor." Mr Goodwin's statement that this is at variance with the 500-mile line is correct, but the comparison is wrong and no statement was made that the 500-mile line did not operate at leading power factor. A comparison of the independent diagrams for 500 miles shows them to be in entire accord with each other.

Mr. Terman raised the question of how the power diagram should be plotted. Apparently we are in agreement on this point

as the derivation of the power equation is on the basis that the following quantities represent lagging power factor.

$R + j\,x$ for impedance
$I_1 - j\,I_2$ " current
$P + j\,Q$ " power

which gives:

$$\frac{Q}{E} = - I_{-2}$$

Therefore, dividing the power equation by E_R^2 gives a current equation where lagging current is plotted lagging, yet lagging power is plotted leading.

Fundamentally, there is no basis for plotting power quantities and voltage and current quantities on the same diagram so that if mathematics rule the case, they should be plotted according to our analysis or if customary convention rules, lagging quantities should be plotted lagging. Our position at this time is to have everyone recognize this distinction so that the Standards Committee can define the plotting of power quantities according to the proper rule acceptable to everyone.

Considerable discussion has centered about the amount of power that can be transmitted 250 and 500 miles. All of this shows remarkable agreement in results and as Mr. Doherty points out in giving his figures, any differences are largely a matter of the conditions assumed. Some of these, I believe, are over-conservative and therefore some of the limitations are a matter of personal opinion. With all conditions considered, I am confident that given the problem to transmit 150,000 kw. per circuit 500 miles we will do it with equipment now commercially available if it is economical to do so at all.

Messrs. Hanker, Fortescue, Wagner, Evans, Bergvall and Shand (communicated after adjournment): The discussions which have been presented on these papers on "Power Transmission" have been very interesting and important. Due to the number and length of the discussions, it will not be possible to comment fully on the individual discussions. The papers were presented as a group, and a general reply will be made jointly by the several authors and supplemented by answers to questions raised on individual papers.

The discussions by Mr. Moreland, Mr. Booth and Dr. Bush will be considered first. Mr. Moreland, in connection with the Canadian power development, is concerned with the problem of determining the highest permissible loading of the transmission line under consideration. He apparently has confused this problem with the related one presented in the group of papers, namely, that of determining the maximum load that could be carried on a given transmission system with definite assumptions as to voltage, line and load characteristics. This attitude is particularly surprising to us in view of the visit to East Pittsburgh by one of his associates to secure information on stability, at which time we presented our methods of calculation and test data and pointed out that the maximum load was considerably in excess of the probable rating of a line. Furthermore, at that time we discussed the effects of electrical and mechanical transients of rotating machines and also we fully appreciated that the complete solution of the stability problem could not be obtained until all of these effects had been evaluated.

The maximum load on a transmission system must necessarily be obtained under steady state conditions, that is, by increasing the load in negligibly small increments. A definite method of solving this problem is presented in the group of papers. The complete solution to the problem of determining the highest permissible load of a transmission system from the standpoint of stability, was not given in the papers, because the problem is extremely complicated and the type of solution will vary with individual cases. The problem is complicated because the solution depends upon transients produced by changes in voltage, excitation, relative angular position of rotating parts, and governor and regulator characteristics. In the very nature of things, a simple solution cannot be obtained, and therefore, no attempt at this time was made to present a complete solution of the problem which Mr. Moreland infers was the object of the papers. The object was to present a general discussion supplemented by actual test data on stability because, in our opinion, the importance of transmission stability was not generally recognized.

The authors, however, did not avoid the problem of determing the permissible loading in view of the transient characteristics, but have indicated a method of calculation and submitted the results of tests. This method for analyzing transient conditions is based on the application of a suitably chosen static stability criterion. This static condition is determined by assuming:

(1) That the changes in the fields of synchronous machines produced by changed load or circuit conditions have been completed, and,

(2) That the machine excitations have not been changed. The static stability limit is easy to determine and has been proven both analytically and experimentally, as developed in the papers.

Mr. Moreland criticized the papers because static stability methods were employed to investigate transient stability, but he failed to read the papers to see how this static stability method was applied by the authors. To illustrate, Mr. Moreland submits a chart, Fig. 1, and implies that the methods given by the authors would indicate that for the conditions assumed, the load could be increased from 100,000 kw. to 190,000 kw., without loss of stability. The authors' method would have given the permissible increase as 38,000 kw. Mr. Booth and Dr. Bush in their discussion give the permissible load for this condition as being more than 40,000 kw., and less than 50,000 kw.

It appears, therefore, that the methods employed by Mr. Moreland and his associates and those employed by the authors give closely the same results, though their methods are based on "transient stability analysis," whereas the method employed by the authors is based on a static stability criterion. Consequently in analyzing Mr. Moreland's discussion, there can be found no support for his contention that the conclusions drawn by the authors are invalid, because of the methods employed to investigate the transient conditions.

Dr. Bush has presented a number of curves giving the results of computations of stability conditions for sudden increases in load. The method that takes into account accurately all the transients involved for changed load conditions (including prime mover governor, not mentioned by Dr. Bush) must necessarily be very complicated and require many assumptions. In the verbal discussion, Mr. Fortescue requested Dr. Bush to submit the basis for his calculations, which has not been given. Consequently, judgment of the value of Dr. Bush's method must be reserved until such time as adequate explanations are made.

It is perhaps desirable to point out some of the reasons why a static stability criterion should give good results for the transient conditions. This method in effect gives the limit toward which the analysis of the transient conditions must approach. Mr. Moreland apparently believes that the static stability method will fail because of the suddenness of changes introduced by switching operations. It is to be pointed out that part of the momentary demands are supplied by the reduction in kinetic energy of the load, condensers and generators at supply and receiver. Furthermore, for loads less than the static stability limit, there are many forces which tend to oppose the forces that would cause the system to pull apart. These forces include the kinetic energy of rotating masses, the transients in the exciter circuits, and the operation of regulators and exciters. During the transient condition, the flux in the main machines does not change instantly, and thus produces in effect an appreciable increase in the leading kv-a. available to hold the system in step. All these actions tend to prevent the instantaneous pulling out of step due to changed circuit or load conditions. It has been

observed on long distance transmission lines where instability occurs that the action of pulling out of step is a relatively slow process, requiring several seconds. The method of static stability analysis used by the authors therefore appears to have a reasonable basis, in assuming that flux in the main machines has been entirely changed in accordance with the new load or circuit conditions; and is pessimistic in assuming that the regulator and exciter systems have not had opporunity to act.

Mr. Booth's discussion on the intermediate synchronous condenser station is pertinent. In particular, he criticises the basis for considering the effectiveness of the intermediate condenser as presented in some of the papers, because the coincident variation in receiver and mid-point potentials is not considered. He feels that the assumptions made do not correspond with the usual operating condition. We do not understand that Mr. Booth questions the calculations submitted on the assumptions stated. Mr. Booth's point is pertinent, and if he had studied Mr. Shand's paper, he would have found that the particular point he raised was investigated at considerable length.

Mr. Booth's discussion leads to a conclusion with which the authors, however, must thoroughly disagree, namely, that the addition of an intermediate condenser station does not increase both the theoretical maximum output and the permissible output for various operating conditions. The calculations given in Mr. Shand's paper for the intermediate condenser stations show an important increase in the maximum load. The tests made in the shop prove very definitely that under favorable conditions, very large increases in the maximum load of a system can be obtained by the addition of an intermediate condenser station. In order to obtain stability, it is necessary, in general, to maintain the voltage adequately. In order to compensate for reduced voltage, the synchronous apparatus connected to the system should be of such design that a reduced voltage will cause an appreciable decrease in the lagging kv-a. or an appreciable increase in the leading kv-a. delivered. Mr. Booth's discussion, however, does bring out this fact that if the intermediate condenser station is of small capacity or high impedance, the increased output may not be important. This difficulty may be avoided by using synchronous condenser of larger capacity and of lower synchronous impedance.

The discussions by Messrs. Summerhayes, Doherty and Worcester and Miss Clarke are very interesting and important, particularly the discussion by Mr. Doherty. The importance of considering generator characteristics was recognized by the authors, but Mr. Doherty is justified in criticising the omission of calculations and data presenting figures on the effect of generator characteristics. His discussion was very clear and convincing, and in a sense rounds out the presentation of the subject by the authors.

The effect of generator characteristics, while important and at all times requiring consideration, is not nearly so great in limiting the power output as one might expect from the comparison of machine synchronous reactance with the reactance of the transmission line. This is due to the fact that the characteristics of the generator are considerably different from that of the line. With a decrease in voltage, a generator will supply an increased amount of reactive power, whereas a transmission line at reduced voltage requires an increased amount of reactive power due to both the increase of the $X\ I_2$ of the line for constant power, and to the decreased charging kv-a. Mr. Shand has carried out his calculations for the problem considered in this paper, and has found that the genertor characteristics limit the maximum output about 8 per cent. The tests given in the Evans and Bergvall paper show that the effect of generator characteristics for the particular system tested had a negligible effect in limiting the output because the test results checked very closely with calculations neglecting generator effects.

The simplified expressions for l, m, and n given in the discussion by Frederick E. Terman are similar to expressions used by one of the authors for some time. He has found them very convenient in studies involving the line alone. Mr. Terman also raises the question as to the correct manner of plotting leading and lagging kv-a. Following the analytical treatment given on page one of the paper by Fortescue and Wagner, one must logically arrive at the method of plotting employed. The basis for the equation:

$$P_s + j\ Q_s = \breve{E}_s\ \hat{I}_s$$

is given in a paper by Mr. Foretscue on "The Measurement of Power in Polyphase Circuits" presented at the Midwinter Convention in 1923. By reference to this paper it can be seen that this method of plotting has a firm analytical basis.

We have read C. A. Nichol's discussion with a great deal of interest. The manner of including the effect of the generator in limiting the power is relatively simple when the constant value of synchronous reactance is used. In work which we have done subsequent to the writing of the papers we have found that it is not sufficiently accurate to use the so-called "synchronous reactance." We have preferred rather to use more accurate regulation charts for the generators and have evolved an approximate method of taking the generator characteristics into consideration, which are quite accurate.

The kinematic device for imitating the performance of long transmission lines which Professor V. Karapetoff is constructing at Cornell University, like his other devices, will undoubtedly prove to be highly instructive. While delighting in the use of mathematics, Professor Karapetoff derives still greater pleasure in demonstrating a phenomena in an entirely unmathematical manner. It would be highly entertaining to see a surge applied to one point of a line and observe its propagation along the line.

Mr. Longbottom has presented an interesting study of effect of the number of intermediate synchronous condenser stations on the performance of a transmission line. His figures show very clearly that under heavy load conditions the total exciting kv-a. required of all the synchronous machines is reduced when the number of condenser stations is increased.

E. B. Shand (Communicated after adjournment): In connection with the theory of transmission systems, there are one or two points I would like to amplify. First, in the paper by Messrs. Fortescue and Wagner, a mathematical analysis is given of the envelope of a certain family of power circles, while in the paper of Messrs. Evans and Sels, the same envelope is referred to as defining one type of power limit. The relation of this envelope to the system may be conceived in somewhat the following way.

When power is transmitted over a reactive circuit, such as a transmission line, the receiver voltage being controlled by varying the reactive current in the circuit, the ordinary relation is that a decrease of receiver voltage is accompanied by a decrease of reactive current (a leading current with respect to the line being considered positive). If the assumption be made that the load is independent of voltage, the power component of current must become greater at an increasing rate as the voltage is lowered, so that a point is eventually reached where the increasing reactive effect of the load current neutralizes the natural tendency for the magnetizing requirements to drop with voltage. For each value of constant power load there will be a value of receiver voltage at which the magnetizing requirements at the receiver end will be a minimum. Letting I_0 represent the magnetizing current at the receiving end, and Q the corresponding kv-a., two critical points may be expressed mathematically as follows:

$$\text{(a)} \quad \frac{S\ I_0}{S\ E_r} = 0 \text{ (For constant power)}$$

$$\text{(b)} \quad \frac{S\ (I_0 \times E_r)}{S\ E_r} = \frac{S\ \ Q}{S\ E_r} = 0 \text{ (For constant power)}$$

The envelope referred to is the locus of the condition represented by (b).

The above expressions represent the actual power limitations for two very special conditions of load and of regulating apparatus. Equation (b), represents the limit where the load has the characteristics of constant power, and zero or constant reactive kv-a. irrespective of voltage. The condenser would also have to deliver constant kv-a. irrespective of voltage. Equation (a) represents a similar condition, except that the reactive current characteristics are constant, rather than the reactive kv-a.

The assumption of a load of constant power and constant reactive kv-a. may often be approximated in actual practise, but the conditions for the regulating apparatus will differ considerably from this assumption. If a static condenser be considered, the reactive current will increase with the voltage, and the kv-a. with the square of the voltage. For a synchronous condenser, the current will increase with a drop in voltage, and within the operating range the reactive kv-a. will also increase as the voltage drops. With a load of the assumed characteristics and a synchronous condenser, the "envelope limit" would be slightly conservative.

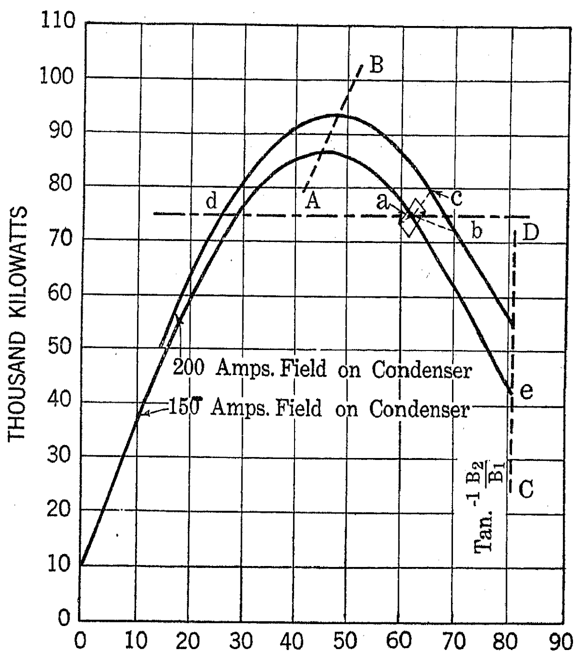

Fig. 55

When compound lines are considered, the reactive kv-a., required by the second section at the mid-point, may be expected to increase rapidly with a decrease of voltage and may more than neutralize the characteristics of the synchronous condenser. Therefore, the kv-a. available for the first section of the line may decrease with the voltage. This is illustrated by the 300-mile compound line, discussed in my paper. The "envelope limit" of this line is approximately 108,000 kw. From Fig. 11 of my paper the actual limit of output, with a size of condenser economically justified, would not be greater than 80,000 or 90,000 kw.

In the paper of Messrs. Evans and Bergvall it is mentioned that in making tests with a line purely of resistance, hunting was observable with practically normal excitation on the terminal condenser and without load on the line. The tendency to hunt, moreover, increased with the excitation. This is logical. A line without reactance becomes equivalent to a d-c. circuit and power can be transmitted only by a drop in voltage and not by a difference of phase angle. Therefore, by increasing the condenser excitation, the receiver voltage would approach the sending voltage, at which value it would be impossible to transmit any power except for the stabilizing effect of the condenser impedance. In this case the latter was comparatively small. These extreme line characteristics are not found in practise, although trouble is occasionally experienced on short high-resistance lines with over-excited synchronous motors at the end.

One further point in the paper of Messrs. Evans and Bergvall, will probably admit additional explanation. In referring to Fig. 5 of this paper the authors state: "If it were possible to get beyond the point of tangency between the two families of curves, an increase in synchronous-condenser excitation would actually decrease the receiver voltage," and further that the cumulative action of the regulator and reduction of voltage would eventually produce pull-out. According to the hypothesis made, *i. e.*, that the operation between the limiting lines A B and C D be stable, the above conclusions are perfectly correct, as may be deduced from the curves; the statement, however, without further analysis conflicts with the conclusions of my own paper regarding the condition of artificial stability, which, although not of great practical importance, is of interest on account of the principle involved.

Neglecting other phenomena which may be taking place concurrently, an increase in the field current of the condenser furnishes additional magnetization to the connected circuit and will increase its voltage. Also, an increase of field-current will increase the amount of power tending to flow over the line, rather than increase the tendency of the line to fall out of step. An exception to this latter statement will occur in a line of high relative resistance, that is, when the operating voltage is lower than the critical voltage $\frac{E_s}{2\,M\,B}$ This is very unusual.

These relations are probably more clearly seen in Fig. 55 in which the data of Figs. 4 and 5 of Messrs. Evans and Bergvall's paper, has been plotted on the basis of phase angles. The lines A B and C D correspond to similar lines in Fig. 5. The zone between these two lines represents the conditions under consideration.

Assuming a load of 75,000 kw. with a field excitation of 150 amperes, and at the point a the system will tend to drift out of step at e as is indicated by the slope of the curve of constant excitation. If the field is being increased so that its effect with respect to change of phase angle may be represented by the line a b, the power available will from that point be less than the requirement, and although pull-out will be retarded somewhat it will not be prevented. The voltage will also be higher than if the field had not been increased. If the rate of field increase were sufficiently rapid to be represented by the line a c, the power available would be greater than the load requirements and the masses would accelerate, stability finally being reached at the point d, which is on the stable slope of the curve.

From this discussion, it is apparent that the action of an automatic regulator in the zone considered will depend upon its resultant speed with respect to changes of angular displacement of the condenser rotor. With this being sufficiently great, the action of the regulator at the point a might be represented by the closed polygon about a, the rotor and the receiver voltage being kept in constant oscillation. This is the condition of artificial stability referred to in my paper.

Fortieth Anniversary Celebration of the A.I.E.E.

Addresses in Philadelphia by Three Charter Members with a Résumé of Electrical Engineering Progress

The 40th anniversary of the Institute was fittingly celebrated during the Philadelphia Midwinter Convention at a meeting held Monday evening, February 4th, at which President Harris J. Ryan presided. Addresses were delivered by Elmer A. Sperry, T. Commerford Martin and Elihu Thomson, all charter members, and by John J. Carty, past-president of the Institute.

President Ryan presided, and in opening the meeting said:

"The hour is one in which we all rejoice to have come to Philadelphia because it was the home city of the first American electrician, the man of whom we all know, and who enabled us to understand very clearly and for the first time in this world what is lightning. From what he did for us in that way, we have had many an inspiration of the most valuable sort to carry us forward to know many of the other things and what they are and why they are.

"Through all this came the inspiration on the part of a group of men forty years ago to give us this, our American Institute of Electrical Engineers. We have assembled to do honor to those men tonight, to remember the beautiful and valuable organization that they gave us through their vision and their enthusiasm as young men. We are glad to know and to be together to rejoice over the considerable number that have lived through the entire generation, the lifetime, the time of one generation of active business at all events.

"The first man I am going to call up who joined with others to give us our Institute in 1884 is the youngest charter member who had at this same time to come the greatest distance for the organization meeting. He came all the way from Chicago to New York. Mr. Elmer A. Sperry."

Address of Mr. Sperry

I feel that the Institute is very young; it is really the youngest member of our technical bodies. You remember the Civils were formed in '52; then the Miners came along some time in '77; then the Mechanicals were organized about 1880, and then this body came into existence in 1884.

These things, of course, don't happen by themselves. The pioneer is doubly in his own way, always having a hard time when he starts, or he imagines he does, then when he comes along later to tell how it did all happen to happen, he gets in the way again, and the youngsters with the forward look and on their toes as the members of this Institute always have been, say, "Well, make it brief." So I will try to make my part of it brief.

There were two groups that had their young enthusiasm and were willing to make some sacrifice to see if we could not have an American Institute of Electrical Engineers. In the Western Group—I was living in Chicago—we had about eight people. Our keynote was that England had had the Institution of Electrical Engineers some four or five years. They had had, it is true, that marvelous body, the Society of Civil Engineers, but we in America had matched that in 1852, as I stated before, but they were definitely ahead of us, and it was a going concern, and the papers that they heard and the scientific matter that they put forth at that time were an envy to us all here. In the Western group we felt as though something should be done. We cast about and found that there was an equally enthusiastic group in the East, but we in the West were all young fellows.

In the East it was quite different. We found a man who was then forty-six years old, who was really the leader, and do you know that we have the great and unusual honor of having him here tonight? It was due to Nathaniel S. Keith, sitting yonder, that the matter was thoroughly stirred up in the East, and finally a petition was circulated, which never got West, by the way, containing the names of those who were willing and anxious to see such a society formed.

That body got together on April 15th in the rooms of the Civils. I have one or two pictures which I have had taken showing how that building looks today and about how it looked when we went up the steps that night, May 13, just one month later.

The meeting in April succeeded in getting ten more names on this list of "Come, let us have one," and the time of the inaugural meeting was then settled upon as the next month, Tuesday, May 13, and then we felt as though we had in sight our Institute, our dream. There were five of us in Chicago who purposed to attend the New York meeting. Two dropped out and finally two more, and it was wished on me to come down and do my part in swinging my arms and seeing to it that the Institute was put on the map.

So I came, arriving in New York as I remember, at ten o'clock in the morning and proceeding directly to

the Astor Library and working there all day. I don't suppose any of you know that the Astor Library never had any artificial illumination. The British museum had found that the products of gas lights ruined the books, so they couldn't have gas, and Edison was confined to the downtown quarters at that time, so they had no artificial illumination and I was turned out at early candle light and proceeded to the rooms of the Civils, away uptown, 127 East 23d Street, to attend the inaugural meeting.

Getting my dinner early in that way, I happened to be about the first, if not the very first, to arrive in the rooms. As I remember, I waited quite a little time and the second man to appear was Dr. Keith, who had come to see his child born. I complained to Dr. Keith, and so far as I can remember, asked him how it came about that his people down here in the effete East talked so much and did so little.

He calmed me down and told me to wait, that the people in the East possibly would be a little late, but they would be right there, which they were. Some forty of us finally gathered there in the rooms.

One little incident in the first meeting was that we had Mr. Edison there, and that was a long time before we knew it was impossible to get him to speak. So T. Commerford Martin, and some of the others concocted a scheme to head him off from going upstairs, and we would rush him from below, and when he got halfway up, we would all cry, "Speech." That was before we knew he would rather climb under the table, which he did at the World's Electrical Congress at Chicago in '93, rather than make a speech. But we totally failed to elicit anything but a bow from Thomas A., although he was the greatest electrician of the time. That was the word that was used, as I will quote presently, and you will notice how different our nomenclature is at the present time from what it was then.

He had not long previous to that time sold to the telegraphic interests his quadruplex and it was noised around that he had received four hundred thousand dollars for it, and that was a stupendous urge to the young imagination. He was himself a young man at that time, as of course, you know.

To indicate the relative importance of factors of electrical activity of the time, I only have to say that we elected Norvin Green as our first President. He was the President of the Western Union Telegraph Company. That was one of the most important factors of electrical engineering then, and a cross-section of the activities of the time indicates that the telegraph had been achieving rapid progress by doing the unheard of thing at that time of getting four messages over a single line at once. Dr. Jewett of the Western Electric Company, here present, would smile at this from the present-day standpoint as his company are now putting a great many telephone and telegraph messages simultaneously over one wire.

In those years the membership was to be as follows: (this is from the *Electrical Review*). Matters in the electrical field were extremely active in those years and history was in the making. Here were three live journals reporting this meeting. The description of who could become members and who could not is rather amusing.

"Members are those who may justly be called electricians because of professional employment and general recognition as such. All others are to be associate members, persons who are connected with electrical matters directly or indirectly, but not ranked as electricians. Thus the president of an electrical company might or might not be entitled to full membership, but there would be no question of the professional electrician, employed by such a company."

Our light at that time was nearly all arc lights. Edison, just a year and a half before in September, had set into operation the Pearl Street Station, and divided electricity, which our English savants said couldn't be done, but he just used horse sense. He said, "The gas mains go down the street and are tapped for individual residences. Let's do the same thing with electricity," and he did it. He put it over, and that is one of the reasons we are here tonight, because the scheme was so wonderfully successful. He had started the Edison Company then only shortly before. The Brush Electric Company was our oldest company, dealing entirely with arc-lights. Streets were illuminated and municipal companies had been formed, but just a little before that time there had been a junction formed between our redoubtable Elihu Thomson, whom you will hear later tonight, and the great C. A. Coffin, whose dream was the General Electric Company. Few people live to see their dreams come into full fruition as Dr. Thomson and Mr. Coffin have. All honor to them both!

It was about this time that Edison saw fit to curtail the great long legs of his generator and find that spindling legs were out of style, that they could be shorter and plumper and still do the same work, and have a higher efficiency.

But Edison in those days refused to have anything to do with alternating current. He rather spurned the idea that a great system could be induced to change its mind as to the impressed potential direction, especially as frequently as one hundred twentieth of a second. The facts are that in those days we had frequencies much higher than this. It was left to Elihu Thomson and others to bring their mathematical conception and intuition to bear and determine, "Yes, we will make the whole network change its mind every one hundred and twentieth of a second, because by so doing we can make marvelous gains in the territory served by a given distribution."

It was the initiation and bringing forward of the alternating current system that was one of the elements of the great expansion of the Thomson-Houston Com-

pany. I was working in Chicago and gradually had acquired my share of the trade in arc lighting in the West. We had a number of cities, Sperry towns we called them, but later the spread of the alternating current gave us hard competition with its ability to distribute much smaller light units.

The Hochhausen Company was in operation at this time and Edward Weston's Company also. When I reached Chicago I found one plant of the Weston operating in the old Palmer House. The Brush Company had been in the field just previous to the others and they had a number of towns both in the East and West lighted by arcs. Soon the Vanderpool Company and others came forward with systems.

One of the great troubles that we immediately discovered when we commenced to put in arc illumination with these municipal plants in the towns, was the terrific interference with the telephone. The telephones in those times, as you remember, were one wire with common ground. Nobody was making any money. They were poor, struggling concerns in little and big towns, as was our own company, and to think of having two wires for one conversation at that time was impossible. It was less than a year until a convention was called together of all the arc-light producers in America, to see what on earth we could do to get rid of the very great interference with the telephone company.

The town council would make us put our poles on one side, and the telephone people theirs on the other side of the street, and yet whenever we started our plants, and especially when the Thomson-Houston Company with its sinful three coils came in, the induction was something fierce and every telephone went bad.

We claimed that the telephone wasn't much good anyhow as it couldn't be used when it stormed nor over any long distance in any event, and they on their side claimed that our lights hissed and were too strong and didn't amount to anything either. There we were.

At the time of this convention, which was the actual formation of the National Electric Light Association, (allow me a word; I told this tonight at dinner, but it is really worth repeating), an envoy from the great Theodore N. Vail rose up in the meeting and said, "I represent Mr. Vail of Boston. He sent his regrets that he couldn't be present in person."

Then he took out of his pocket a little document which showed the greatness of Theodore N. Vail even at that early date. The document went on to say, "It is a thing that we will overcome, this interference of the service one with the other. All we have to do is be patient with one another. Be patient and you will find us ready to do everything we can to help the cause along."

Think of the beautiful cooperative spirit! There is in this room, and is to speak from this platform, the boy that solved that problem within that year, General J. J. Carty. He found such wonderful effects by using two wires for one conversation without ground return that it spread like wildfire. Before the year was over, our telephone companies, though poor, adopted the system and our troubles were over. So it was the telephone company after all that did it. We swung our arms and found much fault, but did very little, and it was through the wonderful initiative of Vail and his great organization that that thing was straightened out.

Now, it is a strange thing that this last winter the meeting of our own Society had as its keynote the very self-same thing, telephonic interference by power lines, and the cycle seems to be about forty years. I should like to be on earth and know what comes around forty years hence. I have made up these remarks from my memory of the impressions I was receiving in those early times when this Society was in the process of formation. I thank you.

Mr. Sperry then showed several views of the first home and the first secretary of the Institute.

President Ryan: The next speaker, who on the occasion referred to by Mr. Sperry could not induce Mr. Edison to speak, did succeed in making him speak. We members of the American Institute of Electrical Engineers as it exists today, have all a great inheritance from him. He did a wonderful work in the early days of the Institute in helping the organization to get down to a plan of running its meetings, conducting discussions, in reporting the same, and in broadcasting the results of these activities. He is one of the Past Presidents of the Institute, one of the early Presidents, Mr. T. Commerford Martin.

Address of Mr. Martin

Fortunately it is not like deciphering palimpsests to get down to the fundamental data concerning the early history of the American Institute of Electrical Engineers. The inmost rings of its growth are still very close to the bark. While not extant in lavish profusion, the printed record may still be found on many library shelves, and stray beams of human memory still flicker over the archives.

The creation of the Institute coincided happily with two other notable occurrences in electrical development on this Continent. It was a corollary of both; while all three events may be definitely traced and attributed to that ancient splendid exemplar of scientific leadership, the Institute so well named after out great pioneer, the Immortal Franklin. Dating from the Centennial Exposition of 1876 with its memorable exhibits such as the Bell telephone, the Edison telegraphic inventions, and the Wallace-Farmer arcs, there had followed a period of electrotechnical advance unparalleled before or since. The Franklin Institute in 1883—with the same prescience that has just led it to bring over J. J. Thomson to lecture on the electron—felt that the times were highly propitious for the First American

Electrical Exhibition, to excell those of London and Paris. The Franklin Institute might well have waited for the full decade after 1876 to elapse; but it is not in the nature of Philadelphia to wait when it wants anything whole heartedly. Moreover, the British Association for the Advancement of Science was meeting in Montreal in 1884 and would bring a whole swarm of European scientists and physicists across the Atlantic. These could be lured Southward from Canada to the projected Electrical Congress the same year, timed to synchronize with the Exhibition; while they would not easily retrace their steps later, if the opportunity to enroll them were pretermitted for a year or more.

Hence, with two such compelling factors as to 1884, the Exhibition and the Congress, it was indeed, inevitable that the foundation of the A. I. E. E. should occur in that year. Possibly there was some propaganda traceable to Philadelphia and the Institute, but it was, if so, wholly desirable and necessary, everybody felt, that not only to greet fraternally the visitors from abroad, but for the sake of the art itself, there should now be a national electrical engineering society, before any time was lost. Crystallizing with energy and enthusiasm, all the ideas and impulses finding vague indefinite expression, Dr. Nathaniel S. Keith published in April, 1884, his memorable circular reprinted on the very first page of Vol. I of the Transactions of that year. That circular, prepared and issued by himself and colleagues, among whom the present writer is proud to be included, was submitted to the leaders in the electrical field in various parts of the country, with separate name sheets that could afterwards be assembled and thus permitted simultaneous canvassing even in quarters that in those highly-strung days were avowedly hostile and antagonistic to each other, but all of which recognized the common need of a central technical authority without bias. It was convincing also to be able to point to the American Society of Civil Engineers founded in 1852; the American Institute of Mining Engineers, in 1871; the American Society of Mechanical Engineers, in 1880, "which have been so prosperous and of such great advantage to their members." Besides that, none of these bodies made any provisions for "electricals" as such, and even if Sir William Thomson said that "electricals" were "nine-tenths mechanical," that would perhaps not always be true; and it needed more than that to thwart the sound normal American instinct to organize another Society whenever a decent chance offers.

All went well. The Roster lists were carried upstairs and downstairs and into the magnate's chamber, and failed not once of the signature sought. Advice and help came freely from the Franklin Institute, never out of touch, and at last on a dirty, miserably wet night, Tuesday, April 15, 1884, the first meeting was held for organization, with an excellent attendance. Preliminary work had been done carefully, and the stage was quickly set for Tuesday, May 13, when the Committee on Organization reported not only a complete slate of proposed officers, but a brief Constitution. Both were unanimously adopted and can be found fully set forth in Volume I of the A. I. E. E. TRANSACTIONS now an exceedingly scarce document, but still available bound up usually with the three subsequent Volumes. The first Constitution, admirably brief, was adequate for the times. It has been frequently enlarged and modified, but Constitutional amendments are not always and wholly admirable.

The rendezvous for all those meetings in 1884 and others, for a year or two later, was the stately old home of the Civil Engineers, 127 East 23rd Street, where its courteous and efficient Secretary John Bogart, later State Engineer and consulting engineer for Niagara Power development extended a most cordial welcome. Then and later, until the splendid gift of Dr. Carnegie came and the United Engineering Building was erected on West 39th Street, the various Societies occupied others like it—fine old typical New York dwellings. Indeed, for the Electricals, a serious effort was soon put forth to secure the charming old home of Morse on West Twenty-second street, just off Fifth Avenue; and to make it possible, the writer offered to occupy with his family one or two of its upper floors for a rental that would guarantee the investment. But negotiations with the owners, the Bourne family, fell through on the score of price. The Twenty-third street region was then at a high crest of values, and was marked for commercial devastation. The Civil Engineer rooms were, moreover, admirable for their purposes, and there were no strings to the welcome except an injunction from Bogart to keep down the gas bills—talk after 11 wasn't worth it.

The Institute was fortunate in its first President, Dr. Norvin Green, a towering, swarthy Southerner, who had long before ridden the circuits as a rural doctor with pills and plasters in his saddle bags, and who out of the ruck of provincial presidencies of subordinate telegraph companies had lifted himself to well won supremacy as head of the Western Union Telegraph Company, with headquarters in New York. He was leadership personified, and out of scant leisure, he gave the best that was in him to the affairs of the tiny Institute, in whose opportunity, necessity and mission he had a profound belief. He was always available for Executive and other Committee meetings, with prompt suggestions for diplomatic and practical disposal of problems. But he was much more than a formal President. His warm Southern blood, like his sympathies, ran swiftly, and he loved to temper debate with anecdote. Pat to the occasion or incident, rollicking good stories would come in delightful succession from their endless store of a born raconteur; and even if it was maybe "at long interval," his board meetings might well be compared with those of Lincoln and his cabinet. It was, indeed, easy for Dr. Green to set an example on attendance, for he lived in cosy apartments quite nearby,

where hospitality was more than the proffer of a dry cracker.

Equally fortunate was the Institute in its first Secretary, Dr. Nathaniel S. Keith, who still lives, unquenched, and can tell his own story, but who deserves the tribute of his colleague and successor. A master of his own mining profession, he was a skilled and accomplished electrical engineer, which then meant more than plain electrician. He was studiously familiar with foreign electrical literature, from which he translated one of the first and one of the best German treatises on dynamo electric machinery, an art then obscure and occult. He was a brilliant technical journalist, and entirely competent in the politic arts and graces of secretaryship. All he lacked just then was the gift of continuity, for no sooner had he seen his hopes and ideals realized in the foundation of the Institution than he went to the furthest West, to stay for years, to grow up with it and electricity, and become the first American to build any kind of electrical machinery on the Pacific Coast. He left as a timid successor and probationer the present writer, his equal only in faith as to that future of the A. I. E. E. which they had forecast with buoyant optimism.

Other honored names might well be mentioned here and dwelt on, of those who at the very start gave their highest endeavor to the fostering and upbuilding of the Institute—in Philadelphia, Carl Hering, E. J. Houston, W. D. Marks; in New York, C. O. Mailloux, Joseph Wetzler, "Steve" Field, nephew of Cyrus, Francis Jones, George Hamilton—in the East, Thomas D. Lockwood; in the West, Elmer T. Sperry—but it must suffice to signalize Franklin L. Pope, the second President, and a Vice-President for 1874-5. Not long before, he and Edison together had in telegraphic journals announced themselves to the world as "electrical engineers;" and diligent search has failed to encover any earlier attribution of that honored title for the new profession and the new practitioner for whose legitimate working spheres no limits have ever yet been found in the electrical era *now* beginning. Pope's brief Presidential valedictory, in May 1887, was characteristic of his broad outlook, and not less typical of his simplicity and modesty in omitting any reference to the highly useful work he had done as organizer and administrator. A scholar and student, author of technical textbooks, he came from that wonderful group of well-trained, well equipped telegraphers whose scientific class room was the noisy- key-clattering office of a commercial company but had there learned the secrets whose mastery carried them to leadership in all our later fields of marvellous electrical achievement. Ponderous in movement, slow in speech, deliberate in action, pontifical in dignity, Pope was far more the conventional Englishman than he was the born Yankee—until some cause like the Institute moved him to unsuspected depths, and he became transfigured with the vision glorious. Never was the chair of the Institute more worthily filled by an "electrical engineer" than by him who first, in unwitting prophecy, gave himself the accolade of that appelation.

Reference has been made to the hospitable halls of the "Civils" as the home of the Electricals, and rallying place they were for a few years. But fortunately, the Institute officers decided early that an annual meeting would not suffice, so the young Society made a practice of getting together at frequent intervals for papers and discussions—in New York, of course, as only there could a good membership attendance then be registered. The writer's report as Secretary—the first ever made to the Institute, dated May, 1885—stated proudly that it then had already 279 members and associates; but they were "in all parts of the country." It has been interesting to see resumed in the last year or two the local New York meetings that marked the initial stage of Institute work, although to insure a good attendance and be comprehensive, topics are now chosen that will interest local members of all the four national engineering societies. The writer has enjoyed lately several excellent meetings of this character. This offsets also the centrifugal tendency which has scattered such members so widely over the huge metropolitan territory, in which one can now hardly ever go home to dinner and get back for the meeting. Forty years ago, most members lived in close proximity to the meeting hall. It was thus found desirable and feasible to get together every few months in "special meetings" when, no matter what the topic, a very large percentage of the local members turned out. Especially was this the case when the meeting was held at some restaurant, with preliminary dinner, and it is curious to note as a sign of local changed times and conditions that some of those meetings were held as far down town even as Broad Street, or else Broadway South of City Hall. One very far northern rallying point was a famous restaurant cafe, Martinelli's, on Fifth Avenue, south of Madison Square. In his Presidential address, Mr. Pope said of the "Special" meetings in his seat that they "have proved to be most successful and enjoyable reunions and have certainly done much to strengthen the Institute."

But all that fades into relative insignificance before the great functions with which in Philadelphia in 1884 the Institute was so closely associated and to promote which it had, on its creation, joined hands most promptly with the Franklin Institute. The first of these was the Electrical Congress of 1884, the first held on the American Continent. It was a most successful affair, marked by large attendance from abroad—notably such men as Sir William Thomson and W. H. Preece—by brilliant and animated debates on the definition and establishment of fundamental electrical units. Even at this remove one can recall vividly the masterly presentation by Prof. Harry Rowland of his great work in the determination of the Ohm. The good results of this first American Congress

made it easy even in the panic year of 1893, to bring together, again with distinguished visitors from abroad, notably Von Helmholtz, the Electrical Congress in Chicago. This again was accompanied by a splendid electrical exhibit as part of the Columbian World's Fair.

But as the Institute is tenting and camping tonight on the old battlefield of 1884 here in Philadelphia, it may forgive—even expect—a casual peep at its own modest little performance of September and October that year. The Exhibition Building was the spacious old West Philadelphia depot of the Pennsylvania Railroad Company. There the Franklin Institute had generously placed two large rooms at the disposal of Dr. Keith. They were fitted up comfortably by him and were open to members and guests from September 2 until October 11. As a great many members were actively connected with the numerous fine exhibits of electrical and steam apparatus, those Institute headquarters were immensely useful and popular. Everybody met there every day. On October 7 and 8, the first convention ever held by the Institute was conducted in the rooms and at the fine old Continental Hotel—the Bellevue-Stratford of its day as to splendor and comfort—but fortunately not as to prices. The report of that 1884 Philadelphia Convention constitutes the bulk of Volume I of A. I. E. E. TRANSACTIONS—traversing such diversified arts as to wireless, underground wires, multiplex telegraphy, earth return, carbon filaments and the incandescent lamp, batteries and electrochemistry, electric roads and subways, the Edison vacuum bulb effect from whose study such extraordinary results in electricity and physics have followed, and some of the first explorations of the dynamo. It was and is all in harmonious precedence and prophecy of such a program as that of this week for the Twelfth Midwinter Convention.

The Exhibition, the Congress and the Convention were soon followed by a most valuable series of Jury Reports issued by the Franklin Institute, on the Exhibits, and to the preparation of which a large number of A. I. E. E. members contributed in various important ways, notably such experts as Prof. E. J. Houston and the indefatigable original "man from Missouri," Dr. Carl Hering. Nor was that all in the way of electrical literature springing from the events of 1884. Dr. Houston, confirmed and inveterate pedagogue, issued during the Exhibition an admirable little series of electrical leaflets. Their matter and manner were cleverly mimicked and plagiarized in a rival series issued by the Mystic Order of Kazoos. Frank and open confession may here and now be made that the cosy rooms of the Institute were just as convenient for their surreptitious writing and publication, as for the preparation of Volume I of the TRANSACTIONS of 1884, then undertaken by the writer with valuable Keith collaboration; soon to be followed by Volumes 2, 3 and 4, from the hands of Secretary Ralph Pope, elected in 1885, author of the excellent first A. I. E. E. YEAR BOOK. Some of the quips and jokes of the priceless Kazoo leaflets were part of electrical haus spreche for many years thereafter. Almost up to the moment when before the Institute a score of years ago, Steinmetz enunciated his epochal "Law of hysteresis," one could hear once or twice a week at least, as comment on alleged advances in the dynamo electric arts, a laughing quotation of the similar Kazoos' apothegm that "Dynamos may be painted any color without increasing their efficiency."

Yes, there is still some vital savor, some drop of red blood, some human appeal in all the dim and dusty records of humble beginnings on which rests with superimposing crush the colossal electrical structure of today. As President in 1887, the writer was proud to assert that the total capitalization of all American electrical industry was about $375,000,000. This week the Institute awards its Edison Gold Medal to the member whom it has recognized as chief engineering exponent of just one of its industries—that of electric light and power—which alone has now attained an investment of Six Billion Dollars, and employs thousands of its member electrical engineers in most varied capacities.

Best of all, perhaps, above and beyond the archaic technical record of those early dingy volumes of "TRANSACTIONS" is the undying evidence they embody that even then while the older men were prophecying estactically as to a world to be wholly electrified in the near future the young men were transforming wild dreams into sober realities as arts and industries, careers and utilities. A great national society that had the courage to take for its third President an untried young man of 30, still calls youth to its banners, must forever renew its own life from the well spring of youth, and will forever with higher aims, higher ambitions, higher aspirations, higher service, interpret the engineering science that leaves no department of human affairs without benefit of its healing touch, and asseverates truthfully and reverentially; "Behold, I make all things new!"

PRESIDENT RYAN: The next speaker is an eminent American who is responsible among other things for having caused General Carty to put those twists into the telephone that serve us so well today. He did many things of wonderful value aside from that. He gave us the first electric meter that the customer could read, and with which to satisfy himself in regard to his bill.

We have had three great international electrical conventions in our country, two of which, as I remember, were referred to by Mr. Martin; the first being the one in Philadelphia under the auspices of the Franklin Institute; the next one in Chicago, in 1893, and the third and last one in St. Louis in 1904.

This gentleman carries the fine distinction for us in this country of having been elected unanimously

President of each of the last two international electrical congresses.

I take very great pleasure in calling him up to speak likewise of the early days of the Institute. Mr. Martin has spoken of the wonderful things that are to be found in the archives of that day. I must speak of the gentleman who will thus quickly be called up as a prophet, for if you do not realize that he is truly one of our great prophets, turn to the TRANSACTIONS in the fall of 1889. He was the President of the American Institute of Electrical Engineers in that year, and while in London was inspired to speak in a prophetic fashion. It is truly wonderful to read what our TRANSACTIONS say at that time.

ADDRESS OF DR. ELIHU THOMSON

In commemorating, on this occasion, the completion of the fourth decade of our Institute, it is difficult for us early pioneers to realize that much of our present membership has no knowledge, from actual contact, of the beginnings of our Institute, from which have been built up the enormous volume of electrical engineering today. Incidentally, it has given birth to the profession which our Society represents, the profession second to none in the wide world.

As its President, as has been mentioned by our own President now, in the fifth year of the existence of the Institute, it was my duty to represent the Institute at a large gathering and dinner at the Guild Hall in London, at which about three hundred of the most prominent engineers of London met, and a visiting body of Americans, mostly Civil, Mechanical and Mining, with a sprinkling only of those who had begun their activities on the electric side of engineering. I felt almost as an interloper, a trespasser on the older domain, but did my best to dignify the new profession in response to a toast to our infant society.

I want to interpose here that just before I was called upon to speak, naturally a youngster among a great many much older men, I received a message. The speaker who represented the American Society of Mechanical Engineers couldn't be heard ten feet away. I was close to him myself, and I couldn't hear what he was saying. He read too meekly altogether, and there was such a roar in the audience that a speaker could not expect to be heard even if talking much louder than he did.

At that moment I received a little scrap of paper from Professor R. H. Thurston of Cornell. He said, "Thomson, it is your turn next. For God's sake, get them back. Get them back, for God's sake."

I nodded to him that I would. Now, it was a big job for any one to do, but I yelled as I never yelled in my life before. I took in my lungs full, and I let it out with almost every word, and the actual fact was that I did get them back.

They quieted down, and I think most of them heard everything I had to say. I have forgotten what it was all about, but I was bound to make this little engineering institute count for something, even among that great body of men, and I was free in my predictions of what was to come in the electrical engineering field, naturally, because I believed they were to be true, and whenever I have made such predictions and found out afterwards that they actually happened, I found that several hundred per cent more had happened than I could possibly predict, so I was justified.

Lord Kelvin, then Sir William Thomson, was there. We had met once before at Philadelphia at the Electrical Congress in 1884, held in connection with the Franklin Institute Electrical Exhibition in the fall of that year. I have liked to regard him as a representative of the theoretical and practical side of electrical engineering. He it was that first understood the meaning of capacity and inductance in submarine cables, which led to the laying of the first Atlantic Cable in 1866 after the failure in 1858, due largely to imperfect knowledge of others.

His insight at that early day was most exceptional. Not since the days of Franklin's kite experiment here in Philadelphia, had there been any electrical engineering undertaking of any magnitude.

Franklin's lightning rod was a great thing and still is the foundation of our protective means for lightning.

Except for a lighthouse lamp here and there run by alternating current, a single generator to a single arc-light, there was not until about the middle of the decade between 1870 and 1880 any marked progress in what might properly be called electrical engineering outside of land and cable telegraphy.

There was no field for one who felt that his tendencies led him in the direction of large electrical application—he must create that field. At the centennial exhibition of 1876 here in Philadelphia, there were only two exhibits of dynamos in action; the Gramme, unique as it was, and the Wallace-Farmer; the latter long ago obsolete because too inefficient. Both of them were a development of the ideas of Paccinotti of the previous decade. There was also a Gramme machine exhibited by Prof. W. A. Anthony—later a President of the Institute—and run at times. I am informed by Dr. Bedell of Cornell that it is still intact being at present used as a motor.

Here and there was an example of the earlier shuttle wound armature Ladd and Wilde machines, and the only one of which I knew as existing in this country was at the University of Pennsylvania in the collection of philosophical apparatus. I knew Professor Robert E. Rogers, who was professor of natural philosophy at the University. When I first saw this early type of dynamo operated in the years just after 1870, I remember standing before it spellbound. Something of the significance of thus turning mechanical power into current for the future overcame me, though the

machine itself was crude and inefficient. The earlier types of permanent magnet machines of Saxton and others made no such impression. The magneto electric had given way to the self-excited field machine of unlimited power and capabilities seen by a sort of prevision. This principle of self-excitation came to be known as the "reaction principle" and was discovered in 1866.

The Gramme exhibit at the centennial in 1876 was made more impressive by the use of such a machine as an electric motor in addition to running single arc-lights, one to a machine.

It is well known that the telephone of Bell was first shown in operation to a body of scientific men among whom was Sir William Thomson, at the centennial in Philadelphia.

A curious accident which may be known to some of you, but not to others, I may as well relate. Sir William borrowed from Bell a couple of instruments, of the magneto telephone type. The two instruments were electro-magnetic, the one to talk into and the other to listen from. He took them abroad with him. He tried to show these two instruments to the Royal Society in England, and he failed in getting the instruments to work. Some little accident had happened to the support of a diaphragm and prevented the operation. That little accident saved the Bell patents in England. If that instrument had worked there would have been no possibility to have had valid Bell patents in England. A patent there depends upon the prior non-introduction publicly of the invention, and as Sir William would have been the one to introduce it publicly and not Bell, Bell couldn't have had any patent.

That was one of the accidents of fate, only it happened in that case favorably to Mr. Bell.

There was another thing that happened in those days, not so favorable to Mr. Bell. It was said that when the German Patent Office was asked to grant a patent on Bell's telephone, they said, "Oh, no, it is too valuable an invention to be patented," and they refused it. In other words, the more valuable a thing a man gets up, from the German standpoint, the more definitely must he be refused protection.

From 1874 on, while living in Philadelphia, I was constructing small machines and using them as motors and at the close of 1876 had finished a machine which required about a horse power to drive it, and which would work a small arc-light. I had wound the field shunt and series as a compound winding and used it as such, subsequently finding that a British patent to S. A. Varley had already shown such a winding in 1876. However, I made use of this machine of mine, in a course of five lectures in electricity given at the Franklin Institute early in 1877, the object of which lectures I had designed to be the demonstration of the fact that electricity from any source was indeed the same.

In 1877 the Franklin Institute appointed a committee to investigate the properties of arc-lights and machines for running them, one machine to one light, of course. Professor Houston and I served on the Committee for the electrical measurements, the first, I think, published. This was in 1878.

Then followed a more rapid advance. The Avenue de Opera was lighted during 1878, exposition year, by Jablochkoff candles, later found too expensive. Brush brought out out early in 1879 his series system of arc-lights, closely followed by Thomson-Houston in the same year.

I may say as a matter of personal note that about four blocks west of where we are now, the first T.-H. dynamo was built early in 1879.

Its armature had on it the first three-phase windings, used with the three segment commutator, of course. The patent application showed the winding of today connected to collector rings for a-c. current.

The machine was the very first of its type though of about five hundred volts and ten amperes or about five kw. No model had been made, but so confident was I of the merit of the construction for constant-current work, that I was willing to risk success. It worked perfectly from the start and lighted a bakery, near where it was built, through the summer of 1879, the room temperature on account of the large bake ovens reaching on a hot night 140 deg. fahr. Why didn't it kill us? It did nearly kill two of us, but I was the one not affected.

I am going to give a piece of advice. Houston had to lie off from heat prostration. Thomas H. McCollin, interested in the matter, had to go off from heat prostration, but I didn't, and the reason was before I got hot enough to feel very uncomfortable I drank quantities of ice water. They said, "You will kill yourself."

"No, I won't. I am keeping my temperature down," and it worked.

In 1880 our newborn enterprise was taken to New Britain, Connecticut, and later to Lynn, forming the nucleus of the great works there.

Another little personal note I may interject here. When I got to New Britain, a manufacturing town in the interior of the State of Connecticut, I found hardware, tacks, nails, hinges, and everything of that kind were made there. They did not know anything about electrical apparatus, and didn't appreciate what we were trying to do. We got to Lynn three years later. There was a Weston plater in one of the shops in New Britain. Probably some of you know the old type of multiple field plater.

I was the electrician (not the electrical engineer) of our Company, The American Electric, at that time, and I was asked to come and see that machine. I said, "Send it over." They put it on a wagon and sent it over. We found it was a machine of fairly large size used for working plating baths in the hardware operations. I turned it over and took a monkey-wrench

and tightened a screw on the bottom. One of the nuts that tightened up the connection was loose, and of course, with such a low voltage as plating voltage, the current couldn't cross that kind of a joint. I gained some prestige from that.

Late in 1879 Edison had settled on carbon as the material for a burner or incandescent lamp filament and the famous Menlo Park exhibition of such lamps running in parallel from a dynamo took place at the close of the year.

Years elapsed before the prodigious work of producing the much-needed appliances in such a new art as incandescent lighting was accomplished. The Pearl Street Station in New York, with its direct connected "Jumbo" dynamos and underground distributing mains, was the outcome in 1882.

The following year the Brockton Edison station was opened as the first example of city distribution by three-wire circuits. The pace of development was from now on rapid, but we have now about reached the time of the organization in 1884 of our Institute, and later that of the first electrical exhibition in the fall of 1884, in Philadelphia, the Franklin Institute exhibition where were shown in one building all the notable advances made in the years preceding.

I will not attempt to catalogue them, only to say that this event was, as it were, a most fruitful and interesting landmark in the electrical progress in our country.

Edison in 1875 had thought he had a new force, etheric force. Prof. Houston and I thought it was electrical and set about proving it. The whole account of it was published in the Franklin Institute *Journal* at the time. At the conclusion of the experiments, I said, "Let's do this thing on a big scale." So we set up a large Ruhmkorff coil on the lecture table attaching one terminal by a wire several feet long to a large tin vessel mounted on a tall glass jar, and the other coil terminal was connected under the table to ground through a water pipe, there being a spark gap between the coil terminals. When we did that we could go all over the building and outside and explore by a pencil point, which by the way, Edison had used as a detector. We went to the observatory, five floors away, and we could get from doorknobs a signal that the machine was in operation on the first floor.

This was at the old Boys Central High School, North Broad Street, about a mile away from here. The building is still there.

Was there in this anything suggestive of wireless? Yes, there was. In the old Boys Central High School, the small set of experiments made in 1875 and 1876, pointed that way. They have been detailed elsewhere.

Was there anything of transformer work known in those days? Yes. In the Franklin Institute lecture room in February, 1879, were run two transformers (induction coils) with their fine coils of many turns in parallel from the collecting ring end of a dynamo which had been constructed to be self-exciting and yield a-c. currents.

There were no incandescent lamps for the coarse short wire secondaries, so we had to be content with semi-incandescent lamps with carbon, and coils of iron wire heated red hot. This is probably the first time such a combination was used, pointing the way to transformer work of today.

In New Britain one of our first jobs (I am trying to give you a picture of the electrical engineering of the time) was to find out what, if any, was the loss in an armature core of a dynamo. Some had said there wasn't any loss in the iron, and others had said there was a lot of loss in the iron. Some had said that if you use insulated wire you wouldn't get any loss, or very little, if you use bright iron wires for winding the cores you will have losses, and this was true.

We didn't have sheet metal. I will tell you later about that.

So we set up a dynamometer, built the armature cores of iron wire and ran them in an excited field to determine how much loss there really was in the iron, and we found the iron varied and the loss was in some cases much greater than in others, and we selected our iron wire accordingly but we always found there was a loss outside of windage air loss, but it was very difficult to determine how much it was. It was not so serious a loss as compared with the resistance loss in the copper. So we had to go along in that way.

I want to say that sometimes we had to go to the Patent Office in those days to tell the Patent Office what we were about. They didn't understand. I tried to tell them something about the reactance or inductance coil, how it worked unlike a resistance. They said, "You can't tell us that."

So I had to make an elaborate description. Think what the trip to Washington cost us in those days! You left Philadelphia and went to Baltimore. Through the streets of Baltimore was a line of mule teams, and they took the railroad coaches and pulled them through the heart of Baltimore. That was in 1880. Those whose memories can carry them back to that time will bear me out. It wasn't an easy job to get to Washington then.

Current control in those days depended on regulation by hand, and it was only later that we got into automatic regulation.

Now, I want to say just a word before I stop as to the handicaps we were working under in the days just before the organization of this Institute.

Wire: How and where could we get wire? In Philadelphia there was a bonnet wire factory. As you know bonnets in those early days were framed of wire, braided or wound with cotton. That bonnet wire factory did on the side a little business of winding cotton on copper. That is the way we had to get the wire for dynamos we were constructing. We had difficulty as late as '84 or '85 in getting the fine wire used in the shunt circuit in arc-lights, which should have the same resistance throughout. We should have coils of the same resistance; we gaged the wire at one end of a hank, and it

was either smaller than at the other end, or larger than at the other end. During the time of pulling the thousands of feet of wire through the wire drawing die of steel, the die wore, and the wire got bigger and bigger all the time. That was one of the difficulties that we had.

How could we make coils that would measure up to any definite resistance? Well, I had to take the wire makers into my confidence and say, "We won't buy that wire unless you jewel draw it. You will have to draw it through jewel dies. That is the way it will have to be done."

They set up the jewel dies. They advertised that they had now the process of producing wire the same at one end as at the other, and they never gave me any credit for it.

It was the same with the insulations. The insulations at first were poor, and our line wire was poor; even bare wire was used in those days to distribute arc-lighting. All of us who go back far enough know that the loops that went into stores and the wires on the poles were bare copper, and machines might have forty arc-lights or more in series.

I know one case where they tried to couple up in 1882 seven forty arc-light machines of the Brush type in Cincinnati on bare wire alone. It is a wonder they didn't set the whole place on fire, but the fact of the matter was, they broke down all the machines themselves so they couldn't set fires. The circuit was off.

We had no slate and porcelain. Mica was used for stove doors, and that was about all the use there was; and it was ourselves that introduced mica and pasted it together for the insulation in our arc-light machines.

Permanent Magnets: We had to study and manufacture magnets for our meters and study the whole case of production of permanent magnets and how to season them so that they would be permanent. Otherwise the meter was no good. Those were the things we had to do. Nothing had been done for us. Remember also that the steel we had at first for magnets was only tool steel. We hadn't any special magnet steel such as we have now.

In 1878 there were no telephones. You couldn't call up anybody by 'phone.

There were no typewriters. We had to do all our writing by longhand, and have it put in a copy book. The typewriter came later. There was an awful lot of work done in those days that people don't have to do nowadays.

There were no suitable steam engines in those days, and that applies directly to the time of the start of the Institute. The engines of those early days, except for some special instances where they were made for it, were not good enough to drive electric machinery. You know the old slide valve engine found everywhere. We would put electric lights on those old engines, and every time there was a fluctuation in speed the lights went up and down.

It was the development of the high-speed engine that made it possible to drive the Jumbo dynamo at a proper speed. In the years before everything was belted instead of direct connection. All the machines were belted to the engine power and subject to the vagaries of old-fashioned governors. One of the earliest cases of direct connection was the famous Gordon alternator in England.

I could go on and tell you more and more about the difficulties, but better things came gradually, sheet metal, sheet iron. We have been even criticized at times by being asked, "Why didn't you use sheet iron in those early machines?"

We couldn't get any sheet iron except stove pipe iron. That wasn't any good for magnetic effects. We would have been glad to get punch presses and use sheet iron, we couldn't get either. More than that, the punch presses in those days were used to punch out pie plates and similar objects only. There was not much done. The punch press room now is the wonderful institution of any great electrical works. We had to design our machines to fit the tools we had in the shop. If we did not have a big enough planer to take a machine, we had to design a machine so the planer would take it. That will explain some of the designs that we had to use. We didn't have any steel castings in those days. There weren't any steel foundries that were producing steel castings. It was only in 1886 that we established a steel casting foundry in Lynn and mainly because we could not get such castings made for us.

I will weary you if I keep on, but I wanted to give you a sort of an idea of the fact that things were not in those days as they are today.

President Ryan: The first year as instructor in college, I was called upon to proctor in an examination in Greek life. It was a new experience. I looked over the list of questions and found that there was but one in regard to which I could conjecture anything. However, I had no responsibilities in the matter in that regard. It didn't matter whether I could conjecture anything or not in regard to the examination. I had not the questions to write or the papers to read. The question that appealed to me was this one: "In the understanding of the wise men of ancient Greece, what was the limit in population of a city?"

When the papers began to come in, I looked them over. Four or five sufficed. It was an easy question to answer, evidently. The answers were all in agreement, and I came to the conclusion I knew the answer. The answer was this interesting one: "No city in the understanding of the wise men of ancient Greece in population could grow beyond a point whereat the people might gather around the city's advocate and hear his voice and learn the truth."

I wonder what a wise man of ancient Greece would think today to come into our country and find that through the wonderful work of the next speaker and the organization that he built up, there is no limit to

the size of a city in population. For in 1915 he extended his lines clear across the continent and from that day to this, at any time if we care to, it is physically possible for us as a nation to sit down at home, or nearly so, and listen to the voice of the President of our great country.

I take great pleasure in calling up as the last speaker in this series, a past President of the American Institute of Electrical Engineers, General Carty.

Address of General Carty

Among the four national engineering societies, composed of Civil, Mining, Mechanical and Electrical Engineers, the Society of the Electricals is the youngest. Of the other societies mentioned, it may be said that the art which they represent existed before they were formed, but of the Electricals it can be said, with pardonable pride, that its members created their own art.

The Centennial Exposition, held here at Philadelphia in 1876, marked the beginning of a new era in electrical development. Prior to that time the use of dynamos had practically been limited to such purposes as electroplating, and electric motors were a curiosity—a toy, not for children, but only for college professors to play with. The principal use of electricity was in the different forms of signaling, of which the telegraph was the most important.

At the Centennial Exposition in Philadelphia, one who was to become a member of the American Institute, and also one of its Presidents, Dr. Alexander Graham Bell, made known to the world his invention of the telephone. This gave a wonderful stimulus to the advancement of electrical science.

Soon followed the invention of the phonograph and the astonishing development of the dynamo and the electric light, which we so largely owe to another who was to become one of the members of our Institute yet to be formed—Mr. Thomas A. Edison.

Working here at Philadelphia about this time, there was another whose name was destined to be memorable in the annals of our Institute—Dr. Elihu Thomson. His fundamental work in laying firmly the foundations of the art of electrical engineering will serve as an inspiration to our members during the years to come.

Between the years 1876 and 1884, such marked progress had been made by the electrical pioneers, the future founders of our Society, that the importance of forming a national electrical engineering society was recognized, so that in 1884 the electrical pioneers of the period joined in the formation of an organization which should be a worthy exponent of electrical progress throughout America.

Prior to the work which was done by these pioneers, many of whom are still alive and active members of our society, there was no art of electrical engineering, and there was no university conferring the degree of Electrical Engineer. Electrical engineering was not even recognized among the professions. Those who devoted themselves to the practical affairs of electricity were known as electricians—a term now generally applied only to electrical artisans.

It was our society and the work of our members which have secured for electrical engineering its present position among the foremost of the learned professions.

Since the formation of the American Institute of Electrical Engineers, progress in electrical engineering has been a record of rapid and continuous and marvelous achievement.

The story of this achievement is to be found in the history of the American Institute of Electrical Engineers and in the careers of its members. So numerous and so important are the contributions of our members that adequately to describe them would require the writing of the history of the art of electrical engineering.

While our colleagues of the Civil Engineers were celebrating the joining of the Atlantic Ocean and the Pacific Ocean by the Panama Canal, the members of the American Institute of Electrical Engineers were celebrating the joining of the Atlantic Ocean and the Pacific Ocean by electric wires spanning the continent and carrying the human voice from coast to coast.

It is among our membership that we find the men, who, taking the feeble telephone which Bell exhibited at the Centennial Exposition in 1876, have built upon it the entire art of telephony, and have constructed telephone lines and installed telephone stations so that it is now possible to transmit the human voice from San Francisco to all of the states in the Union, connecting with wire systems reaching more than fifteen million stations and aggregating more than forty million miles of wire, representing an investment of more than two billion dollars, and carrying more than nineteen billion messages in a year.

In our membership are to be found men who have developed the wonderful art of electric power transmission, whereby the melting snows of our mountains are transmuted into power and light and heat and current for transmitting speech, for lighting the homes of our nation, for propelling railroad trains and ministering in countless ways to the happiness and welfare of our people.

It is a great satisfaction to our members to observe these important contributions which they have made to the comfort and beauty of the homes and the halls of our country.

In the progress of society from the primitive conditions found in former times to the present high state of civilization, communication and transportation have been the two great forces in the building up of the civilized state. It was said before the founding of our government that west of the Alleghanies there never could be a people which could form a part of a nation

on the Atlantic Coast. This was because of the impossibility of communications and transportation, which are essential to a community of interest and common action.

This indeed was true at the time, and would still be true were it not for the work of engineers. Communication north and south along the Atlantic Coast was accomplished well enough at the time by coasting vessels plying between the numerous harbors which there abound, but it was not until the advent of railroads, which were the work of engineers, both civil and mechanical, that the growth of our country westward as a permanent part of our nation, was assured, and it was not until the great State of California was connected by rail with the East, that our Union was complete.

Coextensive with the development of the railroads came the telegraph, supplying communities with the great essential, quick communication. Thus, with the railroad, the telegraph and the mail, the essentials of growth for the time being were provided, but as our progress has become more complex, further development of transportation and communication was required.

Our members have provided these in the telephone and in the electric railroad. The telegraph and the steam railroad connect places; the telephone and trolley reach directly to homes and to offices. They connect not only places, but they connect people. In many other ways that are little thought of, our membership has contributed to the upbuilding of our nation.

The American Institute of Electrical Engineers stands for the highest achievement in electrical engineering and for the most distinguished attainments among its members.

From the art of electrical engineering as its exists in the world today, take away the contributions of the members of the American Institute of Electrical Engineers, and that which would be left would make a sorry showing by comparison.

The art of telephony would disappear and all of those wonderfully coordinated activities of both peace and war, depending upon that means of communication, would instantly be paralyzed.

In electric lighting and power and current distribution, the contributions of our members have been so fundamental, so important and so numerous that it is impossible to picture the chaos which would result if, by some black magic, their wonderful work should be undone.

By its papers and meetings and discussions, by the spread of knowledge through its published JOURNAL and TRANSACTIONS, and above all, by the high ideals of its members and by the unsurpassed character of their achievements, the Institute has taken a foremost place among the forces making for the welfare and unity of mankind.

It is with feelings of pride and satisfaction that today we celebrate the fortieth anniversary of the founding of the American Institute of Electrical Engineers.

We are holding this celebration in the Golden Age of Electricity—the age of electrical communications, of electrical transportation, the age of light and power. What words these are to conjure by! Light to see, and power to move and to do—to do that which no man has done before. What inspiration they send forth, urging our members to still higher achievement!

Gaseous Ionization in Built-up Insulation—II

BY J. B. WHITEHEAD

Fellow A. I. E. E.

Dean, School of Engineering, Johns Hopkins University

Review of the Subject:—*It has been suggested frequently that the failure of high-voltage armature bars might be due to deterioration caused by gaseous ionization in entrapped air spaces. In an earlier paper a series of tests on a number of 6600-voltage mica folium armature bars made up with different degrees of mica content was described. The variations of the dielectric losses with voltage and with temperature were studied and by means of the application of pressure it was shown to what extent losses due to internal ionization were present. The influence of these ionization losses on the life of the bars was also studied.*

The tests of the foregoing paper are continued in the present paper, extending to a wider range of type of armature insulation. The general results are as follows:

1. The absolute values of loss due to internal ionization in well constructed armature bars are small compared with dielectric losses of other types.

2. The losses due to internal ionization do, however, cause a progressive deterioration of the insulation. This is shown by a gradual increase in the loss and power factor of the insulation.

3. It is indicated that the principal function of mica in this type of insulation is in the reduction of the conductivity of the insulation and the withstanding of the action of internal ionization. The indications are that full mica folium content can be safely reduced only by use of the best grade of mica folium and the best conditions of application without variation. Several bars having relatively low mica content have compared favorably with those having the maximum mica content, indicating reliable insulation over long periods. It appears that high mica content is necessary in order to maintain a high factor of safety to cover the variations in factory processes.

4. In the drying out period this type of insulation is subject to great danger from relatively brief periods of application of voltage. During these periods the losses are high, internal temperature is raised, with further increase of loss, leading to breakdown. The greatest increase of loss in this danger period is in the range 25 deg. to 50 deg. cent.

5. The drying out period at 125 deg. cent. and during which normal voltage may not be applied to the insulation for more than a minute or two, varied in the specimens studied from fifteen days to three months.

In a foregoing paper, under the above title, a series of tests has been described, investigating the presence of gaseous ionization, or corona, in various types of armature insulation, with particular reference to its magnitude and its influence on the life of insulation. It was shown that the magnitude of the power loss due to ionization is relatively small, as compared with the dielectric loss due to other causes. It was shown that under sustained voltage and temperature the loss in those bars which initially had the highest ionization loss, increased gradually, indicating a progressive deterioration of the insulation due to these causes. These life tests were made on bars No. 33, 46 and 49; the two former having standard 6600-volt mica folium insulation, and the last a slightly smaller proportion of mica.

In the present tests the study of the progressive changes in the internal loss is continued, the principal purpose in view being to investigate the influence of varying degrees of mica content in two groups of bars, one having paper, and the other treated cloth, as the supporting binder for the mica folium. A description of the make-up of the various bars is given in the foregoing paper.

The general outline of the present tests is indicated by the following list of the bars tested. The list includes the bars upon which report has already been made as indicated. The remaining bars have been selected as having decreasing amounts of mica, and as having the greatest percentage corona loss in their respective groups. However, in two groups of paper bars no bar showed a corona loss higher than 2 per cent.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

Thus as regards the influence of corona, No. 39 is the most conspicuous new case in the paper group.

TABLE I.

Paper Insulation	Cloth Insulation
No. 33—full mica folium (92 per cent) 14 per cent corona loss—already studied	No. 46—full mica folium (no cloth) 92 per cent, 3 per cent corona—already studied
No. 36—70 per cent mica folium 2 per cent corona	No. 49—73 per cent mica folium 37¼ per cent corona—already studied
No. 39—50 per cent mica folium 14 per cent corona	No. 54—42 per cent folium 28 per per cent corona
No. 41—28 per cent mica folium 2 per cent corona	No. 55—22 per cent mica folium 32 per cent corona
	No. 60—0 per cent mica folium 14 per cent corona

Bars 36, 39 and 41 were placed in one oven and Nos. 54, 55 and 60 in a second duplicate oven. These ovens were of the Fries type and were electrically controlled up to about 135 deg. cent. maintaining temperature constant to about 2 deg. in the upper range. In the tests the temperature was raised by steps lasting several days each, to a maximum of 125 deg. cent. The ovens were equipped with high-voltage bushings and 10-kv. was applied for 16 out of every 24 hours continuously, to the central conductors on the sample bars. Other leading-in bushings afforded connections to the central test electrodes and to the guard ring electrodes on each bar. At stated intervals the voltage was interrupted and measurements made of dielectric loss and charging current at 7.5 kv. and also of insulation resistance as based on application of continuous voltage for one minute. The alternating frequency was 60 cycles. Other conditions surrounding the methods of measurement are described in the earlier paper.

Experimental Results

The general results of the tests may be seen in Fig. 1, which gives the record of continuous observation on the

bars mentioned, subjected to continuous temperature over a period of ten months. The continuous application of voltage was possible over a period of six months only, on bars Nos. 36, 39 and 41, and not at all on Nos. 54, 55 and 60 for reasons described below.

Before beginning the temperature run the losses in all of the bars were measured at atmospheric temperature, and the values compared with those taken one year previously, when the measurements, described in the earlier report, were taken. The values of loss in bars Nos. 36, 39 and 41 were found to be practically unchanged indicating no alteration on standing idle at temperatures in the neighborhood of 25 deg. over a period of one year. On the other hand, the bars of the cloth group showed increases in loss as follows: No. 54—15 per cent; No. 55—6 per cent; No. 60 (no values permitting the application of voltage over reasonable periods of time. The continuous application of voltage was possible only after 3½ months, on the bars having the larger percentage of mica, and on two of the bars low in mica it was never possible, as described below. During the initial period, therefore, measurements were made only on bars Nos. 36 and 54 as pilot bars for their respective groups.

Internal Losses

Referring to Fig. 1 the sharp increase in dielectric loss following the increase in temperature is at once evident by the rise between 24 deg. to 42 deg.; the losses in each of the bars 36 and 54 are practically doubled. There is little change in the loss at this temperature and on increasing to 63 deg. there is a further increase

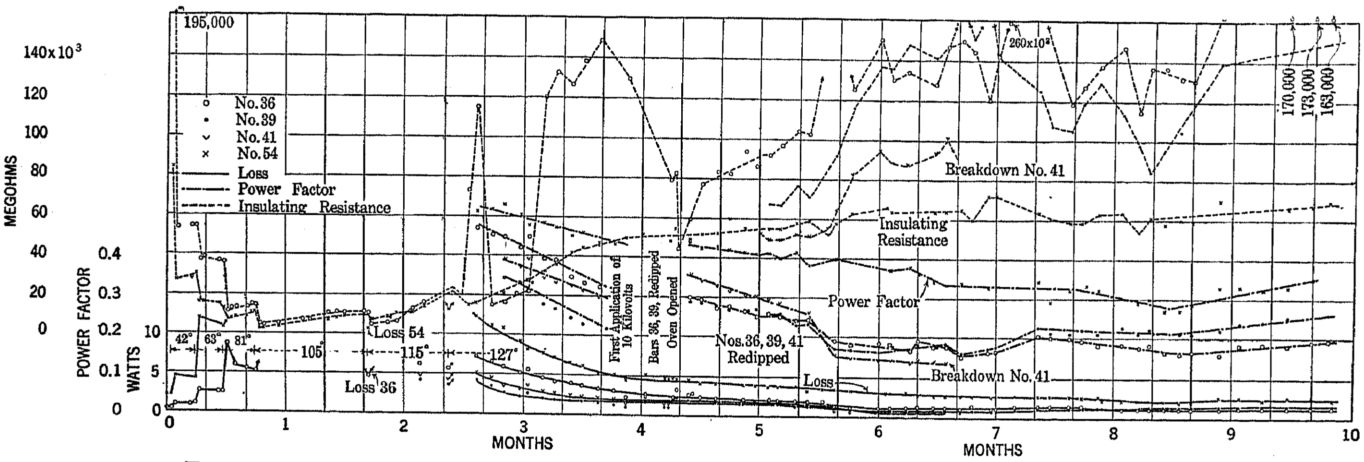

Fig. 1—Losses in Armature Insulation at High Temperature and High Voltage

mica)—40 per cent; thus green bars having cloth as a supporting binder show a tendency to increase their internal losses with age. Absorption of moisture suggests itself as the most probable cause of this increase.

After assembling in the ovens the bars were first measured at atmospheric temperature 24 deg. cent. The temperature was then raised to 42 deg. for 6 days, then to 63 deg. for 7 days, then to 81 deg. for 8 days, to 105 deg. for 29 days, to 115 deg. for 20 days, and finally to 125 deg., at which value it was held continuously. The duration of the run at each temperature was determined solely by the behavior of the insulation as regards its internal loss. Every elevation of temperature was followed by a marked increase in the internal loss, the value of the loss thereafter decreasing at various rates. During the later increases of temperature the losses increased so sharply as to make it impossible to apply voltage continuously, as breakdown would follow after very short intervals. In fact, above 81 deg. it was found inadvisable to apply the measuring voltage of 7½ kilovolts over the period of 8 minutes, necessary for the measurements, for fear that breakdown would occur. It was only after two months, and after the insulation had been subjected to 115 deg. for sometime, that the losses had fallen to of loss by about 2½ times. At sustained 63 deg. there is a tendency to a decrease of loss. On raising the temperature to 81 deg. the voltage cannot safely be applied to No. 54, and No. 36 shows an 18-fold increase of loss over its initial value. At 81 deg. however the loss falls off fairly rapidly, although it increases again sharply when the temperature is raised to 105 deg. From this point onward for a period of nearly two months, it was not possible to make complete loss measurements owing to the high values of loss. The conditions of the bar could be told by a brief application of voltage in its effect on the wattmeter reading. A slowly increasing wattmeter indicates internal heating of the bar, and the danger of the continuous application of voltage. Isolated readings are shown toward the end of the second month. A regular program of loss measurements was begun after about two and a half months, when the bars had been raised to 125 deg. cent. and maintained at that temperature for several days. During this early period regular readings of insulation resistance were possible, and these also afforded some information as to the condition of the insulation. Comment in this connection is made below.

Bars Nos. 55 and 60 after their initial reading at atmospheric temperature would at no time stand 7½

kv. for a period sufficiently long to obtain the loss measurement. They showed a rapid increase in wattmeter readings and when subjected to voltage on January 26th, after nearly three months, No. 55 punctured under this test. In the earlier report several curves are given showing the increase of internal loss under the continuous application of potential. In Fig. 2 herewith is shown this effect as applied to bar No. 56 of the same group as No. 55 taken at atmospheric temperature. For the same reasons, although the regular loss measurements on the remaining bars began at two and one-half months, it was not possible to apply 10 kv. continuously to them until well on to the end of the third month. For example, No. 54 early in the third month showed an increase of 25 per cent in its internal loss in a period of 20 minutes.

It is noteworthy that in the present tests this initial period of high loss and unstable condition, often referred to as the drying out period, extended over a period of four months, whereas in the tests of the earlier report, having to do with insulation having high mica content, this period was limited to only about 15 days. While the losses were somewhat high after that period they were still sufficiently low for measurement, and as to cause no steady rise due to internal heating. In fact, comparing the results of the present tests with those on the bars having higher mica content, we find that the initial rises of loss with increasing temperature are less for the high mica bars and of shorter duration. After one month all three high mica bars show less than 3 watts each at 110 deg., while after two and one-half months the low mica bars are at from 3 to 12 watts each at the same temperature. The low mica bars dried out much more slowly and approached constant values at six months as against two and one-half months for those high in mica. Note, however, that the final constant minimum values of low mica bars (0.6 to 1.25 watts) are only slightly higher than those high in mica (0.6 to 1 watt).

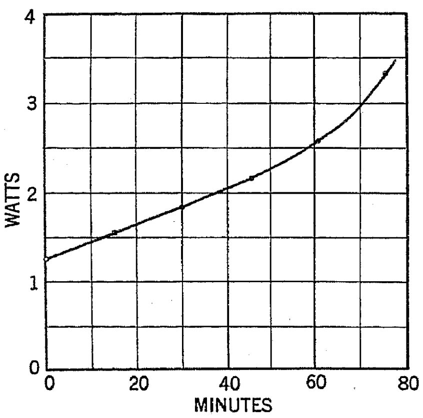

Fig. 2—Loss-Time, Bar 56, 7.5 kv.

The conclusion from these facts is that in some way the presence of mica affects not so much the ultimate values of the dielectric losses themselves, but the way in which they change when subjected to temperature. Observations on the values of dielectric absorption for this type of insulation give indications that the major proportion of the dielectric loss is due to absorption. Consequently, the variation in behavior between high mica and low mica insulation with time, will probably be found to lie largely in the variation of dielectric absorption.

The regular decrease in values of loss under continuous high temperature, as indicated in Fig. 1, begins toward the end of the second month. Toward the end of the third month 10 kv. was applied to the bars for 16 out of each 24 hours, together with the sustained temperature of 125 deg. cent. These conditions were continued until the end of the test. Occasional irregularities in these curves were caused by temporary fluctuations in temperature, and on two occasions it was necessary to open the ovens and re-dip one or more bars in insulating compound. This insulating compound was necessary to prevent surface discharge between the exposed end of the central conductor and the measuring electrodes. It will be observed, however, that even at these points of irregularity in the curves the relative values of the losses in the several bars remain approximately the same.

Considering the results plotted in Fig. 1 we may note as follows:

Of the six bars investigated only three, Nos. 36, 39 and 54, survived the test of ten months of high temperature and continuous application of voltage.

Bar No. 36, 70 per cent mica folium and 2 per cent corona, shows throughout a very low value of loss. In the earlier stages this loss was slightly higher than those of No. 39 and 41 although the three had much the same value of loss in the sixth month, when No. 41 broke down. After seven months No. 36 had the lowest loss and lowest power factor and remained in this position until the end of the run, showing, therefore, best prospect for long life. No. 36 started with the lowest initial corona loss and its good showing at the end of the test is in accord with the results of the tests described in the earlier paper, in which the bar showing least initial corona loss, showed in the final stage lowest total loss and best prospect of long life.

Bar No. 39, 50 per cent mica folium, 14 per cent initial corona, shows throughout a very low value of loss. During the seventh month, however, its loss gradually rises above that of No. 36, its insulation resistance falling at the same time. This increase in loss is attributed to the presence of internal ionization in No. 39, and its gradual influence in causing deterioration of insulation. The effect is also seen in the curves of power factor.

Bar No. 41, 28 per cent mica folium, 2 per cent initial corona. This bar is especially interesting because notwithstanding its low mica content it showed from the beginning a very low value of loss, this value being comparable with that of Nos. 36 and 39 after four

months. This low value of loss was maintained for six and one-half months, when unfortunately the insulation punctured. The breakdown occurred to a guard ring electrode, and so the approach to the breakdown condition was not observed on the instruments. The final low value of loss of this bar is the same as that obtained in bar No. 46 of the first report, which had full mica folium content, and which showed the best performance in the earlier tests. The low loss in No. 41 is significant as showing that low mica content may under some conditions give as good characteristics as high mica content. It appears that No. 41 must be regarded as an exceptional case in which a relatively low mica content, well preserved, after careful application, results in good electrical characteristics which, however, can hardly be considered as typical in view of the history of other low mica bars. In fact, as stated, this bar broke down after six months.

Bar No. 54, 42 per cent mica folium, 28 per cent corona, is the only bar in the cloth group surviving to the final period. It shows a relatively high loss which is to be attributed rather to its low resistance (*i. e.* high absorption) than to its high initial value of corona. There is little, if any, evidence of increase of loss in the final stages. However, it is to be noted that on account of its high total loss it was not possible to submit this bar to continuous high voltage. Therefore, it offers no conclusion as to the influence of internal ionization on its life.

Bars Nos. 55 and 60 never reached a stage at which voltage could be continuously applied. Both of these bars had high loss at atmospheric temperature, preventing power measurement for sometime after their temperature was raised. No. 55 broke down at the end of two months, at 115 deg. cent. during an attempt to measure its power loss. At the start at atmospheric temperature the resistance of No. 55 was 6500 megohms, and that of No. 60 340 megohms, showing the very great influence of the mica in No. 55. Two months later at 115 deg. No. 60 showed 16.5 megohms which, however, rose under sustained temperature to 47 megohms in another month, and 236 megohms in four months. These bars were then removed from the oven to make room for the others. No. 60 is interesting in several ways. In spite of its very low insulation resistance when cold it had the relatively low value of loss of 5.35 watts. Dielectric absorption in No. 60 is completely masked by its high conductivity. The value of insulation resistance given above is determined from a one minute reading at continuous potential, but this value remains practically unchanged over one-half hour or more. The value of resistance so computed, however, accounts for only 16 per cent of the total dielectric losses. Although the absorption is masked it is present, as is shown in another section of this report, and we have here clear evidence of the importance of dielectric absorption as distinct from conductivity in causing the losses in dielectrics.

INSULATION RESISTANCE

The curves of insulation resistance in Fig. 1 are plotted from observations with continuous potential in the neighborhood of 200 volts, and current in a high-sensitivity galvanometer. The galvanometer reading was taken at exactly one minute after the application of voltage. The insulation was then short-circuited one minute and a galvanometer reading with reversed voltage at the end of another minute again taken. The mean of these two readings was used in computing the resistance. As is well known, the value so obtained does not represent the true ohmic resistance but merely gives one point on the absorption curve. In many cases and particularly in some of the bars under observation, a steady reading of the galvanometer only results after a long period of time, say one hour or more. It often happens that the one minute reading is many times greater than the final approximate steady value. However, except under conditions in which the shape of the absorption curve is materially altered, the proportionate relation between the one minute and final readings remains constant under a variety of conditions. While, therefore, the curves in Fig. 1 do not give, as suggested, the final values of resistance, they do represent in their mutual relation the relative changes in the final resistance of the several bars. They probably represent more exactly the relative values of the absorption, since the one minute reading is in most cases well up on the initial steep portion of the absorption curve. In taking this point of view it should be noted that high values of insulation resistance indicate low values of dielectric absorption and vice versa. It is highly probable that the major portion of dielectric losses are due to absorption, and it is for this reason that there is a fairly uniform relation between the so called insulation resistance curves and the loss curves. The relation, however, is total loss and absorption, rather than loss and final ohmic resistance. Referring then to the insulation resistance curves, it will be seen that at atmospheric temperature they indicate a very high value of resistance and that this resistance decreases very sharply when passing from 24 deg. cent. to 42 deg. cent. The decrease here is much greater than in any other of the successive temperature steps leading up to 125 deg. cent. It is especially significant that absorption should be relatively low in the green state of insulation, at room temperature, and be greatly increased by a slight elevation of temperature. This moderate elevation of temperature leads to a condition of high absorption, low resistance, and high loss extending over a period of two or three months. If this change of condition is due to the presence of moisture, which is the only influence which suggests itself, would it not be possible to assemble and apply this insulation at 40 deg. or 50 deg. cent. and so avoid the low dielectric strength of the weak period, and also its long duration? Under the influence of higher temperatures, the insulation resistance after a time begins to rise again, gradu-

ally increasing in value and being accompanied always by corresponding decrease in the values of loss. The readings of the galvanometer in these regions of high resistance become quite erratic and apparently the condition of the insulation as regards resistance and absorption is in a continual process of change. For example, the readings immediately following the removal of the alternating test voltage (10 kv.) from bar 36 will be quite different from those taken 15 minutes later. The first application of high alternating test voltage evidently causes some shake up in the structure of the insulation, and it is followed by a change in the value of the insulation resistance. The opening of the oven for a brief period may also be followed by changes in this quantity. Expansion of the sides of the bars, particularly those containing mica, following long periods at high temperature, lead to thicker air layers, a high resistance, and also probably to unstable mechanical structure. The insulation resistance curves, therefore, in their regular progress are to be regarded for the light they throw on the variation in dielectric absorption. In their upper erratic ranges, however, they give evidence of little else than unstable internal condition. See Appendix A.

Influence of Compression

Since internal ionization takes place in entrapped air layers, compression of the insulation should reduce the volume of these layers, or increase the density of the entrapped gas, and so reduce the loss due to ionization. At the same time pressure will reduce the total thickness of the insulation, and thus increase the voltage gradient and the losses in the solid parts. In the earlier paper it was shown that in far the greater number of cases the reduction of the ionization greatly offsets any increased dielectric losses, and that an increase of loss on compression appeared in only two bars out of 30 investigated, and in each case the increase was very small.

Under sustained high temperature the insulation on the flat sides of armature bars tends to expand forming a curved, instead of a flat surface. This obviously causes increase in the thickness or number of the enclosed air spaces, resulting in a decrease in loss in the low-voltage range, and a greatly increased loss if the voltage is above the ionizing value for the entrapped air or gas. This expansion also causes a loosening up of the structural rigidity of the insulation, probably causing the shifting of mica, and so further increasing the likelihood of failure. The expansion of the insulation in the present tests is undoubtedly greater than could occur in the slot of a generator armature, but even in the latter case the assembly clearance provides space for some expansion. It is, therefore, important to know whether a solid structure under compression, reducing the internal gaseous ionization, and maintaining fixed position of all interior layers, would result in longer life for the insulation.

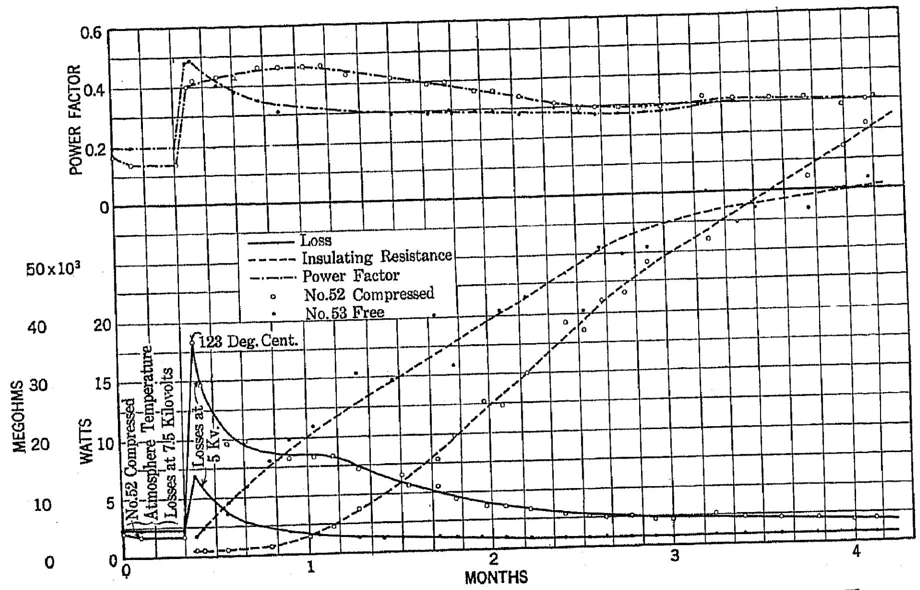

Fig. 3—Losses in Armature Insulation Influence of Compression and Temperature

For test of this question bars No. 52 and No. 53 both of the same structure (treated cloth and 42 per cent mica folium) were used. The insulation under the electrodes of No. 52 was tightly compressed with steel plates and screw clamps, that on No. 53 being left free. Each was dipped in insulating compound to prevent surface leakage and the two set up in one of the constant temperature ovens, at 125 deg. cent., replacing No. 55 and No. 60, withdrawn for reasons described above. The continuous record of this test is shown in Fig. 3. The loss measurements at atmospheric temperature were made at 7.5 kv. Those at higher temperatures were made at 5 kv. instead of 7.5 kv., since in the early stages the losses at 7.5 kv. were so high as to endanger the insulation.

Referring to Fig. 3, the initial readings were taken at atmospheric temperature and with no compression on either bar. The readings of the second day were

taken with No. 52 firmly compressed as described and No. 53 free, both at atmospheric temperature. An 8.5 per cent reduction of the losses in No. 52 is evident. This reduction is due to the decrease in the loss due to internal gaseous ionization. These readings were repeated a few days later and the bars were then dipped and placed in the oven and their temperature raised to 123 deg. cent. This rise in temperature is accompanied by the usual sharp increase in dielectric loss, and increase of absorption, *i. e.*, decrease in insulation resistance. It is especially interesting to note that the increase in the loss of bar No. 52 under compression is very much greater than that of the free bar No. 53, in spite of the initial lower values of the former. This immediately suggests that the compression of the insulation greatly retards the drying out process. This bears out the conclusion reached in the foregoing section of this report, that the greater part of the reduction in insulation resistance, or the increase in absorption, takes place during the first stage of temperature rise, and also takes place quite rapidly. Whatever the process of drying out may be, such as the driving out of water, it is apparent that it is seriously retarded by the compression of insulation. The insulation resistance curves also clearly indicate this condition. Immediately following the sharp decrease in resistance attendant upon high temperature, the resistance of No. 53 begins to rise rapidly while that of No. 52 remains practically stationary over several days and begins to rise quite slowly. The further history of the bars over the period of four months shows that No. 53 maintains its lower value of loss but that of No. 52 is gradually approaching it. It is to be borne in mind that the values of loss shown by these curves are taken at 5 kilovolts, at which voltage the losses of internal ionization are very low. It would appear that No. 52 should ultimately fall below No. 53 since it was lower at the start. The tendency of the insulation resistance curves indicates this more definitely than do the loss curves. It will be noted that in the final stages the resistance of No. 53 is increasing less and less rapidly, while the rate of increase of the resistance of No. 52 is rising more rapidly and, therefore, tending to higher values than that of No. 53. Apparently, however, considerable further time would be necessary to bring the two bars to their final constant values of loss. Unfortunately the work was of necessity interrupted before it was possible to apply continuously, the normal operating voltage on these bars, and to continue observations on them so as to make a relative study of their life histories. It would appear that a continuation of tests of this character should give important information as to the influence of ionization and compression on the life of this type of insulation. See Appendix B.

Conclusions

From the results of the life tests as shown in Fig. 1 we conclude as follows:

1. The conclusion in the earlier paper that internal ionization increases the dielectric loss and tends to shorten the life of built up insulation is supported by the results of the present tests. In each group in which comparison is possible the longest life is associated with low corona loss. In the two groups, highest and next to highest mica, the bars having high initial corona loss, at the end of the test, show evidence of gradual deterioration as compared with steady conditions in the bars initially showing low internal ionization.

2. Considering in general the influence of the amount of mica content: In the earlier test the best showing was made by a full mica (92 per cent) bar (No. 46). In the present test the best showing is made by a second group bar, No. 36 (70 per cent mica folium), and No. 39 (50 per cent mica folium) a third group bar is also still in good condition at the end. Moreover, No. 41 (28 per cent mica folium) made a run of six months with very low losses. These, however, are the only ones in which a relatively low content of mica folium gives a performance approximately that of full mica folium content. Note for example that No. 54 (42 per cent mica folium) and No. 55 (22 per cent mica folium, were not in condition after ten months drying out to stand the constant application of voltage. Throughout the course of both series of tests there have been a number of instances of high internal loss and heating and several cases of breakdown. These cases for the most part have been found in bars of the third group, or below, that is, those having less than 70 per cent mica folium content.

3. In general the indications are that the principal function of mica is in the reduction of the conductivity of the insulation, and in withstanding the action of internal ionization. While definite conclusions are scarcely permissible from the small number of bars tested, the indications are that the full mica folium content can be safely reduced only by insuring the best grade of mica folium, and best conditions of application, as regards uniformity and compact structure, these conditions being maintained to a high degree in continued factory production. Several bars having relatively low mica content have compared favorably with those having the maximum mica content. They are relatively few, however, in the total number studied. It appears that high mica content is necessary in order to maintain a high factor of safety to cover the variations in factory process. On the other hand, it has been shown that under best conditions considerably less than the full mica content may yield reliable insulation.

4. In the present tests the drying out period is much longer than that of the earlier tests, and the increase of loss with increase of temperature, much greater. The average mica content was higher in the earlier test, although in one case bars of the same group showed the difference noted. The greatest step in the

increase in loss and decrease in insulation resistance occurs in the change from 25 deg. to 50 deg. cent.

5. An uncompleted study of the relative performance of compressed and free insulation, indicated that the former passes through a more dangerous drying out period, but ultimately approaches equality with the free bar. From then on it should show superiority owing to the higher internal ionization loss in the free bar. This test should be continued.

Appendix A

Insulation Resistance

Irregularities in the one minute galvanometer readings for insulation resistance have been attributed, in the foregoing, principally to a continuous process of

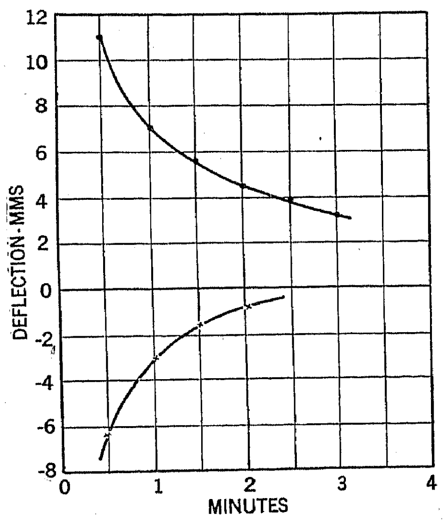

Fig. 4—Residual Charge After Alternating Voltage

alteration of the structure of the insulation under sustained high temperature and high voltage. The matter has been studied further, and apparently the principle influence in causing the variation in the galvanometer readings is the residual or absorbed charge in the insulation, resulting from the sustained alternating voltage which was interrupted only for the brief intervals required for loss and insulation resistance measurements. A series of continuous charging current observations was taken on bar No. 56 immediately following the interruption of the 10-kv. alternating voltage, 30 seconds being required for the change of connections. Right and left galvanometer readings one minute after the application of the continuous voltage, and with one minute short circuit in between, showed great irregularities. The values of the readings in either direction, and the relative values between right and left readings, varied widely. Thus in two successive observations the right and left readings were 6 and 8, and 12.5 and 6 mm. respectively, at 285 volts d-c.

A series of discharge curves was then taken. As promptly as possible after the removal of the 10-kv. alternating, bar No. 36 was connected for discharge through the circuit used for insulation measurements (see former report) the resulting deflections were right and left without regularity, and the curve showing the change of deflection with time has the characteristic form of the discharge of dielectric absorption. Fig. 4 shows two of these curves one of right and the other of left hand deflection. These curves, surviving after a 30-sec. interval necessary after interruption of the alternating voltage, but of irregular initial value and polarity, show clearly the residual absorption due to the foregoing alternating voltage. In the course of the life tests the insulation resistance measurements were taken sometimes immediately after interruption of the alternating voltage, and sometimes after the power measurement, and without regulation of the time interval following the removal of the alternating voltage. Hence it seems clear that the variation in the values of insulation resistance is in large measure due to this cause.

Appendix B

Influence of Compression

It is significant that towards the end of the run of Fig. 3, bar No. 52, under compression, is tending to a lower power factor, and a higher insulation resistance than No. 53, and that its loss is still falling while that of No. 53 is about constant. If continued with the application of sustained high voltage this test probably

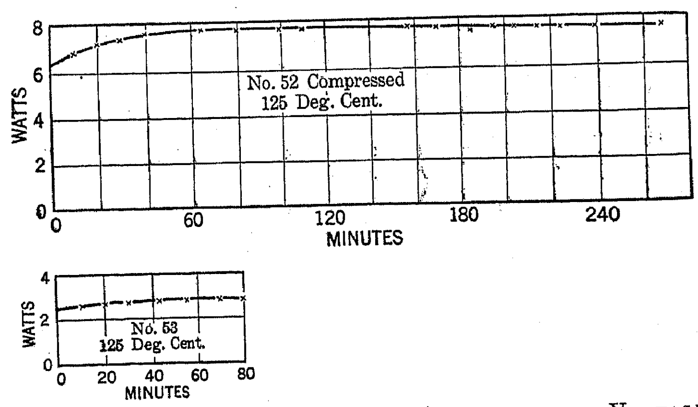

Fig. 5—Influence of Continued Application of Voltage on Dielectric Loss

would have shown next a decreasing resistance and an increasing loss for No. 53 due to its internal ionization. The original ionization loss in bar No. 53 was about 25 per cent, that or No. 52 at the beginning of the present test being considerably less, and reduced to a minimum by heavy compression.

Fig. 5 shows the results of a continuous run for a few hours at 10 kv. on both these bars to determine whether they were ready for the continued application of alternating voltage. It is seen that there is no increase in loss in either case after the first hour and thus that the internal losses are dissipated as fast as generated. The initial greater rise in loss in No. 52 is due to the elevation of internal temperature due to its greater losses. It is unfortunate that this run was of necessity interrupted at a time when the bars were just ready for studying the influence of voltage and internal ionization.

Discussion

F. M. Farmer: I just want to mention one thing you may be interested in. Dr. Whitehead has referred to the critical point in the curve between the dielectric losses and voltage. It is proposed to use this characteristic in a practical way in connection with paper-insulated cables. As you all know, a paper-insulated cable is an impregnated laminated structure, and we have always felt that an important element in the satisfactory operation of such a cable is thoroughness of impregnation. The question is, How are we going to tell when the insulation is thoroughly impregnated, that is, free from moisture and voids?

It has been proposed that we use this critical point. (Illustrating on the blackboard). A little easier and more practical method is to use power factor, instead of voltage. Normally the curve between power factor and voltage is horizontal with the abscissa, up to this point which Dr. Whitehead has called the critical point. At that point the line will depart. This point is generally referred to as the point where ionization begins.

Now, if ionization is a matter of variation in impregnation, we get some kind of a measure of impregnation by the slope of this curve, particularly the slope of this line beyond the critical point,—in other words, the change in power factor with a given change of voltage.

It is proposed that such a test could be applied to every reel of high-tension cable as a test of thoroughness of impregnation. It is a test that can be made fairly easily, and is a perfectly practical one, but the question still in the minds of a good many of us is just how important is it? We need quantitative information as to just how significant a given change in the slope of this line is as an indication of the quality of the insulation.

Dr. Whitehead's experiments seems to show ionization produces a destructive effect. But we need more experimental evidence before we can draw definite conclusions because there seem to be a good many cases where high voltage cables have been in service for many years at a voltage considerably above this critical point or ionization voltage without giving any trouble whatever.

Everett S. Lee: Professor Whitehead in giving his paper has attempted to make a statement regarding practically all of the variations which have come about, and in most cases I think we can say that we would agree with him. In other cases, other statements might be made that would equally fit the case, particularly in connection with the insulation resistance. Although I noted that in his remarks he cautioned us about making too much use of it, I just want to dwell on that point for one moment because it does seem that in the results which he obtained, the insulation-resistance curve, as shown in Fig. 1 did seem to show in an inverse way, about the same thing as the loss curve showed.

Now, if that is true, it is just one more phase in the insulation game which makes us pause and consider, because of the fact that the losses were obtained at 60 cycles, at a potential of about 5 kv., whereas, the insulation resistance was obtained with dire electromotive force of about 200 volts, the time of application being about one minute.

In other words, if we can connect up quantities obtained under such widely varying conditions, it is very interesting indeed, and the only way we can really determine it is to examine closely all of the available data to see if that is true. I know in a great deal of our experience we have come to the conclusion that we could not tie up these two factors, and although it has been done in Professor Whitehead's paper to some extent, I think the statement that he made in his paper bears the conclusion out that so far anyway we do not have a good direct relation between the two quantities of insulation resistance, taken as we take it, and dielectric energy loss obtained, as we take it.

I was impressed, upon reading the paper, that on making the measurements of loss, it was almost impossible to obtain them, because of the fact that the loss increased considerably even in a few moments, causing an increase of temperature which we know is cumulative, higher temperature resulting in higher loss, and even going so far as causing two of the samples to break down.

It is quite significant to note that one sample which broke down had practically the lowest loss of all, and there again we find a condition here which we meet in practise, That is, we have material which has a very low loss and yet we find its dielectric strength may also be low.

The general law, therefore, from our experience seems to be, that if we have relatively high loss we may expect low dielectric strength, whereas, if we have low loss we will not necessarily get high dielectric strength. There seems to be a point of low loss beyond which it is not necessary to go, to have high dielectric strength.

Further, in connection with the paper and also in connection with what Mr. Farmer has said, I would call to your attention the use of the property of power factor. If we express our results of tests upon insulation in terms of loss, in order that we may compare the results obtained by one observer with those obtained by others, we must know the exact physical dimensions of the samples, and it is very important because the loss measurement gives the total loss in the sample, and that will be determined by the size of the sample, the manner in which it is built up, the manner in which the voltage is applied, the kind of electrodes, etc.

Now, we have a property which, although varying to some extent, eliminates quite a few of those factors, and that, I believe, is the property of power factor, and if we could use power factor in our results, I believe it would come nearer to being a term which when one observer expressed his results as such and such a power factor, it could be used by other observers in comparing their results.

Now, if that is true (and I hope we may have other discussions on that), I believe it would be well worth while for us to consider that, because as I understand it, the insulation section of the engineering division of the National Research Council is interested in having available as far as possible the results of different observers, and if we can agree on some term in which we can express our results, so that they will be more nearly comparable, that of itself will be a step in advance.

W. A. Del Mar: There are two elements in research work which I think are not always recognized. The first element is the gathering of information, *i. e.*, the building up of knowledge in experimental work.

The other element is the inspirational, where the subconscious mind brings these data into juxtaposition and produces a new idea. Real progress in research cannot be made without these two elements.

Thus far, insulation research has been mostly of the former type, but the insulation problem is not like many of our problems, a matter of discovering some equations or series of equations which will give an answer to our questions. We are concerned with something that is very complicated, involving the effect of small quantities of air, small quantities of moisture, and the motions of exceedingly small particles of matter. We also have chemical problems. When there is ionization, nitrous oxide and ozone are formed, both of them exceedingly active chemically, and Professor Whitehead has shown us how those materials affect the insulation; but there is another effect that ionization produces. It changes mild surface leakage into streamer discharges thus setting up local surges of an exceedingly high frequency, and often of a violent character. It may be that most, or possibly all cases of laminated insulation failure are due to those local surges. It seems to me doubtful whether the actual voltage that you measure on the voltmeter is the real voltage that causes the disruption at a given point in the insulation. I think in every case there is a local gradient which is not measured on the instruments.

In the matter of cable performance, this matter of ionization is, as Mr. Farmer pointed out, a very live question. There are cables, to my knowledge, which are working with considerable ionization and working satisfactorily. There are others which are failing and apparently the failure is due to the presence of air. We don't understand the reason why in some cases the air seems to cause trouble and in other cases it does not. There is a big field for research work of a very interesting and important character. Mr. Whitehead's researches on ionization show a thorough realization of the vital point of attack in the insulation problem.

P. L. Alger: In looking over Mr. Whitehead's paper, I thought it would be interesting to bring out the relation between the state of the art as indicated by his results, and the parallel arts of cable insulation and condenser insulation. It is customary, I believe, in the manufacture of cables to operate at a voltage stress of perhaps fifty or sixty volts per mil and to have a power factor of five per cent or less. In condensers made of oil and paper it is usual to operate at several hundred volts per mil and to have power factors of one-half of one per cent, whereas in Mr. Whitehead's paper the experiments show a stress of perhaps forty volts per mil under normal conditions and a power factor of perhaps two-tenths. Of course, there are differences in the manufactures of the different types of apparatus which partly account for these differences in stress and power factor—for example in cables the insulation is protected from air by the outside sheath.

In armature coils the insulation is exposed to air, and therefore moisture and oxidation both give trouble. But I believe the major part of the differences is due to the fact that the binder used in the armature coil insulation is ordinarily some kind of shellac or other material, which is not physically stable at normal temperatures and which gives off volatile gases or boils at temperatures of fifty deg. cent. or more.

For this reason I feel that such a power factor-voltage curve as Mr. Farmer has drawn is not entirely reliable unless the temperature around the cable is lowered as the voltage is raised so as to preserve the same temperature inside the insulation throughout the tests. In this way only will a true curve of power factor against voltage that is independent of the temperature be obtained. I feel that the rise of power factor with temperature shown by Mr. Whitehead is due to the boiling away of some of the sticker or compounding material used, and consequently, that the best way to advance in this armature insulation art is to study the stability of the materials used under high temperatures. No electrical tests at all seem essential until a material is found which is satisfactorily stable and which will not give off gases until after temperatures of perhaps one hundred degrees are attained.

Alexander Nyman: I was particularly struck by the statement of Mr. Whitehead that on applying the pressure to insulation, the losses due to corona effect were reduced.

In building static condensers, particularly of the mica type, this effect is very pronounced. We find that in making condensers we have to apply the pressure whether mica or paper is used as insulator.

We have made samples of condensers where it was possible to observe the corona effect, visually, and we found in these condensers that even with the highest pressure applied, although the corona effect was reduced, it was not eliminated at high voltages, except by a special construction.

The only way to minimize the corona effect is to fill up all the smallest crevices in the insulation, with some other insulating compound, wax or varnish or anything that will eliminate air entirely. It is therefore necessary not only to apply the pressure, but also to evacuate the particular piece of apparatus and then impregnate it with the necessary material.

I would very much like to know what pressure Mr. Whitehead applied to the insulation in order to eliminate the losses altogether. The reason for the corona losses disappearing on this curve is, I believe, that the dielectric losses are large, and when you apply the pressure although the corona losses are not eliminated, they are so small that they become negligible compared to dielectric losses. In static condensers where the insulation is pure mica, the dielectric losses are small and the corona losses become important even at very high pressures.

In paper condensers, the effect is exactly the same as in mica condensers. You must not only apply the pressure but also fill in all the minutest spaces with some impregnating compound. There are different types of paper used in static condensers. For instance, I believe that some condensers have been manufactured with paper which has been impregnated before applying the condensers. I believe this is a mistake.

In general it will be found that with that kind of paper, although you can eliminate most of the air spaces, you can't eliminate all of them and there will still be losses. It is only a paper that can be impregnated throughout by some suitable compound that would give reduced losses.

I believe this will possibly shed some light on cable construction as well. I heartily agree with the statements of one of the speakers on the use of power factor in determining the quality of an insulation as far as dielectric losses are concerned.

Herman Halperin: Dr. Whitehead has stated that the $I^2 R$ loss in insulation is a small part of the dielectric loss and I understood Mr. Lee to say that the insulation resistance did not give any indication of the dielectric loss.

It has been found for the impregnated paper insulated cables bought for the Commonwealth Edison Company that as long as the manufacturer was using about the same kind of impregnating compound and paper, a curve of dielectric loss versus insulation resistance, similar to the one below, would be obtained.

I wish to agree with the other speakers in regard to the value of plotting the power factor of the charging current instead of dielectric loss, against voltage. As a matter of comparison between the various kinds of built-up insulation on cables, it might be well to use the maximum dielectric stress in the cable for the abscissa instead of the voltage, since it appears that the ionization in the cable starts at some definite dielectric stress for a given insulation.

I also want to emphasize the remarks made by one of the speakers as to the great value of any investigations along the lines of dertermining the effect of this ionization loss on the life of the insulation.

H. L. Curtis: One of the most interesting points in Dr. Whitehead's paper was his statement that he had come to the conclusion that there is no definite relationship between insulation resistance and dielectric loss. That is quite generally agreed to by most physicists. But dielectric loss is probably connected in some way with dielectric absorption as Professor Whitehead has said, though the exact way, the mathematical formula by which it is connected, we do not yet know.

It is a very difficult question as to how to measure insulation resistance. Much of the work that is reported as measurement of insulation resistance is merely a measurement of some type of absorption. The last speaker did not say how he measured his insulation resistance but I am of the opinion that he did not measure what we may call the true resistance, but in some way he was measuring an absorption phenomenon, and he is showing by that exactly what Dr. Whitehead brought out, namely, there is a connection between dielectric absorption and power factor.

J. C. Lincoln: The point brought out by Dr. Whitehead that mica was not injured by the effects of ionization was new to me. The question I want to ask is this: I imagine that the reason for the destruction of fibrous material is the production of ozone and nitrous oxides from the ionization of the gas.

I would like to know if that is the case, and also if these same materials, ozone and nitrous oxide, will affect such materails as rubber. I imagine they will, but are there other materials besides mica which are not affected by the production of ionization?

J. B. Whitehead: Several of the speakers beginning with Mr. Farmer have mentioned the power-factor curve as being perhaps the best method for determining the point at which losses begin. In the first section of my paper, presented at Swampscott, a number of power factor curves are given, and from the beginning we attempted to use the power factor curves as a means for detecting the point at which internal ionization begins.

In no single case did the power factor curve serve us in that connection. The power factor curves seem to run in a very erratic way, and show no marked breaks at the point at which the ionization sets in as determined by our own methods.

There was a definite break in the logarithmic curves and we have attributed this break to the beginning of ionization, particularly as pressure reduces the break in the curve.

It does not take a great deal of ionization to cause trouble. In the extreme cases we found the losses from ionization, those portions of the loss we could squeeze out of the sample, were relatively small. I have been wondering whether the ionization losses don't begin far down on the curve, but are still sufficiently small as not to reflect themselves very prominently. May we not have loss and still not yet reach a point where the cable is actually beginning to overheat, where the absorption itself and the major part of the dielectric loss which I take to be due to absorption, is not yet setting in in such a marked way that the cable itself is becoming unstable.

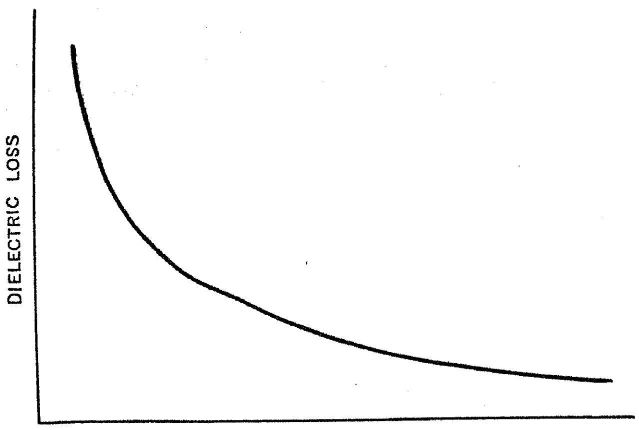

FIG. 1

If you carry any of this insulation sufficiently high in voltage you get to a point where the loss is cumulative, not due to ionization, but due to the increasing temperature caused by the dielectric loss directly due to dielectric absorption.

It seems to me there is one other reason why we should not rely too much on power factor as a quantity for defining the ionization point. Power factor, after all, involves two quantities, the dielectric costant, of course, and such losses as are in the dielectric. Why try to tie those two things together when they certainly may vary, each of them independently of the other.

As regards the destructive effects: I have another paper which was published I think in the December number of the JOURNAL which is a by-product of the work described in the present paper. The title of it is "The Influence of Gaseous Ionization on Fibrous Materials and Mica." The results are qualitative, but do show that gaseous ionization in very small amounts is quite sufficient to cause the most serious kind of deterioration of fibrous insulation of any kind within a few hours. Papers lose their calendered surfaces, lose their tensile strength. The whole mechanical structure of fibrous materials goes to pieces very soon, within the course of a few hours. We tried a number and none of them would stand up against ionization.

I think we also concluded very definitely that the most active agent was ozone. Nitrous oxides do not exist in air, in their own state, in any quantity, at least, at temperatures below several hundred degrees, so that it is fairly evident as shown in the paper referred to that the active agent is ozone. It is a slow oxidation, not rapid by any means. The results of this deterioration do not show up as ordinary combustion, as the blackening of the insulation. The deterioration seems to penetrate into the material in paths by some form of slow oxidation.

Mr. Lee pointed out in one case, at least, an armature bar having a very low dielectric loss was one of those to break down. That is perfectly true, but in the paper it is pointed out that the problem in applying mica in insulation of this character is largely one of uniformity and of being able to obtain a continuous product of high dielectric strength and good insulating properties uniformly through a course of continued factory production. So occasionally we unquestionably do find a bar well wrapped, in which the insulation is tight, and the internal ionization is low and which nevertheless fails. However, I think we reviewed a quite sufficiently large number of these bars to show that the one case of that kind that we found was simply fortuituous.

Mr. Del Mar has pointed out the importance of approaching this whole subject of insulation from a higher standpoint than we have done in the past and I simply want to call attention to the fact that the Engineering Committee of the National Research Council which is made up of our own research members, is attempting to take this higher viewpoint of the large mass of data that has been accumulated in this field of insulation. We are looking for assistance in carrying on that work, and if there are any here who themselves are interested, or know of others who are interested in the field of insulation, and are willing to take part in our present efforts of coordinating the results of the past, I would greatly appreciate it if they would communicate with me. We can give somebody a good, interesting and important job.

Mr. Alger, I think it was, pointed out his belief that the increase in the power factor is due to the boiling away of the material, the material of the binder. I don't know that I can make any comment on this except to point out that we have traced in this paper a very direct relation between the ionization loss itself and the life of the bars. We find that a bar which has low ionization loss, when it is tightly wrapped, and in which it is impossible to squeeze out any ionization loss is the bar which goes on and shows the longest life and vice versa. Unquestionably the bars with the greatest amount of ionization loss in them immediately show a tendency to run down or break down.

Mr. Dawes' comments were really made principally on the other paper I have referred to, which was published in the JOURNAL and which we are not discussing here.

As regards the pressure: One of the speakers, Mr. Nyman, has asked what the pressure was that was used here, and raised the question as to whether all of the ionization loss was squeezed out. I quite agree with him that it is not all squeezed out, but we were able to squeeze it down to a point where the logarithmic loss is very straight. It did not seem to be worth while to attempt to measure the actual pressures that were used in this case. It was quite evident that this ionization loss must be very variable; it must be present in varying amounts, even in different parts of the same sample, and so the difficulty that would be encountered in measuring pressures, while one is also applying high voltage, led us to simply try to obtain approximately the same pressure for all these samples. That we did by constructing a special form of clamp in which the screws of this clamp were applied uniformly all over the surface and tightened up approximately to the same amount.

Mr. Halperin raises the question as to the $I^2 R$ square loss. $I^2 R$ loss as computed from the insulation resistance of the sample is unquestionably a very small part of the total loss. In that connection we can only consider the resistance as determined from the final value of the leakage current through the sample. If you apply continuous voltage, leave it long enough for the current to maintain a steady value, use that current

as the basis of calculation of resistance, and then compute loss on the basis of that resistance, it will be found to be an extremely small part of the total observed loss.

As regards my comments in connection with insulation resistance, I mean to point out only that it seemed to me that it would be better if we used dielectric absorption itself as a means and a method of describing the material, rather than to speak of the insulation resistance. There is undoubtedly a very definite relation all the way through an experiment of this kind, between the value of the direct current which will be observed after one minute, and the alternating current dielectric losses which will be observed. In other words, as the resistance curves go up, indicating increased resistance, the loss curves come down, but the same thing would be found for a continuous curve measured at any other interval, whether one or two minutes, or one or two hours, and the connection is between absorption and loss and not between resistance and loss. I think it must be conceded unless there is some feature that hasn't come to my attention, that it is perfectly obvious that the great portion of loss of dielectric is due to the dielectric absorption and to nothing else.

Overdamped Condenser Oscillations

BY CHARLES P. STEINMETZ*
Fellow, A. I. E. E.
Chief Consulting Engineer, General Electric Co.

Review of the Subject.—*In the classical equations of the discharge of a condenser of capacity C into an external circuit of resistance r and inductance L, it is found that the discharge is oscillatory if* $r < \sqrt{\frac{4L}{C}}$, *and is impulsive if* $r > \sqrt{\frac{4L}{C}}$.

As the perfect condenser can never be realized in practise, it is the purpose of this paper to show the effect of the condenser leakage on the discharge wave.

The imperfect condenser is represented by the perfect condenser C shunted by the conductance g. This condenser discharges into the circuit L and r as above. The mathematical discussion shows that no matter what the relation between r and $\sqrt{\frac{4L}{C}}$, *there may always exist some value of g for which the discharge is oscillatory. This is the case when*

$$(r/L - g/C) < \sqrt{\frac{4}{LC}}$$

$$i, e., r < \sqrt{\frac{4L}{C}} + \frac{gL}{C}$$

It is to be borne in mind that the above holds true only when r, L, C, and g are constant. If the resistance is that of a third class conductor, the discharge will always be oscillatory.

An apparent paradox is found in the statement that the current may be more than 90 deg. out of phase with the voltage. A study of the derived equations, remembering that the current under consideration is only one of the two components forming the total discharge current $\left(C\frac{de}{dt}\right)$ *of the condenser (the leakage current ge being the other), will show that this is true. A study of the oscillograms will further confirm the theory.*

I. General and Experimental

THE classical equations of the condenser discharge through an inductive circuit show that the discharge is oscillatory, if the resistance of the discharge circuit is less than a certain critical value $2\sqrt{L/C}$; and in this case the damping of the wave is goemetric, that is, the quotient of two successive half waves is constant. The discharge is impulsive, if the resistance of the discharge circuit is greater than the critical value.

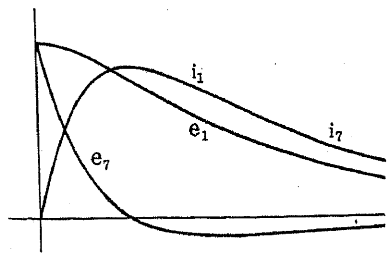

Fig. 1

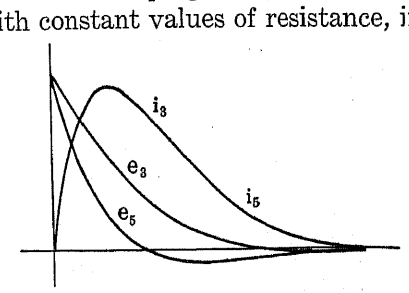

Fig. 2

This, however, applies only if the circuit factors: resistance, inductance and capacity, are actually constant. It does not apply if the resistance is that of a third class conductor, that is, if the potential drop across the resistance decreases with increase of current. In this case the discharge is always oscillatory, but the damping is either arithmetic, that is the difference of two successive half waves is constant, or it is a combination of arithmetic damping and geometric cumulation.[1]

Even with constant values of resistance, inductance, and capacity, the classical condenser discharge equations hold only for the *ideal condenser*, that is, a condenser in which no energy losses occur. *If energy losses occur in the condenser*—as is usually the case—*the discharge remains oscillatory even for values of the discharge resistance greater than the critical value* $2\sqrt{L/C}$, and the discharge oscillates the more, the higher the

*Deceased.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

1. See A. I. E. E.

energy losses in the condenser. No matter how high the resistance of the discharge circuit, there always exists a value of energy loss in the condenser (which depends on the value of the discharge resistance) at which no impulsive discharge is possible, but the discharge is always oscillatory. This occurs when the

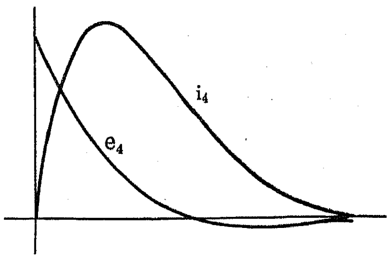

Fig. 3

damping of the wave due to energy losses in the condenser, equals that due to the discharge resistance. The damping is then geometric.

The frequency of the oscillation, and the limit up

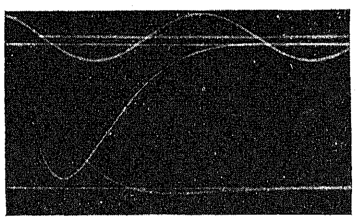

Fig. 4

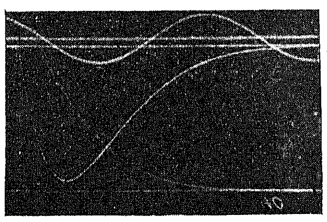

Fig. 5

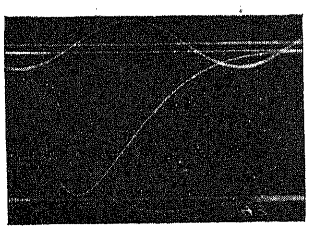

Fig. 6

to which the discharge is oscillatory, depends on the *difference* between the power dissipation in the discharge resistance, and that in the condenser losses, while the attenuation or damping of the discharge wave depends on the *sum* of the losses. As a result of the combined losses, such discharge waves may have rates of attenuation far greater than possible in the classical equations of the ideal condenser. They may therefore be called *Overdamped Oscillations*.

In such overdamped discharge oscillations of the imperfect condenser, only a fraction of the first half wave may be of appreciable magnitude. That is, in

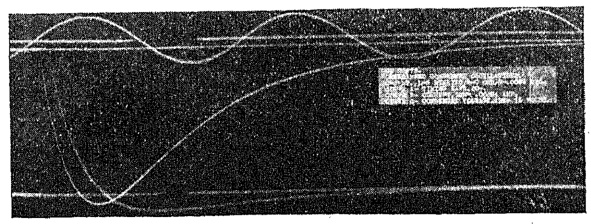

Fig. 7

the current wave, the maximum (which with the alternating wave occurs at 90 deg., and with a wave of low damping near 90 deg.) may occur at 20 deg. to 30 deg. and still earlier; the wave from then is very much steeper than the wave tail, similar to the case in the non-oscillatory impulse; the wave shape however,

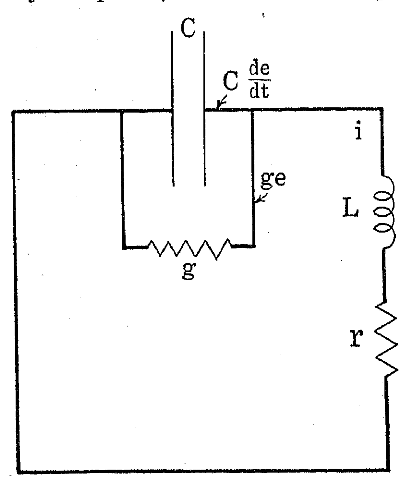

Fig. 8

differs from the latter, and the current and voltage wave pass through zero at a definite point, while in the non-oscillatory impulse they never reach zero, but gradually fade out.

As illustrations are shown in Figs. 1 to 3 the calculated current and voltage waves and in Figs. 4 to 7

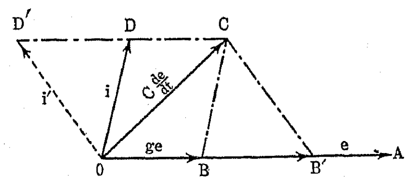

Fig. 9

the observed oscillograms of a series of such overdamped condenser discharge waves, for a condenser of $C = 5\ \mu$f. capacity discharging through an inductance of 5 henrys. This gives the critical resistance $r_0 = 2\sqrt{L/C} = 2000$ ohms.

As (1) is shown the discharge, given by the classical equations for zero condenser loss and a discharge resistance of $r = 2400$ ohms, that is, an impulsive or unidirectional discharge.

In (2) the discharge resistance has been reduced to 2100 ohms (which with a loss free condenser would still give an impulsive discharge) but such a power dissipation in the condenser has been assumed, as to give the same damping constant as (1). The discharge then has become oscillatory.

(3) to (7) give the discharges for successively lower discharge resistances. $r = 1800$, 1200, 600, 300 and 0 ohms, but with successively increased power dissipation in the condenser, so as to give the same total resultant dissipation constant. As seen, in (7), for zero discharge resistance, the discharge has again become impulsive, due to the strong damping by the condenser losses, although the shape of the voltage impulse is very different from that in (1). The frequency of the discharge increases with increasing condenser losses, up to (4), the case at which the condenser losses equal the losses in the external circuit and the condenser losses neutralize the effect, on the frequency, of the discharge resistance, and the frequency is the same as that of an undamped wave.

(1) to (7) thus give forms of waves, of the same condenser discharging through the same inductance with the same damping, that is, the same attenuation constant, but the losses, that is, the power dissipation which causes the damping, shifting from all in the external circuit and none in the condenser, in (1) to all in the condenser and none in the external circuit, in (7). As seen, the current waves in (7), (6) and (5) are the same as in (1), (2) and (3); but the voltage waves are materially different.

As a further illustration, the current and voltage discharge waves of the same condenser are calculated, $C = 5\ \mu$f. over the same inductance $L = 5$ henrys, and a constant discharge resistance $r = 2400$ ohms, and with amounts of power dissipation in the condenser, varying from zero in (1), up to a value in (5), which doubles the dissipation constant of the discharge.

II. Mathematical

Let:

C = Capacity of the condenser

L = Inductance of the discharge circuit

r = Resistance of the discharge circuit (including the effective resistance representing the energy losses in the inductance).

If energy losses occur in the condenser, an energy component occurs in the condenser current, which can be represented by an effective shunted resistance or shunted conductance. Thus let:

g = Effective shunted conductance representing energy losses in the condenser.

We thus have, in the general case:

C = Coefficient of energy storage by the voltage, in the capacity of the condenser

L = Coefficient of energy storage by the current, in the inductance of the external circuit

g = Coefficient of power dissipation by the voltage in the effective shunted conductance of the condenser

r = Coefficient of power dissipation by the current, in the (effective) resistance of the external circuit

Let:

e = Voltage at condenser terminals, with $e = e_0$ a initial value at time $t = 0$

i = Current in the external circuit, with $i = 0$ a initial value.

It is then:

In the external circuit:

$$e = L \frac{d\,i}{d\,t} + r\,i \qquad (1$$

In the condenser:

$$-\,i = C \frac{d\,e}{d\,t} + g\,e \qquad (2$$

Substituting (1) and its differential into (2) give the differential equation of current:

$$\frac{d^2 i}{d\,t^2} + 2\,u \frac{d\,i}{d\,t} + \frac{1 + r\,g}{L\,C}\,i = 0 \qquad ($$

where:

$$u = 1/2\,(r/L + g/C) \qquad ($$

is the attenuation constant, and

$$m = 1/2\,(r/L - g/C) \qquad ($$

is the distortion constant.[2]

Equation (3) is integrated in the usual manner terms of the form:

$$i = A\,\epsilon^{-ct}$$

which, in the case that c becomes imaginary, combine a term:

$$i = B\,\epsilon^{-ct} \sin q\,t$$

and by the substitution of the terminal conditions, giv

A. Impulsive Discharge

$$m^2 > \frac{1}{L\,C}$$

$$i = \frac{e_0}{2\,s\,L}\left(\epsilon^{-c_1 t} - \epsilon^{-c_2 t}\right)$$

$$e = e_0\left(\frac{m+s}{2\,s}\,\epsilon^{-c_1 t} - \frac{m-s}{2\,s}\,\epsilon^{-c_2 t}\right)$$

where:

$$\left.\begin{aligned} c_1 &= u - s \\ c_2 &= u + s \end{aligned}\right\}$$

2. See A. I. E. E., "The General Equation of the Ele Circuit," 1907. Also: "Theory and Calculation of Tran Phenomena, Section IV," page 462, 509.

$$s = \sqrt{m^2 = \frac{1}{L\,C}} \qquad (10)$$

The current is a maximum at the time:

$$t = \frac{\log c_2 - \log c_1}{2\,s \log \epsilon} \qquad (11)$$

B. CRITICAL DISCHARGE

$$m^2 = \frac{1}{L\,C} \qquad (12)$$

$$i = e_0/L\,t\,\epsilon^{-ut} \qquad (13)$$

$$e = e_0\,\epsilon^{-ut}\,(1 + m\,t) \qquad (14)$$

The current is a maximum at the time:

$$t = \frac{1}{u} \qquad (15)$$

C. OSCILLATORY DISCHARGE

$$m^2 < \frac{1}{L\,C} \qquad (16)$$

$$i = \frac{e_0}{q\,L}\,\epsilon^{-ut} \sin q\,t \qquad (17)$$

$$e = e_0\,\epsilon^{-ut}\,(\cos q\,t + m/q \sin q\,t) \qquad (18)$$

where:

$$q = \sqrt{\frac{1}{L\,C} - m^2} \qquad (19)$$

The current is a maximum at the time:

$$\tan q\,t = q/u \qquad (20)$$

As seen, with increasing energy loss in the condenser, m decreases to zero and then becomes negative, and the phase relation between voltage and current thus changes from less than quadrature to quadrature to more than quadrature.

Although at first glance this statement may seem impossible, and may be impossible for steady conditions, we believe that this, like many other seeming paradoxes in the study of transients, is perfectly true.

Referring to the diagrams, in Fig. 8 the capacity c, shunted by the conductance g, represents the imperfect condenser.

$c \dfrac{d\,e}{d\,t}$ = current supplied by condenser

$g\,e$ = current through g (through imperfect condenser)

i = current through L and r (external circuit)

e = condenser voltage

(1) The current $g\,e$, being through the pure resistance g, must be in phase with the voltage e.

(2) The vector sum of the currents through the external circuit (L and r) and through g must be equal to the current supplied by the condenser.

In Fig. 9

$A\,O$ represents the condenser voltage e

$B\,O$ represents the current $g\,e$ in phase with e

$C\,O$ represents the condenser current $C \dfrac{d\,e}{d\,t}$, out of phase with e by the angle $C\,O\,A$

$D\,O$ represents the external current i, out of phase with e by the angle $D\,O\,A$

Now, change the circuit constants (g, L, and r) so that $C \dfrac{d\,e}{d\,t}$ has the same relation to e as before, but $g\,e$ has taken the position $O\,B'$. Then, as the vectorial sum of $i/g\,e$ must be equal to $C \dfrac{d\,e}{d\,t}$, then i must take the position $O\,D'$ which is displaced from c by the angle $D'\,O\,A$ obviously greater than 90 deg.

A study of oscillograms for cases 5, 6 and 7 of the first instance given in the paper will corroborate the above analysis.

D. NOTES

The energy dissipation in the system is given by the same equations in all three cases, as:

$$r\,(I^2) + g\,(E^2) = r \int_0^\infty i^2\,d\,t + g \int_0^\infty e^2\,d\,t$$

$$= \frac{r\,e_0^2\,C}{4\,L\,u\,(l + r\,g)} + \frac{g\,e_0^2\,(l + u\,r\,C)}{4\,u\,(l + r\,g)} \qquad (21)$$

The current slope is a maximum for:

$$\left|\frac{d\,i}{d\,t}\right|_{t=0} = e_0/L$$

The voltage slope is a maximum for:

$$\frac{d^2\,e}{d\,t^2} = 0$$

at:

$$\tan q\,t = \frac{q^2 - u^2}{2\,q\,u}$$

$$\frac{d\,e}{d\,t} = -\,e_0\,\epsilon^{-ut}\,(u \cos q\,t + q \sin q\,t)$$

In the classical equations of the condenser discharge, the term $\dfrac{r}{2\,L}$ takes the place of both of the terms, u and m, of the general equations.

III. Instances

As an instance, let: e_0 = 10,000 volts.

C = 5 μf. = 5×10^{-6} = capacity of condenser

L = 5 henrys = inductance of discharge circuit, thus:

$z_0 = \sqrt{L/C}$ = 1000 ohms = surge impedance, and

$r = 2\,z_0 = 2000$ ohms = critical resistance, at which the discharge of the ideal condenser changes from oscillatory to impulsive.

$$\frac{1}{L\,C} = 200 = \text{frequency constant.}$$

Choosing then the discharge resistance r, and the shunted conductance of energy loss in the condenser g, so as to give a constant attenuation, that is, at constant total attenuation u, the energy losses are divided between the external circuit and the condenser, in different proportions.

$$u = 1/2\,(r/L + g/C) = 240$$

Seven cases are given in Figs. 1 to 3 and oscillograms Figs. 4 to 7, for the constants:

	(1)	(2)	(3)	(4)	(5)	(6)	(7)
No. Figs.	1	..	2	3	2	..	1
	..	..	4	5	6	..	7
$r =$	2400	2100	1800	1200	600	300	0 ohms
$g =$	0	0.3	0.6	1.2	1.8	2.1	2.4×10^{-3} mhos
thus $m =$	240	180	120	0	−120	−180	−240
$q = \sqrt{\frac{1}{L\,C} - m^2} =$	..	87.2	160	200	160	87.2	..
$s = \sqrt{m^2 - \frac{1}{L\,C}} =$	132.6	..	..	..	..	..	132.6

Current	Terminal Voltage at Condenser
(1) $i = 7.55\,(\epsilon^{-107.4t} - \epsilon^{-372.6t})$	$e = 10000\,(1.41\,\epsilon^{-107.4t} - .41\,\epsilon^{-372.6t})$
(2) $i = 23\,\epsilon^{-240t}\sin 87.2t$	$e = 10000\,\epsilon^{-240t}(\cos 87.2t + 2.07 \sin 87.2t)$
(3) $i = 12.5\,\epsilon^{-240t}\sin 160t$	$e = 10000\,\epsilon^{-240t}(\cos 160t + .75 \sin 160t)$
(4) $i = 10\,\epsilon^{-240t}\sin 200t$	$e = 10000\,\epsilon^{-240t}\cos 200t$
(5) $i = 12.5\,\epsilon^{-240t}\sin 160t$	$e = 10000\,\epsilon^{-240t}(\cos 160t - .75 \sin 160t)$
(6) $i = 23\,\epsilon^{-240t}\sin 87.2t$	$e = 10000\,\epsilon^{-240t}(\cos 87.2t - 2.07 \sin 87.2t)$
(7) $i = 7.55\,(\epsilon^{-107.4t} - \epsilon^{-372.6t})$	$e = 10000\,(-.41\,\epsilon^{-107.4t} + 1.41\,\epsilon^{-372.6t})$

In the oscillograms, as nearly as possible the same constants were chosen, and as seen, the oscillograms are identical in wave shape with the calculations, (except for a slight inductive effect at the beginning of the voltage wave). For convenience, the current is shown in reverse direction, and as time measure, a 60-cycle wave is given.

As a second instance, consider:

The same e_0, C, L, z_0, etc. but a constant value of the discharge resistance:

$$r = 2400 \text{ ohms}$$

and various values of shunted conductance g, from zero to a value equal in energy dissipation to r. That is:

	No.	(1)	(2)	(3)	(4)	(5)
	$g =$	0	.3	.6	1.2	2.4×10^{-3} mhos
thus	$u =$	240	270	300	360	480
	$m =$	240	210	180	120	0
	$q =$	..	..	87.2	160	200
	$s =$	132.6	64.2	..	..	..

Current	Voltage at Condenser Terminals
(1) $i = 7.55\,(\epsilon^{-107.4t} - \epsilon^{-372.6t})$	$e = 10000\,(1.41\,\epsilon^{-107.4t}\epsilon .41\,\epsilon^{-372.6t})$
(2) $i = 15.6\,(\epsilon^{-205.8t} - \epsilon^{-334.2t})$	$e = 10000\,(2.14\,\epsilon^{-205.8t} - 1.14\,\epsilon^{-334.2t})$
(3) $i = 23\,\epsilon^{-300t}\sin 87.2t$	$e = 10000\,\epsilon^{-300t}(\cos 87.2t + 2.07 \sin 87.2t)$
(4) $i = 12.5\,\epsilon^{-360t}\sin 160t$	$e = 10000\,\epsilon^{-360t}(\cos 160t + .75 \sin 160t)$
(5) $i = 10\,\epsilon^{-480t}\sin 200$	$e = 10000\,\epsilon^{-480t}\cos 200t$

Discussion

Prof. V. Karapetoff: I should like to draw your attention to a simple mechanical model which is represented mathematically by the same differential equations as the electric circuit discussed in the paper. Think of a horizontal helical spring attached at one end to an immovable wall and at the other end to a mass supported on frictionless rollers. Let there also be a tank with viscous fluid, and let a vane attached to the mass be immersed in it. Without this viscous fluid we would have a simple oscillating system; by starting it from a position which is not one of equilibrium, and letting it go, we would produce oscillations which theoretically would go on forever. By adding a vane and a viscous liquid we get damped oscillations; mathematical equations for this system are exactly the same as the equations for a circuit containing R, L and C, but no leakage.

Now, to imitate the circuit which Dr. Steinmetz considers, we shall remove the solid wall and replace it by a yielding reaction which we can imagine to be a cylinder, with a piston, a piston rod to which the above spring is attached, and a by-pass between the two sides of the piston. Let the cylinder be filled with a viscous fluid. The liquid circulating through the by-pass will constitute a yielding support for the spring.

If the support is immovable, there is only one differential equation, but by adding this yielding support, you add a second equation, namely, that the velocity of motion of the mass consists of the velocity due to the compression of the spring plus that due to the conductance of the by-pass. This gives Steinmetz' second equation. This model enables us to study and to visualize, so to say, this electric circuit. If you cannot see from the equations why the circuit becomes more oscillatory by the addition of that by-pass, your engineering intuition might tell you that this is so from an inspection of the model.

If for purely qualitative analysis, this model is too complicated, you can use a simple pendulum. Suspend a simple pendulum in a viscous fluid and you get the first equation in the paper. Add a yielding support, and kind of imperfect support, and you get the second equation of the paper. To record the phenomenon under discussion put a soft brush on the pendulum, dip it in ink, and let the brush make a record on a piece of paper moving at a uniform speed past the pendulum.

Free Convection of Heat in Gases and Liquids-II

BY CHESTER W. RICE

Associate, A. I. E. E.

Research Laboratory, General Electric Co.

Review of the Subject.—*The present paper is an extension of my earlier work which was found necessary in order to account for the observed convection for both large and small temperature differences.*

General expressions are developed, by the method of dimensions, which enable us to calculate the convection from any system of similar bodies when the three undetermined constants K, m, and n have been experimentally determined.

The available experimental data for horizontal and vertical cylinders, spheres and plane surfaces have been analyzed and the results expressed in the form of simple equations.

Introduction

In the discussion of my recent paper on convection,[1] Montsinger called my attention to the fact that the free convection from large vertical plane surfaces varies as the 5/4 power of the temperature difference, whereas my equations made the watts convection vary approximately as the first power of the temperature difference for small temperature rises.

A careful study was therefore made of the available data on free convection from plane surfaces. The previous theory assumed that the film thickness was independent of the temperature difference and merely depended upon the ambient properties of the fluid. The watts convection should therefore be directly proportional to $\Delta \varphi$. In Fig. 3 the available data on free convection from vertical plane surfaces have been plotted against $\Delta \varphi$ and also against Δt on log: log paper. A 45 deg. line has been drawn through the w_c vs. $\Delta \varphi$ points as required by the previous theory. Above 100 deg. cent. temperature difference the agreement is satisfactory but for the lower temperature differences the points depart systematically from the 45 deg. line by more than the probable errors. On the other hand it will be seen that the data are well represented by the 5/4 power of the temperature difference.

We are therefore forced to conclude that at least for large surfaces and small temperature rises the film thickness is a function of the temperature difference. Langmuir[2] has pointed out that for extremely small temperature differences the film thickness should increase without limit. It may be of interest to know that when the previous work was being written a more general dimensional expression for the film thickness which included the additional variables of temperature difference and temperature coefficient of density change was investigated and abandoned because the simpler expression appeared to satisfy the data then under investigation.

In view of the lack of agreement between theory and experiment for low temperature differences it seemed desirable to re-examine the high and low temperature data on the basis of the most general expression for the film thickness so as to obtain if possible a single expression which would be universally applicable for both large and small temperature differences. In the following paper it will be shown that the desired universal expression exists.

General Expression for Effective Film Thickness in Free Convection

Assume that the film thickness will depend on the temperature difference, the coefficient of density change per degree temperature change, the acceleration of gravity and the density and viscosity. Thus the driving force of the convection currents will be proportional to the difference in density produced by the expansion times the acceleration of gravity and it is the viscosity which opposes this driving force. The motion will obviously depend upon the shape of the hot body. The film thickness may also depend upon the rate at which heat is transmitted through the film and the specific heat. The addition of these variables also allows us to include the effects of heat carried by the slow mass motion within the film. We will therefore assume that the ratio of film thickness to the size of the body is given by the following expression.

$$B/D = K\,(\alpha\, g)^x\, \Delta\, t^y\, D^z\, \mu^p\, \rho^n\, k^m\, c_p^{\,r} \tag{1}$$

where B = Film thickness (L)

D = A linear dimension (L)

K = A numerical constant

α = Coefficient of density change per deg. cent. (θ^{-1})

g = Acceleration of gravity $(L\,T^{-2})$

Δt = Temperature difference deg. cent. (θ)

μ = Viscosity of fluid $(L^{-1}\,M\,T^{-1})$

ρ = Density of fluid $(M\,L^{-3})$

k = Heat conductionly of fluid $(H\,L^{-1}\,T^{-1}\,\theta^{-1})$

c_p = Specific heat per gram at constant pressure $(H\,M^{-1}\,\theta^{-1})$

Substituting the dimensions of the various factors in equation (1) we obtain

$$O = (L\,T^{-2}\,\theta^{-1})^x\,(\theta)^y\,(L)^z\,(L^{-1}\,M\,T^{-1})^p\,(M\,L^{-3})^n\,(H\,L^{-1}\,T^{-1}\,\theta^{-1})^m\,(H\,M^{-1}\,\theta^{-1})^r \tag{2}$$

2. Irving Langmuir, *Trans.* Amer. Electro-Chem. Soc., Vol. XXIII, page 318, April 1913.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924. An abstract of this paper was presented at the Cincinnati meeting of the Am. Phy. Soc. Dec. 1923. See also discussion Jour. A. I. E. E., Dec. 1923. A companion paper on Forced Convection of Heat in Gases and Liquids-II will be presented at the April meeting of the Am. Chemical Society.

From which we obtain the following system of simultaneous equations:

$$\left.\begin{array}{ll} \text{By Length} & O = x + z - p - 3\,n - m \\ \text{Mass} & O = p + n - r \\ \text{Time} & O = -\,2\,x - p - m \\ \text{Heat} & O = m + r \\ \text{Temperature} & O = -\,x + y - m - r \end{array}\right\} \qquad (3)$$

The solution of the simultaneous equations (3) gives the following relations:

$$\left.\begin{array}{l} x = n/2 \\ y = n/2 \\ z = \dfrac{3\,n}{2} \\ p = -\,n - m \\ r = -\,m \end{array}\right\} \qquad (4)$$

From physical considerations we know that the film thickness should increase with the viscosity of the fluid. We therefore change the sign of n and substitute the relations (4) in equation (1) and obtain

$$B/D = K\left[\frac{\nu}{(\alpha\, g\, \Delta\, t)^{1/2}\, D^{3/2}}\right]^{n}\left(\frac{k}{\mu\, c_p}\right)^{m} \qquad (5)$$

where $\nu = \mu/\rho$ = Kinematic viscosity of fluid.

Free Convection from Horizontal Cylinders

In order to correlate the data in different fluids and at different temperature differences, it was necessary to determine the temperature at which ν, α, k, μ, c_p, should be taken. A study of the data in gases and liquids showed the best agreement by taking the value of the variables at the average of the surface and ambient temperatures.

In Table I the available data have been recalculated from Tables VII and X of the free convection section of the previous paper.[1] For perfect gases the factor $k/\mu\, c_p$ in equation (5), is practically independent of temperature and pressure and does not vary greatly from one gas to another.[3] For gases this factor was therefore omitted and the calculated values of B/D were plotted against $\nu_{avg.}/[(\alpha\, g\, \Delta\, t)^{1/2}\, D^{3/2}]$ on log:log paper. The points all fell on a smooth curve as demanded by the theory. An exponent $n = \frac{1}{2}$ was selected as a close approximation and the corresponding values of K_1 have been calculated in Table I, column XIII. Inspection of column XIII under liquids, shows a different value of K_1, from that obtained for the gases and also a variation of the constant among the different liquids. It is therefore apparent that the factor $k/\mu\, c_p$ in equation (5) cannot be neglected. By trial it is found that an exponent of $m = \frac{1}{4}$ brings the data for gases and liquids into agreement. In Fig. 1 we have plotted $(B/D)\,(\mu\, c_p/k)^{1/4}$ vs. $\nu_{avg.}/[(\alpha\, g\, \Delta\, t)^{1/2}\, D^{3/2}]$ on log:log paper. It will be seen that all of the points fall on a single curve within the probable experimental errors. There seems to be a tendency for the slope of the curve to gradually increase for large values of $(B/D)\,(\mu\, c_p/k)^{1/4}$. The single straight line which best represents the points, has a slope of $n = 0.54$. The value of K found by averaging all of the points, assuming $n = 0.54$, is $K = 2.60$. The line of slope $n = \frac{1}{2}$ has been drawn in such a manner as to give most weight to the last 17 points, since the accuracy of determining $(B/D)\,(\mu\, c_p/k)^{1/4}$ is greater for thin films, assuming equal accuracy in determining the watts convection. Thus for $n = \frac{1}{2}$ we take $K = 2.12$.

The values of $k/\mu\, c_p$ for gases in column XIV were obtained by dividing the value for $k/\mu\, c_v$ given by Jeans[3] by the values of γ as function of pressure from Landolt Bornstein Tabellen. The values assumed for the liquids will be found in Table II of the next section.

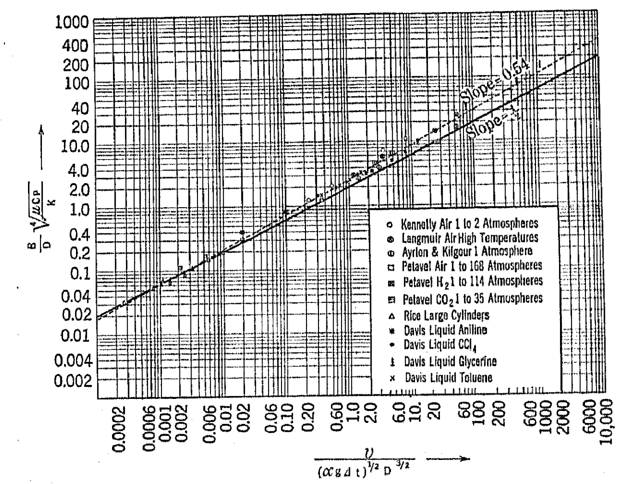

Fig. 1

Calculation of Heat Conductivity of Liquids from Free Convection Tests

The assumptions of the previous paper[1] lead to equations from which the heat conductivity of fluids could be calculated from convection tests when the viscosity and density were known for the ambient temperature alone. The more general expression (5) now found to be necessary, to completely satisfy the available data, requires a knowledge of the viscosity, density and temperature coefficient of density change, as functions of temperature, as well as an approximate knowledge of the heat conductivity and specific heat, before calculations of the heat conductivity can be made. It is therefore now apparent that free convection tests do not constitute a primary method of obtaining heat conductivities. It will be observed, however, that the heat conductivity enters the equation for the film thickness to the $\frac{1}{4}$ power only, so that the method is still of interest where an approximate value of the heat conductivity already exists. In Table II we have recalculated the heat conductivities on the present basis from the data given in Tables IX and XI of the previous paper.[1] The film thickness

has been determined from equation (5), in which $K = 2.60$; $n = 0.54$ and $m = \frac{1}{4}$. The available data on viscosity as function of temperature appear to be satisfactory except for glycerine and olive oil. For glycerine the existing data have been extrapolated to higher temperatures by plotting the fluidity $1/\mu$ against temperature on semi-log paper, since, under these conditions, the points lie almost on a straight line. For olive oil a pure guess has been made, as follows: Osborne Reynold's data[4] on fluidity for a certain olive oil have been plotted on semi-log paper and a parallel line drawn through the fluidity given by

Davis[5] for olive oil at the assumed temperature of 18 deg. cent.

In Fig. 2 the calculated heat conductivities have been plotted against temperature, from which we see that the temperature coefficients are now negative for all the liquids except for olive oil, whereas, the method of the previous paper [1] gave positive temperature coefficients. There are very little data in the literature on this susbject and of this some investigators find negative and others positive values for the coefficient for the same liquid. It is interesting to note that

5. A. H. Davis, *Phil. Mag.*, Vol. 44, p. 929, 1922

Bridgman's[6] recent determinations show negative temperature coefficients of conductivity for all of the fifteen liquids which he has studied. In Table III I have, therefore, compared the present calculated heat conductivities with the data by those investigators who have found negative coefficients where available. The value calculated for olive oil cannot be given much weight, due to the uncertainty of the viscosity value.

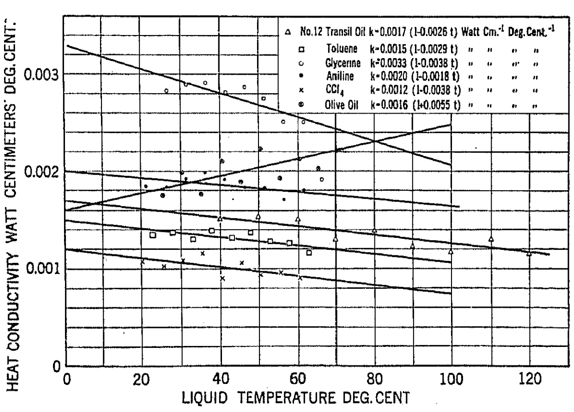

FIG. 2

FREE CONVECTION FROM LONG VERTICAL CYLINDERS

For this case we have the data by Griffiths and Davis[7] on a series of cylinders 17.43 cm. diam. and of various lengths up to 263.5 cm. In these experiments we are dealing with thin films and moderate temperature differences and may therefore write

$$W_c = (A/B)\, k_{avg.}\, \Delta\, t \text{ watts convection} \qquad (6)$$

Since the tests are made in air we may omit the second factor in equation (5) and express the film thickness as

$$B = K_1 D \;\{\nu/[(\alpha\, g\, \Delta\, t)^{1/2}\, D^{3/2}]\}^n \text{ cm.} \qquad (7)$$

When we plot the watts convection per unit length against the temperature rise on log:log paper for the four longest cylinders we find that all points fall on a single curve as should be the case, when the length is large compared with the diameter. Actually the shortest of the four cylinders is only a little over three times the diameter. From the slope of the curve we find that the watts convection per cm. length is approximately proportional to the 4/3 power of the temperature difference. If we put $n = 2/3$ in equation (7) and substitute the value of B in equation (6) and take ν at the average of the surface and ambient temperature we obtain.

$$W_c = \frac{\pi\, D\, L\, (\alpha\, g)^{1/3}}{K_1}\, (k/\nu^{2/3})_{avg.}\, \Delta\, t^{4/3} \text{ watts} \qquad (8)$$

This equation is seen to be of the proper form since the factor $k/\nu^{2/3}$ only varies by about 4 per cent in the temperature range covered by the experiments. In the last column of Table IV the values of K_1 have been calculated from the data on the longest cylinder. Data in liquids are needed in order to determine the exponent m in equation (5).

FREE CONVECTION FROM SPHERES

In the first paper[1] Compan's[8] data on the free and forced convection from spheres were used to determine the convection laws. In the course of the present work I have re-examined Compan's data and compared them with the work of Péclet[9] and M'Farlane[10] with the result that Compan's experiments do not agree at all with the others. It seems probable that the trouble with Compan's work is due to the use of a small sphere covered with a thick coat of lamp black. For small spheres the ratio of film thickness to diameter is greater than for larger spheres, but the actual film thickness will be smaller, and therefore a relatively thin coat of poorly conducting lamp black may easily double the effective film thickness on small objects. The total emissivity for a lamp black surface calculated from Compan's data gives $E = 0.43$ at 200 deg. cent. as compared with the now commonly accepted value of approximately 0.9. We are thus led to conclude that Compan's thermocouple did not give the surface temperature. In the present work his data have therefore been discarded.

Péclet worked with three hollow copper spheres, 7.46, 10.58 and 15.38 cm. in radius, filled with water. These were placed in a water-jacketed constant-temperature cylindrical enclosure 100 cm. high and 80 cm. in diameter. The water in the sphere and jacket of the enclosure was kept in constant agitation and the surface temperatures assumed to be the same as that

of the water. He eliminated the radiation from his observations in the following manner: He determined the total rate of heat loss under given temperature conditions for a lamp-black-covered copper sphere and later under the same conditions, except that the sphere surface was highly polished. The difference of these results gives the difference in radiation for lamp black and polished copper surfaces, since the convection is independent of the nature of the surface. He next obtained the ratio of radiation from a lamp black surface to that of a polished copper surface by measurements with a thermopile. Having thus determined the difference in radiation and the ratio of the two radiations he solved for the absolute value of each. The lamp black surfaces were obtained by first covering the object with paper and then depositing lamp black on the paper from a flame. To see whether the presence of the paper influenced the convection he determined the total rate of cooling with 1, 2, 3 and 4 sheets of paper applied to the object without finding any noticeable change. For spheres of this size in air the film thickness is of the order of ½ cm. and since the conductivity of paper is approximately 4 times that of air only a small proportion of the total temperature drop will be consumed by the paper.

In this manner Péclet obtained the following equation for the free convection per square cm. of surface for his spheres.

$$w_c = 0.000064\,(1.778 + 26./D)\,\Delta\, t^{1.233} \text{ watts per cm.}^2 \quad \mathbf{(9)}$$

where D = sphere diam. in cm.
In his experiments $\Delta\, t$ varied from about 25 deg. cent. to 70 deg. cent.

In the above experiments we are dealing with thin films and small temperature differences and therefore obtain the following relations from equations (**6**) and (**7**).

$$\text{If } n = 1/3;\ w_c \propto \Delta\, t^{7/6}/D^{1/2} \text{ watts per cm.}^2 \quad \mathbf{(10)}$$

$$n = 1/2;\ w_c \propto \Delta\, t^{5/4}/D^{1/4} \text{ watts per cm.}^2 \quad \mathbf{(11)}$$

Péclet's data give approximately,

$$w_c \propto \Delta\, t^{1.233}/D^{0.412} \text{ watts per cm.}^2 \quad \mathbf{(12)}$$

Thus from temperature we would select equation (**11**) while by size we find a closer agreement with equation (**10**).

M'Farlane[10] measured the rate of cooling of a 4-cm. diam. polished and lamp black covered copper sphere placed in a water-jacketed enclosure at atmospheric pressure for temperature differences up to 60 deg. cent. The size of the enclosure is not stated.

In correcting M'Farlane's data for radiation we have assumed $E = 0.9$ for the lamp black surface and $E = 0.15$ for his polished copper. The total emissivity for polished copper calculated from the relation given by Foote[11] is $E = 0.0116$ at O deg. cent. and $E = 0.0161$ at 100 deg. cent. A study of the measurements of total emissivity of various metal surfaces by Randolph and Overholzer[12] as function of time and temperature makes it seem likely that some degree of oxidation had taken place before M'Farlane's tests were started. We have therefore assumed an average value for the temperature range of $E = 0.15$. On this basis the convection from the polished copper surface is approximately 15 per cent greater than for his lamp black surface. The lamp black surface is probably subject to some correction for the temperature drop through the deposit.

On the above basis we find that for M'Farlane's sphere the convection varies approximately as the 1.12 power of the temperature difference and is therefore in better accord with equation (**10**) than (**11**).

						Avg. =	8.65

In Table V we have given the values of K_1 as calculated from equation (**6**) and (**7**) on the two alternative assumptions. The extensive work of Dulong and Petit[13] on the cooling of large spherical thermometer bulbs accords best with assumption $n = ½$. Until further data are available it is probably safest to calculate the free convection from spheres using $n = ½$ and $K = 2.0$ in equation (**5**). Data on the convection of spheres in liquids are needed to determine the exponent m.

FREE CONVECTION FROM VERTICAL PLANE SURFACES

The available data on convection from vertical plane surfaces do not belong to any definite system of similar plane figures, *i. e.*, similar rectangles, triangles, etc., or circular disks of varying diameters, and therefore, strictly speaking, cannot be correlated.

An interesting type of vertical plane surface consists of a long horizontal ribbon whose thickness is small com-

							Average K_1	= 2.02..................		0.574

pared with the vertical height. As a rough approximation we will assume that the available data are applicable to this case and determine the constant K_1 and exponent n of equation (**7**). For narrow ribbons the shape factor will require evaluation as the flow between confocal elliptical cylinders, but for thin films the shape factor takes the simple form, $S = A/B$. For thin films and moderate temperature differences we will determine the convection from equations (**6**) and (**7**). For our ideal ribbon surface the horizontal length is large compared with the vertical height and therefore the convection per unit length will be independent of the length. We will therefore associate D in equation (**7**) with the vertical height H.

Langmuir [2] studied the convection from one side of a circular disk 19.1 cm. diameter under various surface conditions. We have selected the values of total loss obtained for the polished silver and calorized copper surfaces since the radiation corrections are fairly definite and rather small. The vertical height H has been taken as the square root of the area.

We have taken the data by Griffiths and Davis[7] for the total loss from one side of a polished aluminum surface 127 cm. by 127 cm. Here we have taken $H = 127$ cm.

Doherty[14] studied the heat loss from a double-sided lamp-black-coated hot plate 25.4 cm. high, 38.1 cm. long and 1.27 cm. thick.

Montsinger[15] studied the loss from a double-sided plate 80 cm. high, 33.2 cm. wide, and 2.7 cm. thick. His original data on the polished nickel and black surfaces have been used.

Griffiths and Davis[7] have studied the heat loss from a series of vertical cylinders of the same diameter and various heights. We have included their data on this series for the four shortest cylinders, since for these the circumference is fairly large compared with the vertical height and therefore may be considered to fit in with the very rough correlation here being attempted.

Griffiths and Davis[7] have assumed that their data on the convection from this series of vertical cylinders of different heights accurately determines the law of variation of convection with respect to height for vertical plane surfaces. This assumption is undoubtedly an oversight, since when the height is great compared with the diameter we are dealing with the problem of convection from long vertical cylinders, in which case, the convection per unit area, or per unit vertical length, should be independent of the total height, and I can see no reason for believing that the conditions are at all analogous with those which apply to the problem of a long horizontal ribbon of negligible thickness and definite vertical height.

The values of *total emissivity* used in deducing the radiation correction for the polished surfaces have been calculated as functions of temperature from the following relation derived by Foote.[11]

$$E_{total} = 0.5736 \sqrt{r\,T} - 0.1769\, r\, T \qquad (\mathbf{13})$$

where T = Absolute temperature of radiating metal surface

r = Volume resistivity in ohm cm. at the temperature T

We have determined r from the usual relation, $r = r_0 (1 + \alpha\, t)$. Equation (**13**) is applicable to unoxidized polished metal surfaces below 1500 deg. cent., or to the spectral region where resonance phenomena do not exist. Foote[11] shows that the experimental values of *total emissivity* for platinum from 0 deg. cent. to 1700 deg. cent. are well represented by the equation.

The radiation corrections calculated on this basis are probably somewhat too small because of the marked effects due to oxidation.[12] In this connection it should be pointed out that where accurate work on convection is attempted provision should be made for a simultaneous determination of the total emissivity of the actual surface. In this manner the uncertainties in the value of emissivity as functions of time and temperature and previous history will be eliminated. Tests in inert gases such as H_2 and N_2, etc. are also recommended.

14. Data kindly supplied by R. E. Doherty. These and additional data will probably soon be published in the A. I. E. E.

15. Data kindly supplied by V. M. Montsinger. A summary of this data is given by Montsinger in his discussion of paper reference (1).

In Fig. 3 we have plotted the watts convection per square cm. of surface against temperature difference on log:log paper. From this we see that the convection per unit area is proportional to the 5/4 power of the temperature difference. Above 100 deg. cent. rise the radiation may be considerably off due to oxidation. If we plot in a similar manner, the convection given by Griffiths and Davis[7] for the four shortest cylinders, excluding the points below 10 deg. cent. rise, we obtain a family of four approximately parallel curves in which the convection per unit area is again approximately proportional to the 5/4 power of the temperature difference. We will therefore *assume* that the watts convection per unit area for our ideal ribbon surface, under the conditions of thin films and moderate temperature differences, will vary as the 5/4 power of the temperature difference. This assumption requires us to take $n = \frac{1}{2}$ in equation (**7**) when combined with equation (**6**). We thus obtain for ideal gases

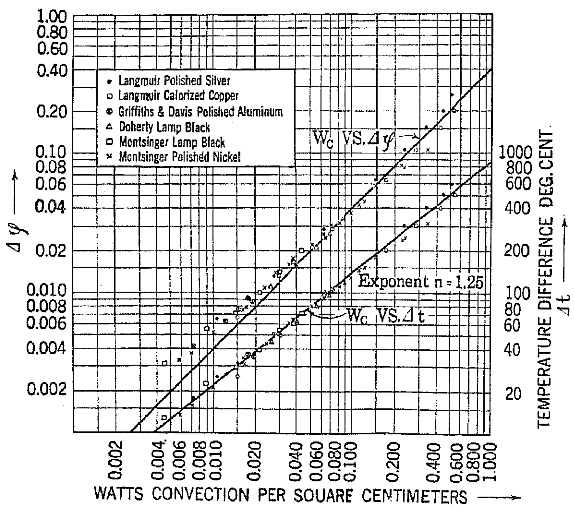

Fig. 3

$$w_c = 1/K_1\,(\alpha\, g/H)^{1/4}\,(k/\nu^{1/2})_{avg.}\,\Delta\, t^{5/4} \text{ watts cm.}^{-2} \quad (\mathbf{14})$$

There are no data available from which the exponent m in equation (**5**) can be evaluated but if we assume $m = \frac{1}{4}$ as was found to be the case for horizontal cylinders, where the exponent n was equal to $\frac{1}{2}$, we obtain

$$w_c = (1/K)\,(c_p\,\mu/k)^{1/4}{}_{avg.}\,(\alpha\, g/H)^{1/4}\,(k/\nu^{1/2})_{avg.}\,\Delta\, t^{5/4} \text{ watts cm.}^{-2} \quad (\mathbf{15})$$

where

c_p = Specific heat at constant pressure for the average of surface and ambient temperatures, joule gram^{-1} deg. cent.$^{-1}$

μ = Viscosity of fluid for the avg. temp. cm.$^{-1}$ gram sec.$^{-1}$

k = Heat conductively of fluid for avg. temp. watt cm.$^{-1}$ deg. cent.$^{-1}$

α = Coefficient of density change per deg. cent. temperature change. For ideal gases $\alpha = 1/273$

g = Acceleration of gravity = 980 cm. sec.$^{-2}$

H = Vertical height of long horizontal plane in cm.

ν = μ/ρ = Kinematic viscosity of fluid at the average temperature cm.^{2} sec.$^{-1}$

$\Delta\, t$ = Temperature difference between surface and ambient fluid deg. cent.

Equation (**15**) in a more compact form becomes

$$w_c = (1/K)\,(c_p\, g\, k^3\, \alpha/\mu\, H)^{1/4}\,\rho^{1/2}\,\Delta\, t^{5/4} \text{ watts cm.}^{-2} \quad (\mathbf{16})$$

It is now interesting to observe that this is practically the equation derived by Lorenz[16] for this case, to which Langmuir[2] has called attention. In our notation Lorenz equation is

$$w_c = 0.548\,(c_p\, g\, k^3/\mu\, H\, T)^{1/4}\,\rho^{1/2}\,\Delta\, t^{5/4} \text{ watt cm.}^{-2} \quad (\mathbf{17})$$

where T = Absolute ambient temperature deg. K. Here the fluid properties were taken for the ambient temperature while in our equation the average values are used. Our equation contains the coefficient of density change per deg. cent. instead of the reciprocal of absolute ambient temperature T.

In Table VI the values of K_1 have been calculated from equation (**14**). As expected the values of the constant varies from one surface to the next since the data do not belong to any definite system of similar surfaces. The average value of the constant K_1 is 1.46. If we assume equation (**15**) we obtain $K = 1.35$ which is not greatly different from the value $K = 1.82$ calculated by Lorenz.

Free Convection from Large Surfaces

A large surface is here defined as one in which the film thickness is small compared with the characteristic dimension of the body. We will also limit the discussion to moderate temperature differences and assume the relation

$$\Delta\,\varphi = k_{avg.}\,\Delta\, t \text{ watts per cm.} \quad (\mathbf{18})$$

The total watts convection is then given by

$$W_c = (A/B)\,k_{avg.}\,\Delta\, t \text{ watts} \quad (\mathbf{19})$$

where

A = Area of surface in cm.^{2}

B = Effective film thickness in cm.

k = Heat conductivity for the average of surface and ambient temperature in watt cm.$^{-1}$ deg. cent.$^{-1}$

$\Delta\, t$ = Temperature difference in deg. cent.

The effective film thickness is given by

$$B = K\,D\,(k/\mu\, c_p)^m\,\{\nu/[(\alpha\, g\,\Delta\, t)^{1/2}\, D^{3/2}]\}^n \text{ cm.} \quad (\mathbf{20})$$

where

K = Experimental constant depending on the system of similar bodies under consideration

D = Characteristic linear dimension of body in cm.

k = Heat conductivity at average temperature watt cm.$^{-1}$ deg. cent.$^{-1}$

μ = Viscosity of fluid at average temperature cm.$^{-1}$ gram sec.$^{-1}$

c_p = Specific heat at constant pressure for average temperature joule gram^{-1} deg. cent.$^{-1}$

m = Experimental exponent

16. L. Lorenz, *Annder Physik*, Vol. 13, p. 586, 1881.

ν = μ/ρ = Kinematic viscosity of fluid for average temperature cm.² sec.⁻¹

α = Coefficient of density charge per deg. cent. for average temperature in deg. cent.⁻¹

g = Acceleration of gravity = 980 cm. sec.²

Δt = Difference between surface and ambient temperature deg. cent.

n = Experimental exponent for the system of similar bodies under consideration

The coefficient α is the coefficient in the familiar equation:

$$\rho = \rho_0 (1 + \alpha t) \text{ gram. cm.}^{-3} \text{ at temperature } t \text{ deg. cent.} \quad (21)$$

where

ρ_0 = density of fluid at 0 deg. cent.

t = Fluid temp. deg. cent.

α = 1/273 for the case of ideal gases and the values for liquids are available in Physical Tables.

If we substitute equation (**20**) in (**19**) we obtain as the general expression for thin films and moderate temperature differences.

$$W_c = (A\,k\,\Delta t/K\,D)\,[\,(\alpha\,g\,\Delta t)^{1/2}\,D^{3/2}/\nu]^{\,n}\,(\mu\,c_p/k)^{\,m} \text{ watts} \quad (22)$$

Where no data are available on convection in liquids we are unable to determine the exponent m. Fortunately for ideal gases, this factor does not vary greatly from one gas to another and may therefore be neglected without seriously affecting the results. On this assumption we obtain for ideal gases

$$W_c = (A\,k\,\Delta t/K_1\,D)\,[\,(\alpha\,g\,\Delta t)^{1/2}\,D^{3/2}/\nu]^n \text{ watts} \quad (23)$$

Equation (**22**) is seen to be similar to the form of relation deduced from certain theoretical considerations by Davis[17] which in our notation becomes

$$W_c = (A\,k\,\Delta t/K\,D)\,[S^2\,g\,D^3\,\alpha\,\Delta t/k^2]^m\,(S\,\nu/k)^r \quad (24)$$

where $S = \rho\,c_p$ = specific heat per unit volume joule cm.⁻³ deg. cent.⁻¹

For *ideal gases* we have from the kinetic theory k proportional to $\mu\,c_p$. If we make these substitutions in equation (**24**) we obtain our equation (**22**). Thus for ideal gases the two methods of attack give the same result but for liquids or imperfect gases the results will be different.

We obtain from the previous paper[1] the following approximation for *air* at *atmospheric pressure*. In the heat conductivity equation we have here assumed the value of specific heat at 400 deg. k. instead of 300 deg. k. so as to obtain a better average value.

$$\nu = \mu/\rho = 7.05 \times 10^{-6}\,T^{1.754} \text{ cm.}^2 \text{ sec.}^{-1} \quad (25)$$

$$k = 3.46 \times 10^{-6}\,T^{.754} \text{ watts per cm. per deg. cent.} \quad (26)$$

We also have for *air*

$$\mu\,c_p/k = 0.74 \text{ numeric} \quad (27)$$

Large Horizontal Cylinder in Gases and Liquids. For this case we substitute D = Cyl. diam. in cm.;

$K = 2.12$; $n = 1/2$ and $m = 1/4$ in equation (**22**) and obtain

$$W_c = 0.472\,A\,[\,(\mu\,c_p/k)\,(\alpha\,g/D)\,]^{1/4}\,(1/\nu)^{1/2}\,k\,\Delta t^{5/4} \text{ watts} \quad (28)$$

For *air* we obtain the following relation by making use of the approximate equations (**25**), (**26**) and (**27**).

$$W_c = 0.000785\,A\,(1/D)^{1/4}\,p^{1/2}\,(1/T_{avg.})^{0.123}\,\Delta t^{5/4} \text{ watts} \quad (29)$$

where

A = $\pi\,D\,L$ = Area in square cm.

D = Cylinder diameter in cm.

p = Absolute air pressure in atmospheres

$T_{avg.}$ = Average of cylinder and ambient absolute temperature deg. K

Δt = Temperature difference deg. cent.

As an example let us apply this equation to calculate the convection from the large cylinder 11.35 cm. diameter and 152.5 cm. long for the atmospheric pressure point.

$$\overline{W}_c = 0.000785 \times \pi \times 11.35 \times 152.5\,(1/11.35)^{1/4} \times 1^{1/2} \times (1/327.9)^{0.123} \times (85.1)^{5/4} = 295 \text{ watts.}$$

The observed value given in the table for this length is 317 watts. Thus, the experimental value is 7 per cent high, which is not far from the probable error.

17. A. H. Davis, *Phil. Mag.*, Vol. 44, p. 938, 1922.

We see from equation (**29**) that for a constant temperature difference the convection will vary approximately inversely as the $\frac{1}{8}$ power of the average absolute temperature. Thus the convection per deg. cent. temperature difference will decrease slowly with rising ambient temperature. In the previous paper[1] an oversight was made in section V under *Effect of Ambient Temperature*. Here the experiments were tested by calculating the film thickness for the high and low ambient temperatures from the observed convection. These calculations showed that the film thickness increased with increasing ambient temperature as was required by the theory, and therefore, the agreement was considered satisfactory. Now the heat conductivity increases with the temperature but not quite so fast as the film thickness increases and, therefore, the convection per deg. cent. should decrease with increasing ambient temperature whereas, the experiments showed an increased convection per deg. cent. for the high ambient temperature. Thus the *Oven Tests* are contrary to the previous as well as the present theory. It is probable that extraneous convection currents were the cause of the trouble.

Long Vertical Cylinder in Ideal Gases. For this case we have only the data by Griffiths and Davis on a single large cylinder. We have, therefore, had to rely solely on the variation of convection with temperature to determine the exponent n and constant K_1 of equation (**23**). The values obtained in Table IV are $n = 2/3$ and $K_1 = 8.65$ and substituting in (**23**) gives

$$W_c = 0.116\, A\, (\alpha\, g)^{1/3}\, (1/\nu)^{2/3}\, k\, \Delta\, t^{4/3} \text{ watts} \qquad (\mathbf{30})$$

For *air* we obtain

$$W_c = 0.00166\, A p^{2/3}\, (1/T_{avg.})^{.415}\, \Delta\, t^{4/3} \text{ watts} \qquad (\mathbf{31})$$

From this equation we observe that for this system of similar figures the convection per unit area is independent of the size.

Large Spheres in Ideal Gases. Here the available data are meager and unsatisfactory. Until further data are available we will take $n = 1/2$ and $K_1 = 2.0$ in equation (**23**) and obtain

$$W_c = 0.5\, A\, (\alpha\, g/D)^{1/4}\, (1/\nu)^{1/2}\, k\, \Delta\, t^{5/4} \text{ watts} \qquad (\mathbf{32})$$

For *air* we obtain

$$W_c = 0.00088\, A\, (1/D)^{1/4}\, p^{1/2}\, (1/T_{avg.})^{0.123}\, \Delta\, t^{5/4} \text{ watts} \qquad (\mathbf{33})$$

A comparison of this equation with the corresponding equation (**29**) for a horizontal cylinder shows that for the same diameter the convection per unit area is approximately the same in both cases.

Large Vertical Plane Surfaces in Ideal Gases. Here we have taken the available data on mongrel types of vertical plane surfaces and assumed that they can be roughly correlated by a vertical plane surface whose horizontal length is large compared with the vertical height and of small thickness. In this manner we obtained $n = \frac{1}{2}$ and $K_1 = 1.46$. If we make these substitutions in equation (**23**) and let $D = H$, the vertical height of our ribbon surface in cm. we obtain,

$$W_c = 0.685\, A\, (\alpha\, g/H)^{1/4}\, (1/\nu)^{1/2}\, k\, \Delta\, t^{5/4} \text{ watts} \qquad (\mathbf{34})$$

For *air* we then obtain

$$W_c = 0.00121\, A\, (1/H)^{1/4}\, p^{1/2}\, (1/T_{avg.})^{0.123}\, \Delta\, t^{5/4} \text{ watts} \qquad (\mathbf{35})$$

It is well to emphasize the fact that these equations can only be used as approximations in engineering calculations. In working up the available data for Table VI it was found that for each type of surface the convection per unit area could be represented by an equation containing a single value of the constant and the 5/4 power of the temperature difference. Under these conditions the method of dimensions shows us that the convection per unit area must also vary inversely as the $\frac{1}{4}$ power of the size factor for strictly similar surfaces. There is of course, no inherent reason why the exponent should remain the same over a great range in either size or temperature but the fact that for horizontal cylinders the exponent changes only slightly over the tremendous range of sizes and temperatures covered by the various experiments makes it appear probable that the same will hold for other systems of similar figures such as spheres similar rectangular, circular disks, similar short vertical cylinders, etc. The values of the constants K_1 for the different systems which have the same exponent have been gathered together below for comparison.

1. Long horizontal cylinders $n = 1/2; K_1 = 2.10$
2. Spheres $n = 1/2; K_1 = 2.02$
3. Langmuir, 19.1-cm. disk inserted in one end of short insulating cylinder 24 cm. diam. by 12.5 cm. deep. Here the characteristic dimension has been taken as the square root of the hot area $n = 1/2; K_1 = 2.00$
4. Griffiths and Davis rectangular plate 127 cm. × 127 cm., back and edged covered by 7.8 cm. thick covering $n = 1/2; K_1 = 1.25$
5. Doherty rectangular plate 25.4 cm. high, 38.1 cm. long, 1.27 cm. thick $n = 1/2; K_1 = 1.68$
6. Montsinger rectangular plate 80 cm. high by 33.2 cm. wide and 2.7 cm. thick with tapered edges and certain edge coverings $n = 1/2; K_1 = 1.32$
7. Griffiths and Davis short vertical cylinder 17.43 cm. diam. by 4.65 cm. high with 7.62 cm. high caps on top and bottom $n = 1/2; K_1 = 0.975$
8. Griffiths and Davis short vertical cylinder 17.43 cm. diam. by 8.0 cm. high, lower cap 7.62 cm. high, upper cap 15.24 cm. high $n = 1/2; K_1 = 1.13$

9. Griffiths and Davis short vertical cylinder 17.43 cm. diam. by 15.2 cm. high upper and lower caps each 7.62 high $n = 1/2; K_1 = 1.35$
10. Griffiths and Davis short vertical cylinder 17.43 cm. diam. by 28.8 cm. high upper and lower caps each 7.62 cm. high $n = 1/2; K_1 = 1.55$

Avg. of 10 values, $K_1 = 1.54$

Each of the above 10 surfaces belongs to a different system of similar surfaces in which the convection per unit area varies approximately as the 5/4 power of the temperature difference but each system requires a different value for the constant.

Strictly speaking, therefore, it is not possible to determine the convection from a transformer tank from experiments on a rectangular plate or from the convection data obtained on a long ribbon surface of the same vertical height. Accurate calculations of convection can only be expected when the exponent n and constant K_1 is known for one, of a similar line of tanks of various sizes. Corrugated cylindrical tanks will be similar, when for each size, the ratio of diameter to height, depth of corrugations to height, size of flange to height, etc., are the same.

Elliptical or rectangular tanks each belong to a separate line of similar tanks. Montsinger's[18] tests on convection from transformer tanks bring out the kinds of variations to be expected for three different types of tank.

The fact that we cannot expect accurate calculations of convection from large surfaces of various types from a single equation does not mean that it is not desirable to take an equation such as (35) and use it as an approximation for engineering calculations, where a closer approximation is not available. For such work, Montsinger has proposed the following equation for air.

$$W_c = 0.000217\, A p^{1/2} \Delta t^{5/4} \text{ watts} \qquad (36)$$

Here the convection per unit area is taken independent of the height of surface.

For surfaces over 100 cm. high the approximate equation suggested by Griffiths and Davis for air at atmospheric pressure gives

$$W_c = 0.000205\, A\, \Delta t^{5/4} \text{ watts} \qquad (37)$$

For a surface 100 cm. high and an average of surface and ambient temperature of 350 deg. our equation (**35**) gives

$$W_c = 0.000186\, A p^{1/2} \Delta t^{5/4} \text{ watts} \qquad (38)$$

The constant in equation (**36**) was obtained by Montsinger from tests on the vertical rectangular surface 80 cm. high by 33.2 cm. wide. The constant in equation (**37**) was obtained by Giffiths and Davis from the long vertical cylinder 17.43 cm. diameter and 273.5 cm. high by forcing the convection to follow the 5/4 power of the temperature difference. The constant in equation (**38**) was obtained from averaging the column of figures in Table VI. By giving different weights to the various experiments we could obtain a considerably larger or smaller value of the constant. In this connection, tests on a series of *similar surfaces* such as large cylindrical tanks would be of considerable interest and value. Highly polished surfaces should be used so as to reduce the uncertainties involved in the radiation corrections.

SUMMARY AND CONCLUSIONS

(1) The more general expression for the effective film thickness, here developed, is seen to be superior to the simpler expression of the previous paper since the resulting equations account accurately for the convection from large and small bodies at both *high* and *low* temperature differences.

(2) The general expression for the effective film thickness obtained by the method of dimensions for free convection is

$$B = K\, D\, (k/\mu\, c_p)^m \{\nu/[(\alpha\, g\, \Delta t)^{1/2} D^{3/2}]\}^n \text{ cm.} \qquad (39)$$

where K = Experimental constant depending on the system of similar bodies under consideration
D = Characteristic linear dimension of body in cm.
k = Heat conductivity at average temperature watt cm.$^{-1}$ deg. cent.$^{-1}$
μ = Viscosity of fluid at avg. temp. cm.$^{-1}$ gram. sec.$^{-1}$
c_p = Specific heat at const. pressure for avg. temp. joule gram.$^{-1}$ deg. cent.$^{-1}$
m = Experimental exponent
$\nu = \mu/\rho$ = Kinematic viscosity of fluid for average temperature cm.^{2} sec.$^{-1}$
α = Coefficient of density change per deg. cent. for average temperature in deg. cent.$^{-1}$, for ideal gases $\alpha = 1/273$
g = Acceleration of gravity = 980 cm. sec^2
Δt = Difference between surface and ambient temperature deg. cent.
n = Experimental exponent for the system of similar bodies under consideration.

(3) When dealing with *ideal gases* the first factor in equation (**39**) can be neglected since it does not vary greatly from one gas to another. Under these conditions we write the effective film thickness

$$B = K_1 D \{\nu/[(\alpha\, g\, \Delta t)^{1/2} D^{3/2}]\}^n \text{ cm.} \qquad (40)$$

(4) The free convection from *a long horizontal cylinder* in *gases* and *liquids* is given by

$$W_c = 2\,\pi\, L\, \Delta\, \varphi/\log_\epsilon [(2\,B + D)/D] \text{ watts} \qquad (41)$$

where L = Length of cylinder in cm.
$\Delta\varphi$ = Thermal conduction in watts per cm.
D = Diameter of cylinder in cm.
B = Film thickness in cm. from eq. (**39**)

A sufficiently close approximation is usually obtained by taking $n = \frac{1}{2}$; $K = 2.12$ and $m = \frac{1}{4}$ in equation (**39**).

(5) The free convection from *a long vertical cylinder* in *gases* is given by equation (**41**) and the film thickness by equation (**40**). The meager available data give

$n = 2/3$ and $K_1 = 8.65$

(6) The free convection from a *sphere* in *gases* is given by

$$W_c = 2\,\pi\,\Delta\,\varphi/\,[1/D - 1/(2\,B + D)] \text{ watts} \quad (42)$$

and the film thickness by equation (**40**) in which

$n = \frac{1}{2}$ and $K_1 = 2.02$

(7) For *large surfaces* the body size will usually be small compared with the film thickness and the shape conductance will then take the simple form $S = A/B$. For moderate temperature differences we may also take $\Delta\,\varphi = k_{avg.}\,\Delta\,t$. Under these conditions our general expression for free convection becomes

$$W_c = (A\,k\,\Delta\,t/K\,D)\,(\mu\,c_p/k)^m\,[(\alpha\,g\,\Delta\,t)^{1/2}\,D^{3/2}/\nu]^n \text{ watts} \quad (43)$$

For *ideal gases* we may omit the first factor without great error and obtain

$$W_c = (A\,k\,\Delta\,t/K_1\,D)\,[(\alpha\,g\,\Delta\,t)^{1/2}\,D^{3/2}/\nu]^n \text{ watts} \quad (44)$$

(8) For *a large long horizontal cylinder* in *gases* and *liquids* we take $K = 2.12$; $n = 1/2$ and $m = \frac{1}{4}$ in equation (**43**).

For the convection in *air* we obtain

$$W_c = 0.000785\,A\,(1/D)^{1/4}\,p^{1/2}\,(1/T_{avg.})^{0.123}\,\Delta\,t^{5/4} \text{ watts} \quad (45)$$

where $A = \pi\,D\,L$ = Area in square cm.

D = Cylinder diam. in cm.

L = Length of long cylinder in cm.

p = Absolute air pressure in atmospheres

$T_{avg.}$ = Average of cylinder and ambient absolute temperature deg. K

$\Delta\,t$ = Temperature difference deg. cent.

(9) For *a large long vertical cylinder* in *gases* we take

$n = 2/3$ and $K = 8.65$ in equation (**44**)

For *air* we obtain the following approximation

$$W_c = 0.00166\,A\,p^{2/3}\,(1/T_{avg.})^{0.415}\,\Delta\,t^{4/3} \text{ watts} \quad (46)$$

(10) For *large spheres* in *gases* we take

$n = \frac{1}{2}$ and $K_1 = 2.0$ in equation (**44**)

For *air* we then obtain the following approximation

$$W_c = 0.00088\,A\,(1/D)^{1/4}\,p^{1/2}\,(1/T_{avg.})^{0.123}\,\Delta\,t^{5/4} \text{ watts} \quad (47)$$

(11) For a *long thin vertical plane* surface (ribbon surface) in *gases* we may take as an approximation $n = \frac{1}{2}$ and $K_1 = 1.46$ in equation (**44**). We also take D equal to the vertical height H in cm. For *air* we then obtain

$$W_c = 0.00121\,A\,(1/H)^{1/4}\,p^{1/2}\,(1/T_{avg.})^{0.123}\,\Delta\,t^{5/4} \text{ watts} \quad (48)$$

(12) The more general theory of the present paper shows that *free convection* tests *can not be used* as a *primary method* of *obtaining* heat *conductivities*. The method however, is still of interest where an approximate value of the heat conductivity already exists. Below the heat conductivities have been recalculated by this method.

No. 12

Transil Oil	$k = 0.0017\,(1 - 0.0026\,t)$	watt cm.$^{-1}$	°C.$^{-1}$	
Toluene	$k = 0.0015\,(1 - 0.0029\,t)$	"	"	"
Glycerine	$k = 0.0033\,(1 - 0.0038\,t)$	"	"	"
Aniline	$k = 0.0020\,(1 - 0.0018\,t)$	"	"	"
CCl_4	$k = 0.0012\,(1 - 0.0038\,t)$	"	"	"
Olive Oil	$k = 0.0016\,(1 + 0.0055\,t)$	"	"	"

The value for olive oil should not be given much weight, due to the large uncertainty concerning the viscosity. The present method gives, excepting olive oil, negative temperature coefficients, whereas, the method of the previous paper gave positive values.

In conclusion, the writer wishes to express his thanks to Mr. V. M. Montsinger for his valuable criticism of the first paper which brought out the limitations of the previous theory and stimulated the present work. The writer is also indebted to Mr. R. E. Doherty for the use of his unpublished data on convection from plane surfaces.

Discussion

V. M. Montsinger: About ten years ago or something over, Dr. Langmuir published his first paper on the film theory, in which he showed the remarkable agreement between the test results and calculations, at high temperatures, principally from 100 up to 1000 degrees. I could never get satisfactory results at temperatures below 100 degrees, which is a very important field for electric apparatus, especially transformers, generators and motors, and in fact, Dr. Langmuir himself agreed with me that the film theory did not check exactly at these low temperatures, and there was some factor that was not exactly known. Now, fortunately, Mr. Rice has shown us the method to use and has introduced a factor that takes care of the discrepancies.

For the first time I feel that we really understand the phenomena of free convection in air for both small and large temperature differences. The solution of this has been made possible principally by the use of the apparently little used and little understood "Method of Dimensions."

It will be worth while to say a few words as to what the Method of Dimensions is and how it is used. Method of dimensions simply means that each factor such as air density, viscosity, conductivity, temperature rise, etc., that affects the rate of transfer of heat from a heated surface to the air is expressed in terms of the dimensions of the body like L for the length and L^3 for the volume or T for time or θ for temperature rise. For instance, density is represented by mass M, divided by the volume L^3. Conductivity is represented by the heat, H, divided by the factors of length, L, time T, and temperature drop θ. In Mr. Rice's equation (1), each factor to start out with has its particular exponent of say, x, y, z, or n, etc. In equation (2) the dimensional equivalents are substituted for the factors themselves such as density, viscosity, etc., but the equation retains its original exponents. By equating the value of the exponents for length, mass, time, heat, and temperature and solving the simultaneous equations any exponent may be expressed in terms of some particular one, like, say n or m.

Having obtained the relationship between the letters representing the exponents, the exponents of each factor in equation (1) can now be expressed in the same terms as for instance; n or $\frac{3\,n}{2}$. It happens however, that all but one can be expressed in terms of n, the remaining one being m.

The numerical value for anyone of these exponents must, of course, be obtained by experimental test. But after we have determined the value of, say n, for one factor like the variation in loss with air density, we also have the solution for the correct exponents for all the other factors because they are also expressed in terms of n. In other words if we find that loss is proportional to the square root of the air density in which case n equals ½, we know how the loss is affected by a change in each of the other factors such as viscosity, temperature rise, or dimensions of the object. Thus by taking advantage of what the method of dimensions can tell us we greatly reduce the number of experiments which have to be tried in order to determine the law for the system of similar bodies under consideration. This is where the Method of Dimensions comes in and serves as a very useful tool.

In addition to the value of the correct exponent for temperature rise, that is, whether the loss is proportional to temperature rise raised to the 5/4 or some other power, there has been a considerable difference of opinion as to the correct value of the exponent for air density. In other words, does the loss vary as the density raised to the ½ or 2/3 power or some other power? The value of exponential values claimed by different investigators has been from about 2/5 to 2/3 or ¾. I have never made any accurate laboratory tests to determine this but from my experience in testing transformer tanks having different shapes of surfaces at different altitudes I have found that the value of ½ checks best the observed values.

In regard to the convection loss varying as the temperature rise raised to the 5/4 power I have been quite certain for several years that this exponential value is about correct.

As mentioned before since the Method of Dimensions shows a definite relationship between the exponents for the different factors if we are certain of one we know also what the others should be. I note with a great deal of interest that according to the Method of Dimensions if the 5/4 power is correct exponent for temperature rise it requires that the exponent must be ½ for air density. I believe therefore that Mr. Rice has proven beyond a reasonable doubt that loss by free convection in air should vary as the square root of the barometric pressure especially for large vertical surfaces.

As to the effect of height of plane on loss by convection my experience has been that for heights over three or four feet the affect of height is very small. I had occasion some two or three years ago to test the efficiency of different shapes of corrugations having a uniform (unity) vertical surface temperature gradient. These tests showed that the convection loss for a height of 72 in. was only about 3 per cent less than the loss for the same corrugations 36 in. in height. In other words the convection decreased roughly 1 per cent for each foot increase in height over 3 ft. In fact in practise I have never made any decrease in loss per unit area of corrugations (where most of the heat is carried away by convection) for heights over three or four feet.

Griffeths and Davis referred to in the paper found that the loss by convection per unit area was approximately the same for heights ranging from about 23 in. to 104 in. although they found that the value of the exponent increased slightly over 5/4 for the higher surfaces. However for heights under about one foot they found that height had a very decided effect on the loss by convection. This is as it should be according to the factor H ¼ in the method of dimensions.

C. W. Rice: There is just one thing which I would like to emphasize in closing the discussion and that is the need of more data on the free convection from various families of similar figures such as spheres, short cylinders, etc.

The Magnetic Properties of the Ternary Alloys Fe-Si-C

BY T. D. YENSEN

Member, A. I. E. E.

Research Engineer, Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

Review of the Subject.—*The variations in the magnetic properties of iron and iron-alloys, even of supposedly constant composition, has been puzzling to the users and investigators of ferro-magnetic materials ever since the introduction of such materials for electrical apparatus. The author started to investigate this problem over ten years ago at the University of Illinois, and has continued it at the Westinghouse Research Laboratory since 1916, concentrating on iron and iron-silicon alloys. While the results obtained do not eliminate 100 per cent of the difficulties, they go a long way in that direction.*

It has been found that carbon is largely responsible for the variations, because of the fact that amounts so small as previously to be regarded as traces—less than 0.01 per cent—remain dissolved in the iron in the solid state, even after slow cooling, and have a tremendous influence on the magnetic properties. Of much less effect is carbon precipitated as pearlite, free cementite and graphite, the effect being in the order named. If the effect of dissolved carbon be represented by 100, the effect of carbon as pearlite is 16.5, of carbon as Fe_3C 2.25, and of carbon as graphite nearly nil. The form assumed by carbon—aside from the carbon in solution—depends largely on the silicon content, and can best be explained by referring to Fig. 29.

Besides carbon, it has been found that the grain size has a large and definite influence on the magnetic properties due to the accompanying inter-crystalline amorphous cement that may be regarded as an impurity similar to other inter-crystalline impurities.

The detrimental effect of sulphur, phosphorus and manganese on pure iron is in the order named, while phosphorous has a beneficial effect on high silicon alloys.

The evidence obtained is to the effect that the increased reluctivity, coercive force, or hysteresis loss due to carbon and other impurities that are precipitated combined with iron—including in this class the inter-crystalline cement—is caused by the inherent corresponding property of these precipitated impurities.

Regarding the tremendous effect of carbon in solution, it is suggested that this is due to the entering of carbon into the more or less stable equilibrium arrangement of the ferro-magnetic structure, upsetting this equilibrium arrangement.

Introduction

THE superiority of silicon-steel over ordinary iron for magnetic purposes was discovered by Hadfield in 1899.[1]

The steel—containing 4 per cent silicon—was first used commercially in England in 1903[2] and immediately proved a decided success.

The first patent in the United States[3] on silicon steel was granted Hadfield on December 1, 1903, but it was not until 1906 that the first transformer was built in this country using the new steel. Since that time silicon steel has been used almost exclusively for transformers, both here and abroad, with an enormous saving in energy, and it is still without a competitor, in spite of the many investigations[4] made for the purpose of discovering one. However, the 4 per cent silicon steel of today is much better, magnetically, than Hadfield's original steel, due to improvements in manufacturing processes, in raw materials and in methods of heat treatment. Roughly speaking, the hysteresis loss is only one-half and the maximum permeability is at least twice that of Hadfield's steel, but these improvements were largely accomplished prior to 1910. During the last ten years the average improvement—as far as can be gathered—has been approximately 10 per cent, and this improvement has been due more to minor improvements in the heat-treatment than to refinements in composition.

Resumé of Previous Investigations

The effect of the ordinary impurities on the magnetic properties of iron and iron alloys has not to any great extent formed the main object of systematic scientific investigations. The most probable reason for this is that the factors influencing the magnetic properties are too numerous and were not sufficiently well known to enable the investigators to eliminate the undesirable variables. The objects have rather been to determine the magnetic properties of alloys of iron with elements that will, or may, bestow decidedly new and useful properties upon the iron, and to disregard the effect of such incidental impurities as usually occur in commercially pure iron of the best grades. Hadfield[5], for example, used Swedish charcoal iron as the base for his investigations and prepared his alloys under commercial conditions. Burgess and Aston[6] on the other hand attempted to get away from this uncertainty and were the first to use electrolytic iron as the base for their alloys. Unfortunately, however, the prep-

1915	Yensen	3.40 per cent Si-Vacuum Iron	63,300	0.08	0.15	280	1025

*1000 ergs/cub. cm./cycle = 0.80 watts/kg. at 60 cycles for 4% Si-Steel (Sp. Gr. 7.5) and = 0.76 watts/kg. for pure Fe (Sp. Gr. 7.9).

arations were made under conditions (a Hoskins carbon plate furnace) that reintroduced carbon in varying amounts into their alloys and they consequently lost the advantage they had in using a pure base. When the writer started his investigations in 1912 he took advantage of the results of Burgess & Aston and prepared his alloys in a vacuum furnace in such a way that carbon was not reintroduced to any appreciable extent, with the result[7] that the magnetic properties obtained, both for pure iron and for iron-silicon alloys, were far superior to those obtained by previous investigators. This improvement is shown in Table I, reproduced from previous publications.[8] The results for pure iron were later confirmed by Gumlich, using Fischer electrolytic iron and vacuum treatment.[9]

In these cases, the efforts were concentrated on eliminating and on keeping away the impurities, but in spite of these efforts it was impossible to obtain consistent results and to duplicate results. Not having control over some of the most important factors, and—what was worse—not even knowing what they were, it was evidently useless to attempt to determine the effect of impurities that might produce changes far less than the changes caused by the uncontrollable impurities. Aside from the usual impurities, the question of grain size enters as an important factor affecting the magnetic properties. Ruder has found[10], in the case of silicon steel that the larger the grain size the better the magnetic properties; he also showed how the grain size could be increased, by cold deformation followed by high temperature annealing, without, however, being able definitely to control it.

Preliminary Work

When, in 1916, the writer transferred his activities to the Research Laboratory of the Westinghouse Company and there tried to duplicate the results previously obtained at the University of Illinois, difficulties were encountered. The results for pure iron checked fairly well but not so for the iron-silicon alloys (Fig. 1). The magnetic properties were generally very much inferior and the more so the higher the silicon content; furthermore, the results varied depending upon the grade of silicon used in spite of the fact that chemical analysis of the alloys revealed no consistent differences. After a great deal of experimentation on 4 per cent *Fe-Si* alloys, it was found that annealing under oxidizing conditions at a temperature of 950-1100 deg. greatly improved the magnetic properties, while annealing in vacuum, hydrogen or nitrogen had no such beneficial effect (Figs. 2, 3, 4). By applying this method of heat treatment to the original series of *Fe-Si* alloys it was found that all of the alloys were susceptible to the treatment. Some responded very quickly (an hour or two at 1100 deg.) while others were much more resistant (requiring 8 to 10 hours) but in all cases, the maximum permeability reached 20,000-35,000 and the hysteresis loss 400-550 ergs per cu. cm. per cycle for $B = 10,000$ gauss (Figs. 5 and 6). Fur-

7. Univ. of Ill. Engr. Exp. Sta. Bull's 72, 77, 83, 95, 1914-17.

8. Bull. No. 83, p. 44, Eng. Exp. Stn. Univ. of Ill. and Trans. A. I. E. E. 34, p. 2601 (1915). It may be mentioned that the last two values of maximum permeability probably are too high, as mentioned in the above papers, due to errors in the Burrows method of testing, when large compensating currents have to be used, so that the true maximum permeability probably is in the neighborhood of 40,000 instead of 60,000.

For a rod sample of electrolytic iron cut from a cathode sheet and annealed in a vacuum furnace at 1000 deg. cent. Gumlich obtained the very low coercive force of $H_c = 0.11_5$ gilberts/cm. after subjecting it to a magnetizing force of $H = 150$, a value that has not been obtained for fused electrolytic iron, the lowest value being $H_c = 0.15$ (See Table 4). However, a value of $H_c = 0.10$ for $B = 15{,}000$ was obtained by the writer in 1915 for ring samples of 3.0 per cent Fe-Si alloys. (See: University of Illinois Eng. Exp. Sta. Bulletin No. 83, p. 67 Table 13, or Trans. A. I. E. E., Vol. 34, p. 2664, Table 10).

10. A. I. M. E. Trans. 1913, p. 2805.

thermore, it was found that commercial 2 and 4 per cent silicon steels could be improved to nearly the same extent as the laboratory prepared alloys (Fig. 7).

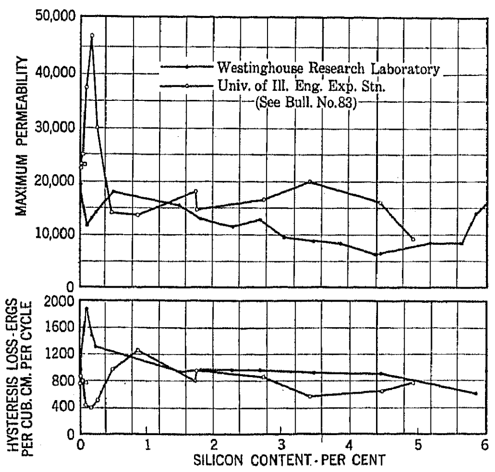

Fig. 1—Magnetic Properties of Iron-Silicon Alloys Annealed at 900 Deg. Cent. in Vacuo

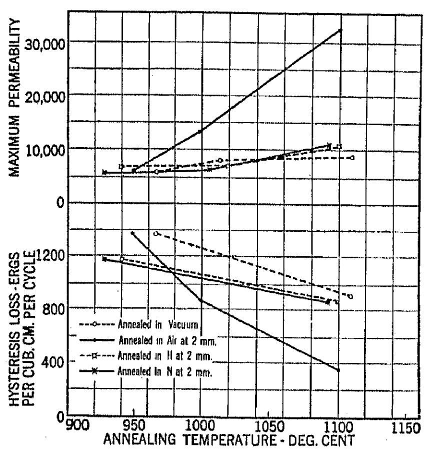

Fig. 2—Magnetic Properties of 4 Per Cent Iron-Silicon Alloys. Effect of Annealing in Vacuum, N, H or Air

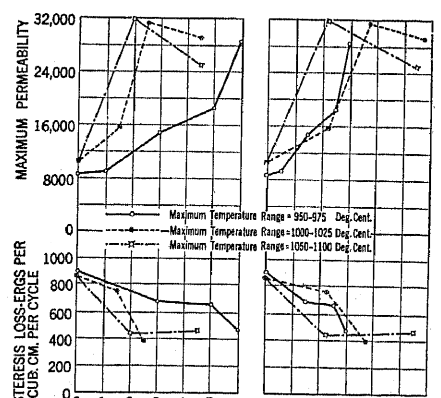

Fig. 3—Magnetic Properties of 4 Per Cent Iron-Silicon Alloys. Effect of Annealing of various Temperatures on Current of Air at 2 mm. Hg.

Analysis of the gases given off during the annealing confirmed the suspicion that carbon was being eliminated and quantitative tests revealed some relationship between the magnetic properties and the amount of carbon eliminated (Figs. 8, 9 and 10). It was concluded that elimination of carbon was the cause of the improvements, although direct evidence in the way of chemical analysis of the annealed test pieces was not yet obtainable for the reason that the methods available were not sufficiently accurate for this purpose, bearing in mind that 0.05 per cent means high carbon. On account of the great importance attributed to car-

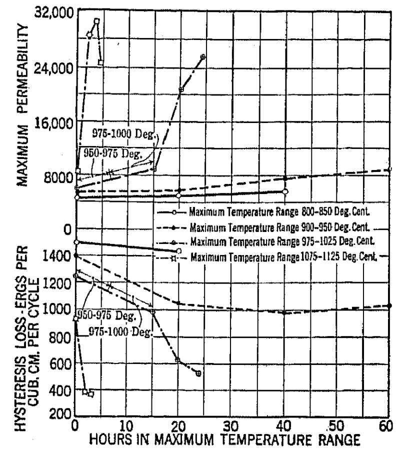

Fig. 4—Magnetic Properties of 4 Per Cent Iron-Silicon Alloys. Effect of Annealing in Current of Air at 10 Hg. at various Temperatures

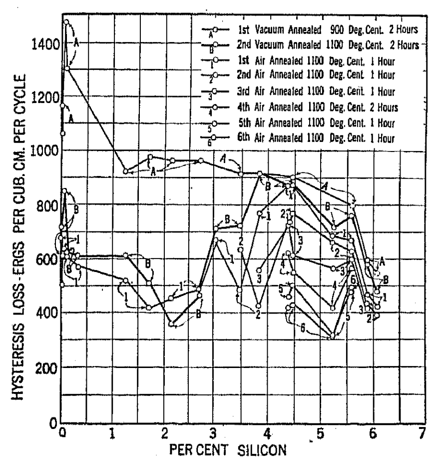

Fig. 5—Maximum Permeabilities of Iron-Silicon Alloys. Effect of Vacuum and Air Treatments

bon a new method was developed for carbon analysis[11] whereby the sample to be analyzed could be heated first to 600 deg. in vacuum and then to 1100 deg. in oxygen, and the resulting CO_2 frozen out in a liquid air trap and measured by the pressure exerted when evaporated into a known evacuated volume (Fig. 11). An accuracy of $\pm$ 0.0001 per cent was obtainable by this method and this furnished the means for getting the desired data.

11. Carbon in Iron, *Trans.* Am. Electrochem. Soc. 37, p. 227, 1920.

A number of samples of 2 per cent and 4 per cent silicon steels variously decarbonized, were tested and analyzed for carbon. The results completely verified the expectations, the curves for hysteresis loss vs. carbon content having the equation (see Fig. 12).

$$W_h = 5370 \times C^{0.425}$$

for 4 per cent Si steel, and

$$W_h = 9650 \times C^{0.493}$$

for 2 per cent Si steel.

These equations forming the first approximation to

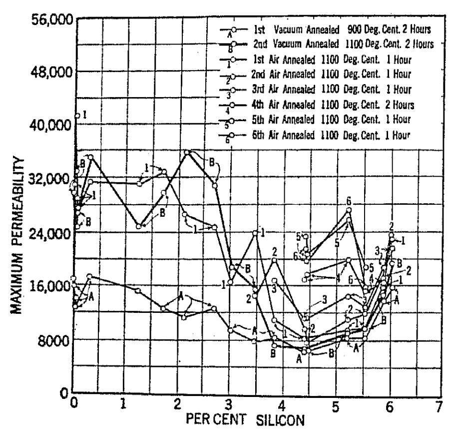

Fig. 6—Hysteresis Losses of Iron-Silicon Alloys. Effect of Vacuum and Air Treatments

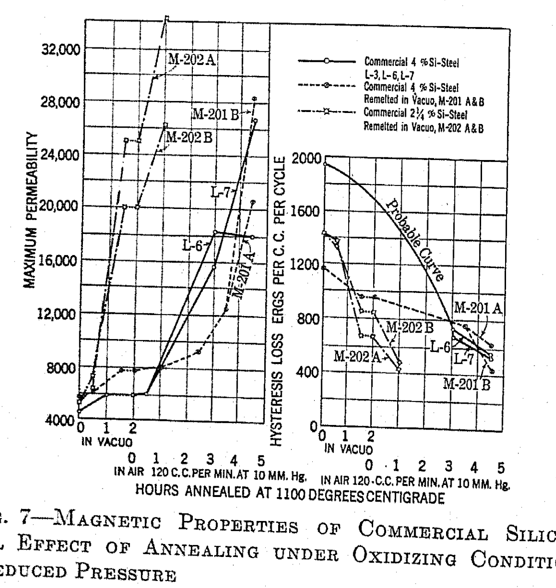

Fig. 7—Magnetic Properties of Commercial Silicon-Steel Effect of Annealing under Oxidizing Conditions at Reduced Pressure

the true relationship between the magnetic properties and carbon, would, if correct for all carbon contents, lead to the startling conclusion that zero carbon should correspond to zero hysteresis loss and that carbon is the only factor affecting the magnetic properties, as none of the other impurities, nor the structural characteristics, were considered in plotting the above data. Before drawing such sweeping conclusions, however, it was deemed advisable to get more reliable data, to use test samples in the form of rings, and to determine carefully the effect of impurities like sulphur, phosphorus and manganese.

In order to cover the range of probable silicon contents it was decided to investigate the four series: 0, 2, 4, and 6 per cent silicon. The effect of sulphur, phosphorus and manganese was investigated for the 0 and 4 per cent alloys only.

A description of the method of magnetic testing and of the general procedure will be found in the appendices to this paper.

FIRST SERIES: 0 PER CENT SILICON

The effect of carbon, sulphur, phosphorus, manganese and grain size on the magnetic properties of pure iron.

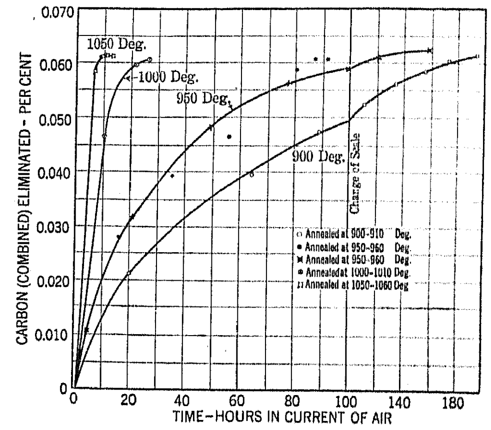

Fig. 8—Elimination of Carbon from 4 Per Cent Silicon Steel by Annealing in Current of Air at Various Temperatures

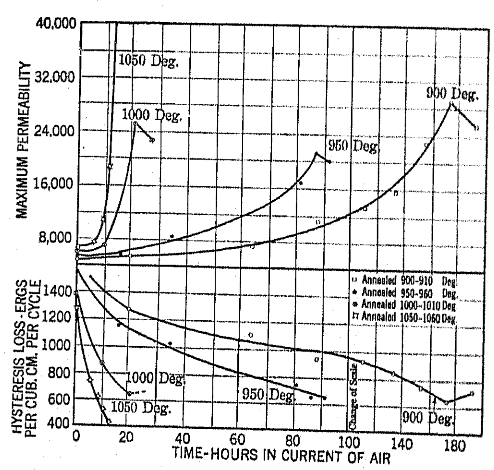

Fig. 9—Magnetic Properties of 4 Per Cent Silicon Steel and the Effect of Annealing under Oxidizing Conditions at Various Temperatures

A large number of samples were prepared both with and without additions of carbon. Analyses of ingots made from electrolytic iron with no other ingredients added are as follows:

C —0.005—0.020 per cent
S —0.001—0.026 per cent
Si —0.020—0.030 per cent
Mn —0.001—0.002 per cent
P —0.002—0.005 per cent

The variations in sulphur content have been found to

be due to the degree of care with which the electrolyte was washed off the electrolytic iron before charging it into the furnace and the variations in carbon to the degree to which the graphite parts of the furnace had been baked out at the time the ingot was made. From

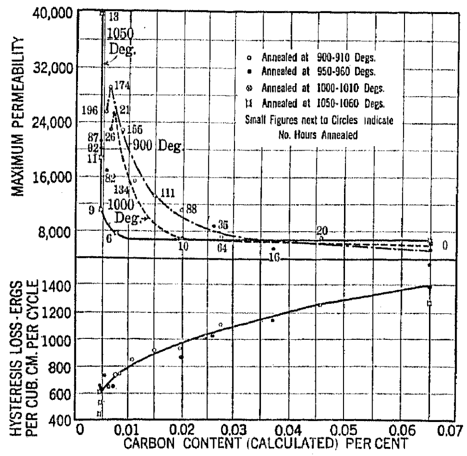

FIG. 10—MAGNETIC PROPERTIES VS. CARBON CONTENT. 4 PER CENT SILICON STEEL (N. 1 AW)

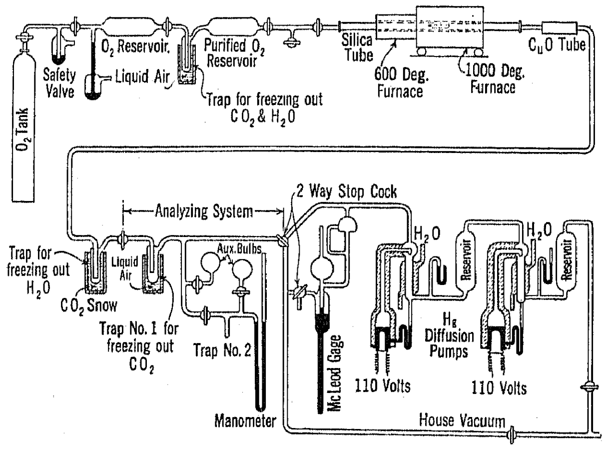

FIG. 11—APPARATUS FOR CARBON DETERMINATION

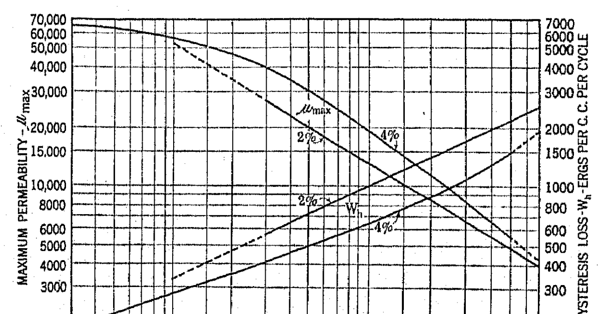

FIG. 12—MAGNETIC PROPERTIES VS. CARBON CONTENT, 2 PER CENT AND 4 PER CENT COMMERCIAL SILICON STEEL

this, it is apparent that it is practically impossible to prepare samples entirely free from all incidental impurities and furthermore, it is also very difficult to prepare a set of samples in which the incidental impurities are constant[12]. On these accounts, it became necessary at first to obtain an approximate relationship between carbon and the magnetic properties by ignoring the incidental impurities (0.01—0.026 per cent S, 0.002—0.005 per cent P, and 0.001—0.002 per cent Mn), then to use this relationship to determine the effect of sulphur, using different samples, containing up to 0.10 per cent S, as this element appeared to be the second most important, and then to use these two approximate relationships to determine the effects of phosphorus and manganese, again using two other sets of samples, one containing up to 0.14 per cent P and the other up to 0.60 per cent Mn. Having done this, the effect of carbon was re-determined making use of the approximate effect of S, P and Mn, just found. This second approximation for the effect of carbon was then used to re-determine the effects of S, P and Mn. This process was repeated until the last determination checked the previous one. To go through this process for all the various magnetic

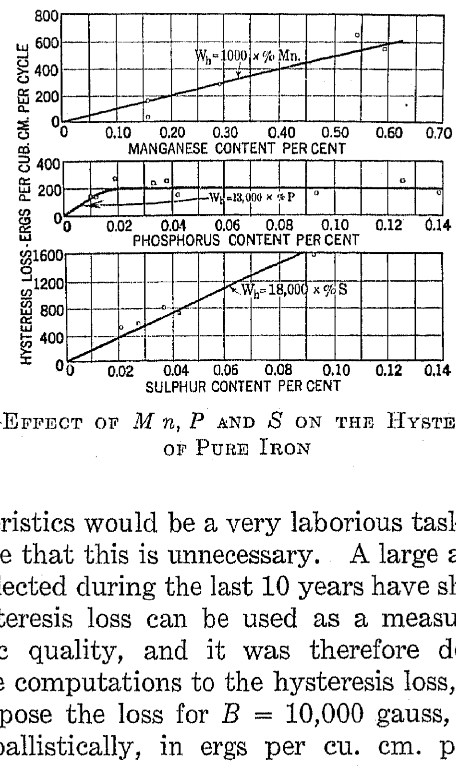

FIG. 13—EFFECT OF Mn, P AND S ON THE HYSTERESIS LOSS OF PURE IRON

characteristics would be a very laborious task and it is fortunate that this is unnecessary. A large amount of data collected during the last 10 years have shown that the hysteresis loss can be used as a measure of the magnetic quality, and it was therefore decided to limit the computations to the hysteresis loss, using for this purpose the loss for $B = 10,000$ gauss, as determined ballistically, in ergs per cu. cm. per cycle. However, additional data in regard to permeability and reluctivity are given in Appendix 3 with no corrections made for incidental impurities. The original data are given in Tables IV-VII. inclusive in Appendix 5.

The final calculations in regard to hysteresis loss have been plotted in Figs. 13, 14 and 15. From these

12. Since the completion, about two years ago, of the experimental work upon which this paper is based, high frequency induction furnaces have been installed, and this, in conjunction with a more careful preparation of the electrolytic iron, has to a large extent eliminated these variables, so that we now can prepare ingots with 0.005 per cent C and 0.004 per cent S, the variations being only ± 0.001 per cent.

curves it will be seen that manganese has a very small effect,

$$W_h = 1000 \times Mn$$

For such small amounts of Mn as occur incidentally, namely 0.001—0.002 per cent, the effect of Mn is to raise the hysteresis loss only 1—2 ergs. However, as the Mn content is increased the effect on the hysteresis loss increases in proportion so that for 0.5 per cent Mn the increase in the loss is 500 ergs.

Phosphorus acts very differently from manganese. For low amounts (up to 0.015 per cent) the hysteresis loss increases in accordance with the formula:

$$W_h = 13{,}000 \times P,$$

but from this point on (0.015 per cent) the effect remains constant (200 ergs) even up to 0.14 per cent. For the incidental amounts of P (0.003—0.005 per cent) the effect is to increase the loss by 25–65 ergs. This effect of phosphorus indicates solubility of P up to 0.015 per cent, followed by precipitation of P as a non-magnetic compound of Fe for larger amounts.

Sulphur again acts like manganese, only to a much greater degree.

$$W_h = 18{,}000 \times S$$

Up to the limit of the present investigation, namely 0.1 per cent S, sulphur thus is very effective in increasing the hysteresis loss, even in the incidental amounts of <0.026 per cent, for which case the increase in loss is 470 ergs.

The previous cases have been investigated partly for the purpose of determining what corrections are necessary due to the incidental impurities in order to determine the effect of carbon. On account of the slight effects of P and Mn these latter are disregarded and the effect of S only is taken into account. Figs. 14 and 15 show the effect of carbon. For carbon contents below 0.006 per cent, and disregarding for the present the effect of grain structure, carbon should increase the hysteresis loss in accordance with the formula:

$$W_h = 220{,}000 \times C$$

Between 0.006 and 0.010 per cent C, the slope is very much less, dropping to 2250 for the upper range. For higher carbon contents, 0.1 to 1.0 per cent, the rate is again higher, being 16,700, but does not begin to approach the rate for very low carbon contents.

A great deal of consideration has been given to explaining this peculiar effect of carbon. As the curve developed, and as it became evident what its shape would be, it was suggested that it be due to different forms in which carbon might exist in the iron. Pearlite being the familiar form, it was natural to suggest that this was the form in which carbon existed in the region 0.1 to 1.0 per cent. It was also thought since the effect of carbon was much less in the region 0.01 to 0.10 per cent that carbon here might be in the form of $Fe_3\,C$ unassociated with ferrite. Finally, it was believed on account of the tremendous effect of carbon in the region below 0.01 per cent that carbon here must be in solution in the iron. At that time the knee of the curve had not been definitely determined, but it was known to be in the neighborhood of 0.01 per cent. In the meantime Mr. N. B. Pilling had been investigating this problem metallographically and it was gratifying to find that his results substantially confirmed the original assumptions. According to his results the knee of the curve was in the neighborhood of 0.005 per cent C and subsequent results obtained magnetically agreed fairly well with this figure. Here is another striking proof that the various physical and structural characteristics go hand in hand. The gradual change in the slope of the curve (Fig. 14) from 220,000 to 2250 indicates that there is no sharp dividing point between the region in which carbon is in solution and the region in which it is precipitated as $Fe_3\,C$. The probability is that carbon continues to go into solution to some extent above 0.006 per cent, perhaps depending upon the annealing conditions. The curves for minimum reluctivity (Fig. 31 Appendix 3) and for electrical resistance (Fig. 37 Appendix 4) indicate that carbon continues to go into solution to some extent up to 0.02 per cent.

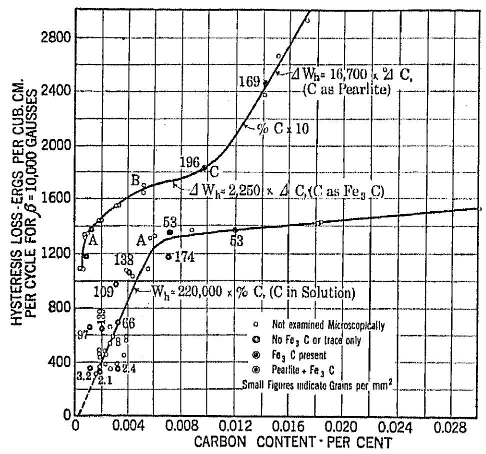

FIG. 14—EFFECT OF CARBON ON THE HYSTERESIS LOSS OF PURE IRON (EFFECT OF GRAIN SIZE NOT ELIMINATED)

A few of the above alloys were examined under the microscope, and photo micrographs obtained (see Fig. 16) using the ordinary etching reagent to bring out pearlite, namely, picric acid, and a magnification of 100 dia. In order to reveal small amounts of $Fe_3\,C$ (cementite) Mr. Pilling developed a new reagent, consisting of a dilute solution of nitric acid and methyl alcohol in nitrobenzol (min. & met. 5, p 31, 1924.) This reagent does not attack the ferrite and so does not reveal the grain boundaries; consequently the $Fe_3\,C$ shows up much more distinctly and there is not the chance of confusion present as is the case when picric acid is used. After the above photo micrographs were taken, the specimens were re-polished, etched with nitrobenzol and examined under a magnification of 1000 diameters, the result of which is given in Table II and in the captions of Fig. 16. In this illustration the alloys are arranged in order of C contents. In the first three the C contents are 0.001,

0.001 and 0.0018 per cent, respectively, and the microanalysis shows no carbide; in the three following the carbon contents are 0.0031, 0.0031, 0.0030 and the microanalysis shows a trace of carbide, *i. e.*, it is doubtful whether there is any carbide present. It is only when we come to the third group where the carbon contents are 0.0071 and 0.012 per cent that the microanalysis shows definite quantities of Fe_3C; and finally when in the fourth group the carbon contents are 0.10 and 0.142 per cent carbon appears as pearlite in addition to free Fe_3C.

Another interesting point to be noted is that the ratio of the slope of the curve (Fig. 14) between C and D (16,700) to that between B and C (2250), 16,700/2250 or 7: 1, agrees very closely with the ratio of the slope of the carbon containing constituent, vs. carbon content for the two cases, pearlite between C and D, and Fe_3C between B and C, namely 7.35.[13] Consequently by plotting carbon-containing constituent as abscissa, the curve B-C-D would be a straight line. In other words, the hysteresis loss for pure iron saturated with C

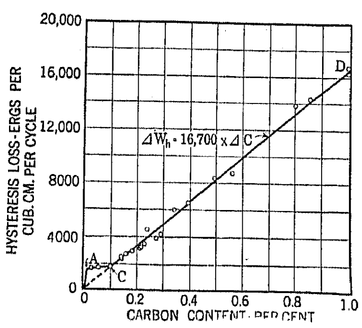

FIG. 15—EFFECT OF CARBON ON THE HYSTERESIS LOSS OF PURE IRON (EFFECT OF GRAIN SIZE NOT ELIMINATED)

in solution is increased in direct proportion to the amount of the iron associated with the precipitated carbon—or the carbon-containing constitutent.

For carbon contents above 0.01 per cent the points deviate but slightly from the smooth curve, while for carbon contents below the knee of the curve there is considerable deviation. Part of this is undoubtedly due to experimental errors both in the carbon determinations and in the magnetic testing. A variation of $\pm$ 0.001 per cent would nearly account for the deviation, but the analyses were carefully checked, and it is felt that the errors due to this source are less than the above figures. The same statement can be made with regard to the magnetic testing. Another variable was therefore looked for and in view of the great importance attributed to grain size by some investigators an approximate determination of the average grain size was made of some of the samples.[14]

In Fig. 17 the points for very low carbon contents (0.001—0.004 per cent) have been plotted.[15] The mean value of the carbon content for the samples with large grains is 0.0020 per cent and that for samples with small grains 0.0026 per cent. By considering the carbon content as 0.0023 per cent the variation is only $\pm$0.0003 per cent and can consequently be regarded as a constant for the present purpose, which is to determine

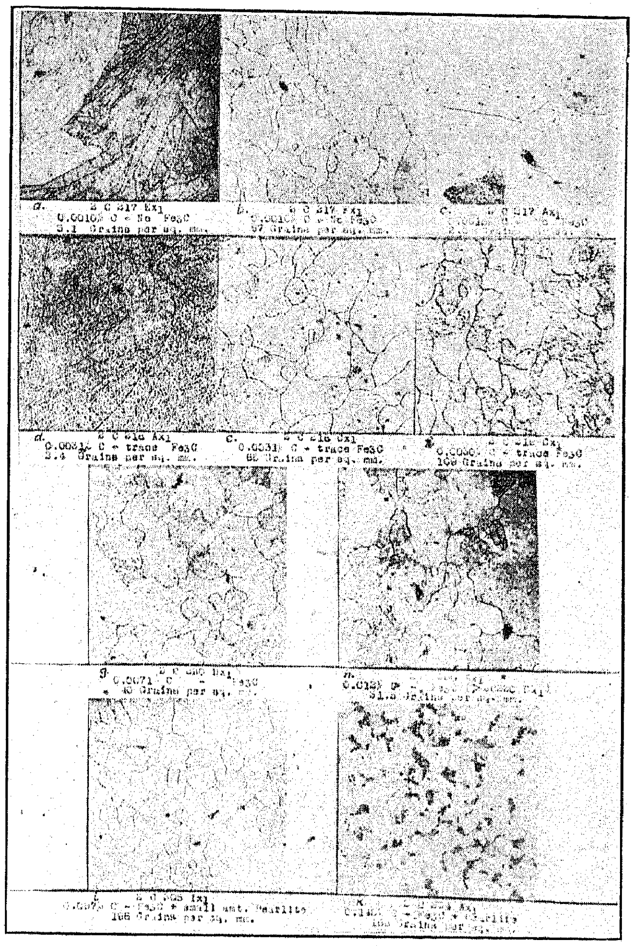

FIG. 16—FE-C ALLOYS. ETCHED WITH PICRIC ACID. 50 DIAM. CARBON DETERMINATION BY VACCUM-LIQUID AIR METHOD. FORM OF CARBON DETERMINED BY MEANS OF NITRO-BENZOL ETCHING REAGENT AND 1000 DIAM. MAGNIFICATION

13. Fe_3C contains 6.67 per cent $C \therefore 1$ part C makes 15 parts Fe_3C. Pearlite contains approx. 0.90 per cent $C \therefore 1$ part C makes 111 parts pearlite.

The ratio $\frac{\text{pearlite}}{Fe_3C}$ (for the same C content) = 111/15 = 7.35 (by weight or volume).

14. The grain size was determined by actual grain count on the ground glass screen of the camera attached to the microscope. On account of the great difficulty of obtaining definite grain boundaries as well as on account of the non-uniformity of the grains, accuracy is, in some cases, not as great as might be desired.

15. It will be noted from Fig. 17 that three out of five of the samples having small grains had been annealed in nitrogen, while all of the samples having large grains had been annealed in vacuum, which would indicate that nitrogen may have some influence on the grain growth—possibly through the agency of minute quantities of iron-nitride, although nitrogen is not supposed to react with iron at any temperature according to Tchijevski (Rev. de Met. 11 E pp. 617-18, 1914).

the effect of grain size upon the hysteresis loss. The carbon content being constant its effect must necessarily be constant, and as the effect of the grain size must be zero when the grain size is infinitely large, (or the number of grains per unit area is zero), the relationship between grain size and hysteresis loss for a constant carbon content may be expressed as

$$W_h = a N^b + K,$$

where N = number of grains per sq. mm. and K = the effect of carbon.

By giving the values of grain size weight in accordance

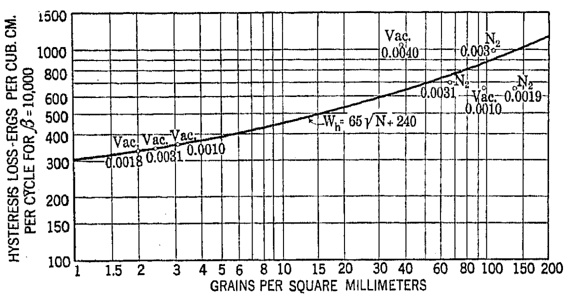

FIG. 17—HYSTERESIS LOSS VS. GRAIN SIZE FOR CARBON CONTENTS OF 0.001-0.004 PER CENT

Vac = Annealed in vacuo N_2 = Annealed in Nitrogen Small figures show carbon content.

with the approximate accuracy with which they could be determined, the weighted mean value of grain size for the upper group of points is 85 grains per sq. mm. corresponding to a hysteresis loss of 810 ergs. The equation for the curve as drawn through this point and the lower points then becomes:

$$W_h = 65\sqrt{N} + 240$$

As this equation holds for a carbon content of 0.0023 per cent this means that 240 ergs is the loss due to 0.0023 per cent C. Hence in general, the effect of carbon in solution on the hysteresis loss can be written:

$W_h = 240/0.0023 \times C = 104{,}000 \times C$ instead of the previously obtained value of $220{,}000 \times$ per cent C.

The next question is whether the above relationship between grain size and hysteresis loss holds when carbon is thrown out of solution. This question will be taken up later under the 4 per cent silicon alloys, where it is shown that for carbon contents between 0.02 and 0.06 per cent, in which range carbon is precipitated as Fe_3C, the effect of grain size can be expressed by the equation:

$$W_h = 3N$$

(see Fig. 23). As there is no reason to suppose that this effect is different in the case of pure iron containing appreciable amounts of Fe_3C, than in the case of 4 per cent silicon alloys, the above equation will be used in order to eliminate the effect of grain size on the hysteresis loss of iron with medium and high carbon contents (*i. e.* with carbon contents of 0.02 per cent and above).

Using these data in regard to grain size and deducting the effect of grain size from the values of hysteresis loss given in Table II, using for this purpose the equations just derived, namely:

$W_h = 65 \times \sqrt{N}$ for carbon in solution, and

$W_h = 3 \times N$ for carbon in excess of 0.02 per cent, the net loss due to carbon is tabulated in the last column of Table II, and plotted in Fig. 18.[16]

This curve then represents the hypothetical hysteresis loss of pure iron-carbon alloys having no inter-crystalline cement, except as far as the carbon containing constituent is concerned, and no other inter-crystalline or intra-crystalline impurities. The equation of this curve is

$$W_h = \underset{C \text{ in sol.}}{104{,}000 \times C} + \underset{Fe_3C}{2250(C - 0.008)} + \underset{\text{pearlite}}{16{,}700(C - 0.09)}$$

upper limits $C = 0.008$ $C = 0.09$ $C = 0.90$

The complete equation for the effect of carbon and grain size on the hysteresis loss of pure iron can consequently be written:[17]

1. For carbon in solution:

$W_h = 65\sqrt{N} + 104{,}000 \times C$ for $C < 0.008$

2. For precipitated carbon:

$W_h = 3N + 830 + 2250(C - 0.08) + 16{,}700(C - 0.09)$

Upper limits $C = 0.09$ $C = 0.90$

3. For small amounts of the common impurities:

$W_h = 65\sqrt{N} + 104{,}000 \times C + 18{,}000 \times S + 1000 \times Mn + 13{,}000 \times P$

Upper limits $C = 0.008$ $S = 0.10$ $Mn = 1.0$ $P = 0.015$

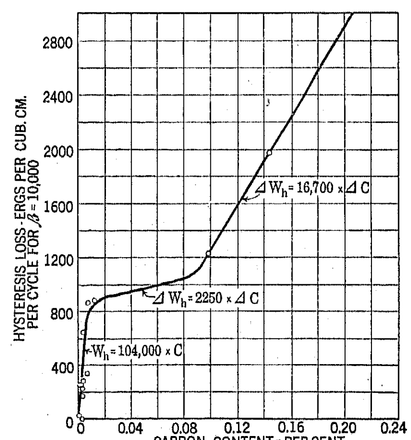

FIG. 18—EFFECT OF CARBON ON THE HYSTERESIS LOSS OF PURE IRON; EFFECT OF ALL OTHER IMPURITIES HAVING BEEN ELIMINATED

Of all the factors influencing the magnetic properties the dissolved carbon is thus seen to be by far the most important. For higher carbon contents (0.5—1.0 per cent), this effect has long been made use of for permanent magnets, by quenching the alloys from a temperature at which the carbon is in solution and thereby preventing it from being precipitated. Other ele-

16. In drawing this curve, use was made of the general shape of the curves of Figs. 14 and 15.

17. N = no. grains per sq. mm. C, S, Mn and P are the percentages of these elements respectively. The upper limits given are the values of the elements (in per cent) above which the constants either do not hold or have not been investigated.

ments like tungsten and molybdenum assist in keeping carbon in solution and are consequently used extensively in the manufacture of permanent magnets. It has hitherto been assumed, however, that the dissolved carbon is precipitated as pearlite by slow cooling from 900 deg. or above. The present results, however, confirmed by the analyses of Mr. Pilling, show that this is not the case, at least not under the conditions of the present investigation, where cooling from 900 deg. or above was done at the slow rate of 30 deg. cent. per hour. Under these conditions 0.006 to 0.008 per cent C remains in solution (martensite) 0.09 per cent is precipitated as Fe_3C (cementite) and any carbon in excess of this is precipitated as pearlite. Were it possible to precipitate all the carbon, we should expect the magnetic properties to be very greatly improved, even though the total carbon content were as high as 0.1 per cent.

Various more or less vague suggestions have been made to explain this tremendous effect of carbon on the magnetic properties. One is that the ferro-magnetic properties are caused by a certain more or less stable equilibrium arrangement of the electrons in the atomic structure and that the carbon entering into solution affects this structure by distorting the space lattice and upsets the equilibrium.[18]

Gumlich and Steinhaus[19] in discussing the effect of dissolved carbon on the coercive force, H_c, give the following figures:

0.01 per cent C as pearlite increases H_c by 0.07 gauss
0.01 per cent C as martensite " H_c by 0.80 gauss

These results were obtained for medium and high carbon contents, in the case of martensite by quenching and in the case of pearlite by slow cooling.[20]

For the sake of comparison the data in regard to coercive force vs. carbon content from the present data have been plotted in Fig. 19, giving the following results:[21]

For $0 < C < 0.006$	$H_c = 80 \times$ per cent C *i. e.* 0.01 per cent C produces a coercive force of 0.8 gilberts per cm.
For $C > 0.09$	$\Delta H_c = 5.4 \times$ per cent ΔC *i. e.* 0.01 per cent C produces a coercive force of 0.054 gilberts per cm.
For $0.006 < C < .09$	$\Delta H_c = 0.8 \times$ per cent ΔC *i. e.* 0.01 per cent C produces a coercive force of 0.008 gilberts per cm.

In other words, the effect on the coercive force of carbon in the three successive regions is as 100:1:6.8 respectively, or practically the same ratios as in the

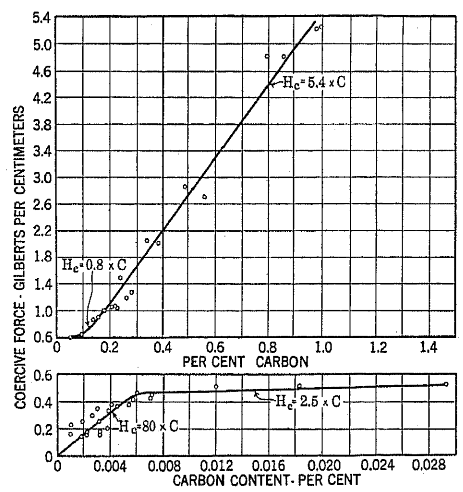

FIG. 19—COERCIVE FORCE VS. CARBON CONTENT FE-C ALLOYS. (EFFECT OF GRAIN SIZE NOT ELIMINATED)

18. Since writing the manuscript for this paper a very interesting contribution to the subject of Solid Solutions has been made by Dr. Walter Rosenhain: 'Solid Solutions' issued with Mining and Metallurgy, TRANS. A. I. M. E. 1923, Reprint No. 1250-N. In this paper Dr. Rosenhain explains the 'Substitution' theory of Solid Solutions, according to which atoms of various metals are capable of displacing each other in the space lattice of the crystal structure. The amount of solubility and the effect the solute has on the solvent will largely depend upon the relative properties of the atoms of the solute and the solvent. Such substitution would in any case result in some change in the forces between the adjacent atoms of the solvent, and some sort of distortion of the lattice is bound to follow, the more so the greater the difference between the two atoms. Most of the well known phenomena of solid solutions are satisfactorily explained by this theory. In regard to carbon and phosphorus, Dr. Rosenhain believes that their atoms are so small compared with those of iron that they can find room in the lattice interstices, but with effects similar to those of 'substitution' atoms. It is readily seen that this theory harmonizes very well with the suggestion given above as to the action of dissolved carbon on the magnetic properties of iron. Dr. Rosenhain purposely avoids discussing the beneficial effect of silicon (and aluminum) on the hysteresis loss of iron, and merely remarks that this effect may be due to a neutralizing effect on the distortions caused by the impurities present. In view of the results given in this paper it would seem, however, that the beneficial effect of silicon is independent of the impurities and is due to the causes stated later on in this paper.

19. "Variations in the B-H curves of Low Hysteresis Materials" *Phys. Tech. Reichsanstalt.*

ETZ 36 pp. 675-77, 691-94, 1915 (Received after the close of the war).

20. Means were not available for analyzing very low carbon contents directly. This was done indirectly, however, by extrapolating the curve between dissolved carbon and H_c to zero, assuming it to be a straight line. Carbon contents below 0.01 per cent were then determined by quenching the previously annealed and tested test pieces in order to get all the carbon into solution, then redetermining H_c and finally from the increase in H_c and the above extrapolated curve obtaining the carbon content. This was then assumed to be the carbon content of the original test pieces. This method is obviously open to the objection that it does not take into account the effect of strain on the magnetic properties caused by the quenching. If it were not for this effect, H_c should be the same before and after quenching for $C < 0.008$ per cent because C is then in solution even after slow cooling. In other words, the increase in H_c by quenching is attributed to strain, and not to a change in the form of carbon, as assumed by Gumlich.

21. In this case the effect of sulphur on the coercive force has been taken into account by deducting from the measured coercive force 4.4 x per cent S, but the effect of grain size has been included in order to compare these results with those of Gumlich & Steinhaus.

case of the hysteresis loss (98:1:7.4). Comparing the above results with those of Gumlich and Steinhaus, it is seen that our coefficient for carbon contents of less than 0.006 per cent check theirs for dissolved carbon (martensite) exactly ($H_c = 80 \times$ per cent C), thus confirming again our previous conclusion that for carbon contents below 0.006—0.008 per cent, carbon is in solution.

In the case of pearlitic carbon, however, the agreement is not so good. Gumlich and Steinhaus give $H_c = 7.0 \times$ per cent C while the present data give $H_c = 5.4 \times$ per cent C. This disagreement is readily understood, if,—as is probable—they assumed that all the carbon is precipitated as pearlite by cooling from 900 deg. or above. On this assumption, by drawing a straight or slightly curved line from the origin through the points obtained for H_c corresponding to carbon contents of 0.1 to 1.0 per cent a coefficient of 7.0 can readily be obtained but based on the present results this is obviously not correct.

In view of the results obtained for hysteresis loss, the magnetic properties depend to a large extent upon the grain size and as the latter does not depend altogether on the carbon content, the grain size should be introduced into the equation for the coercive force in order to reconcile it with the experimental facts. If this be done in the same way as it was done above in the case of the hysteresis loss the following equation is obtained:

$$H_c = 0.025 \sqrt{N} + 40 \times C$$

for carbon in solution and corresponding equations for precipitated carbon.

The electrical resistance of the *Fe-C*, *Fe-Mn*, *Fe-S* and *Fe-P* alloys as tabulated in Tables 4-7 in Appendix 5 have been plotted in Fig. 37 in Appendix 4. From this it will be seen that carbon in small amounts, (less than 0.02 per cent) increases the resistance by $82.5 \times$ per cent C, whereas carbon in larger amounts increases the resistance by only $4.5 \times$ per cent C, that is, in the ratio of nearly 20:1. All evidence, therefore, is to the effect that small amounts of carbon remain in solution in iron at ordinary temperature, in spite of very slow cooling from above the A_3 transition point.

Maximum permeability and minimum reluctivity curves will be found in Appendix 3 (Figs. 30 and 31 respectively.) It will be seen that the reluctivity curves are of the same general shape as the hysteresis loss curve indicating that carbon is all in solution up to 0.006 per cent and continues to go into solution to some extent up to 0.02 per cent. It is interesting to compare the slopes of the curves for the hysteresis loss, coercive force, and minimum reluctivity in the three different regions (effect of grain-size not eliminated):

	Carbon in Sol.		Carbon as Fe_3C		Carbon as pearlite
Hysteresis Loss..	98	:	1	:	7.4
Coercive Force	100	:	1	:	6.76
Min. Reluctivity	94.5	:	1	:	6.78

As these ratios are very nearly the same it may be concluded that the above properties all are identical functions of the carbon content and of the state of the carbon.

Second Series, 4 Per Cent Silicon

The effect of carbon, sulphur, phosphorus, manganese and grain size on the magnetic properties of 4 per cent iron-silicon alloys.

In case of the 4 per cent silicon alloys the same procedure was followed as in the case of the simple iron-carbon alloys, *i. e.* the effects of sulphur, phosphorus and manganese were determined, so that the effect of carbon could be more accurately ascertained. Three series of alloys were prepared. The first series, in which Goldschmidt-Thermit Co. 91 per cent ferro-silicon was used, was furthermore divided into two groups: Group "a" in which electrolytic iron was used as a base and containing all the alloys used for obtaining the effects of sulphur, phosphorus and manganese, and group "b"

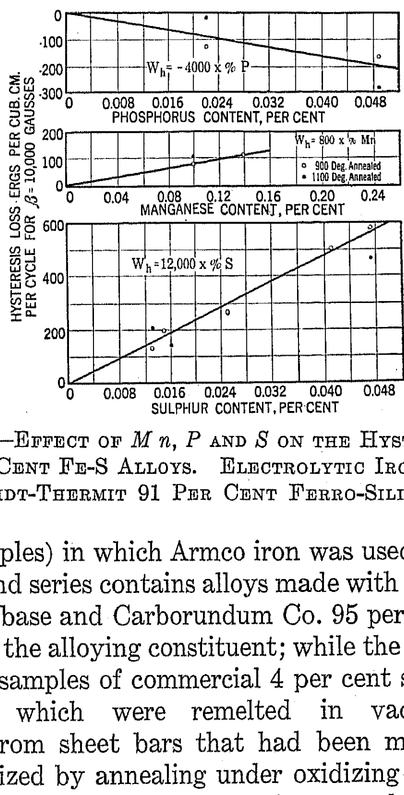

Fig. 20—Effect of Mn, P and S on the Hysteresis Loss of 4 Per Cent Fe-S Alloys. Electrolytic Iron Base and Goldschmidt-Thermit 91 Per Cent Ferro-Silicon

(two samples) in which Armco iron was used as a base. The second series contains alloys made with electrolytic iron as a base and Carborundum Co. 95 per cent ferro-silicon as the alloying constituent; while the third series contains samples of commercial 4 per cent silicon steel two of which were remelted in vacuum and six cut from sheet bars that had been more or less decarbonized by annealing under oxidizing conditions.

The effects of sulphur, phosphorus and manganese are shown graphically in Fig. 20 and can be expressed by the equation,

$$W_h = 12{,}000 \times S + 800 \times Mn - 4000 \times P$$

In other words sulphur and manganese affect the magnetic properties of 4 per cent *Fe-Si* alloys in the same way as—although to a slightly smaller degree than—they affect the magnetic properties of unalloyed iron. Phosphorus, on the other hand, improves the properties of the 4 per cent *Fe-Si* alloys while it has the opposite effect on unalloyed iron.

After eliminating the effects of the above impurities the effect of carbon is shown graphically in Figs. 21

and 22. Fig. 21 for 3.48 – 3.70 per cent *Si* and Fig. 22 for 3.70 – 4.30 per cent *Si*, disregarding for the present the effect of grain size. For carbon contents below 0.007 per cent carbon is in solution and the relationship of hysteresis loss to carbon content can be expressed by the equation:

$$W_h = 110{,}000 \times C$$

Carbon probably continues to go into solution to some extent up to 0.02 per cent but is largely precipitated as Fe_3C up to 0.10 per cent, while for carbon contents in excess of 0.10 per cent carbon is precipitated not as pearlite as in the case of unalloyed iron, but as graphite, with a correspondingly slight effect. These conclusions are confirmed by the minimum reluctivity curves shown in Fig. 32 in Appendix 3.

Another difference between these two materials is that relating to grain size. Under the conditions of the present investigation the grain size of unalloyed iron with low carbon (< 0.006 per cent) may vary from large

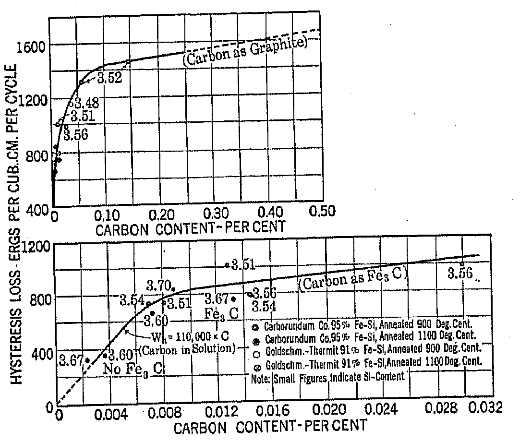

Fig. 21—Hysteresis Loss vs. Carbon Content. 3.5 Per Cent Fe-Si Alloys (3.48 – 3.70 Per Cent Si). Effect of Grain Size not Eliminated

to very small (2-100 grains per sq. mm.) and for medium carbon (0.01-0.10 per cent) the grain size is very small (see Fig. 14). For 4 per cent *Si*, on the other hand, the grain size is large both for low and medium carbon contents. In order to determine the effect of grain size on the properties of 4 per cent *Si* alloys it was therefore necessary to produce alloys with small grains and to treat them in such a way that extensive grain growth could not take place. Two separate alloys had been so treated. Samples had been rolled at 600, 800 and 1000 deg. in order to test out the effect of various rolling temperatures, and separate samples had been annealed at 900 and 1100 deg. tested magnetically and inspected microscopically. Three other samples, 26, 31 and 14 mils, respectively, were also tested. In order to get data in regard to alloys with medium carbon content and small grains it was necessary to make use of samples of commercial 4 per cent *Si* steel, because with the methods available at the laboratory the rolling operation would decarbonize the samples. Finally, four samples of decarbonized steel were included. The data have been plotted in Fig. 23.[21] The samples arrange themselves in two distinct groups, one including those having carbon contents of less than 0.005 per cent *C*, and the other composed of those with carbon contents of 0.020-0.060 per cent *C*. The equation for the curve drawn through the centers of density of the points for low carbon contents is so nearly the same as in the case of unalloyed iron that the two can be regarded as indentical, namely,

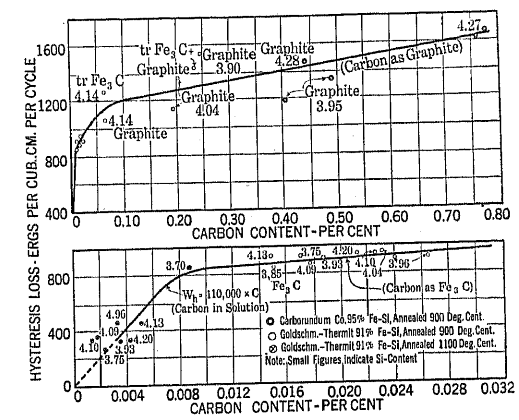

Fig. 22—Hysteresis Loss vs. Carbon Content. 4 Per Cent Fe-Si Alloys (3.70 – 4.30 per Cent Si). Effect of Grain Size not Eliminated

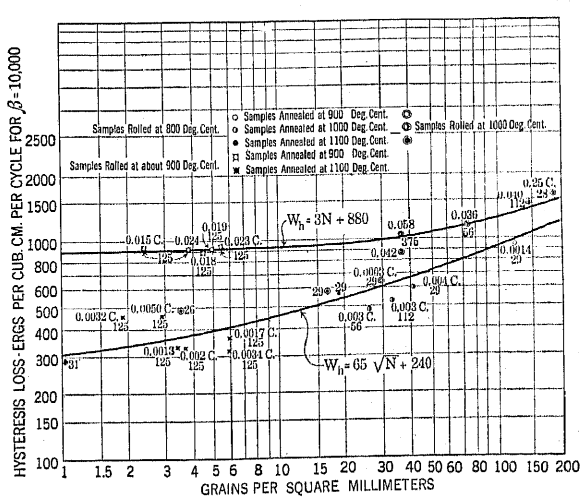

Fig. 23—Hysteresis Loss vs. Grain Size. 4 Per Cent Fe-Si Alloys small Figures show Carbon Content and Thickness of Samples (Mils)

$$W_h = 65\sqrt{N} + 240$$

where the first term, $65\sqrt{N}$, represents the effect of grain size and the second term, 240, represents the effect of carbon, which in this case averages 0.0020 to 0.0025

21. In order not to introduce unnecessary variables the results for the 14 mils samples were not plotted, because of the excessive oxidation these were subjected to during the rolling operation. Furthermore, the results for the samples rolled at 600 deg. were not plotted. Although no apparent reason is yet known for disregarding these samples the rolling temperature is so far below the standard that it is believed preferable to leave them out for the present purpose.

per cent. The hysteresis loss for 0 per cent silicon and for 4 per cent silicon having the same carbon content (less than 0.005 per cent) is consequently the same and depends primarily upon the grain size. For higher carbon contents (0.020-0.060 per cent) where carbon in excess of about 0.010 per cent is precipitated as $Fe_3\,C$ the effect of grain size is not nearly so large. As the effect of a small variation of carbon in this case is already known to be very small (see Fig. 22) the carbon content and its effect on the hysteresis loss may for the present purpose be regarded as constant, and the relationship between grain size and hysteresis loss for this carbon content can be expressed by the equation

$$W_h = 3\,N + 880$$

where the first term, $3\,N$, represents the effect of the grain size, and the second term, 880, represents the effect of the carbon which in this case averages 0.03 per cent.

Deducting now the effect of grain size in accordance with the above equations, from the loss due to the com-

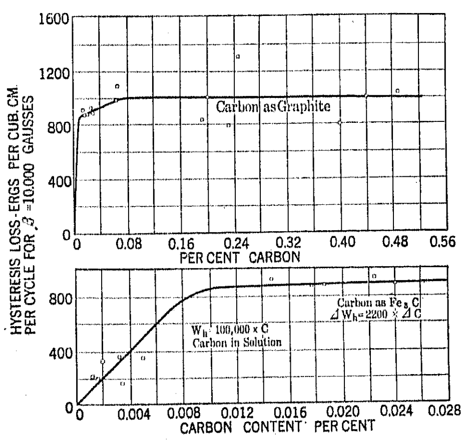

Fig. 24—Effect of Carbon on the Hysteresis Loss 4 Per Cent Iron-Silicon Alloys; Effect of All other Impurities having been Eliminated

bined effect of grain size and carbon the net loss due to carbon is obtained. The result is plotted in Fig. 24. The equation for the compound curve thus obtained is,

$$W_h = 100{,}000 \times C + 2200\ (C—0.0085) + 0\ (C—0.08)$$

Upper limits $C = 0.0085$ $C = 0.08$ $C = 0.50$
(C in solution) (C as $Fe_3\,C$) (C as graphite)

Comparing this curve with that for 0 per cent Si, it will be seen that the two are practically identical up to a carbon content of about 0.080 per cent. From this point on carbon is precipitated as pearlite for 0 per cent Si, with the result that the loss increases by 16,700 $\times$ C, while for 4 per cent Si carbon is precipitated as graphite with practically no additional increase in the hysteresis loss.[22]

What at first, therefore, appeared as a difference in the effect of carbon on the two materials (unalloyed iron and 4 per cent Fe-Si alloys) has resolved itself into a difference caused by the action of silicon: Firstly, by its action on the grain size, namely, that *without* silicon the normal grain size is small and it is difficult to get large grains, while *with* silicon (4 per cent) the normal grain size is large due to the absence of the A_3 transformation point, and small grains can be had only by severe mechanical working; secondly, by the action of silicon on the form of carbon, namely, by precipitating it as graphite instead of as pearlite for carbon contents in excess of about 0.08 per cent. The conclusion can, therefore, be drawn that the effect of carbon is the same on unalloyed iron and on 4 per cent Fe-Si alloys and depends only upon the form in which it occurs.

To summarize, the effect of carbon and grain size on 4 per cent Fe-Si alloys can be expressed by the following equations:

1. For dissolved carbon

$$W_h = 65\sqrt{N} + 100{,}000 \times C \qquad \text{for } C < 0.0085$$

2. For precipitated carbon

$$W_h = 3\,N + 850 + 2200\ (C—0.0085) + 0\ (C—0.08)$$

Upper limits $C = 0.08$ $C = 0.50$

For small amounts of impurities:

$$W_h = 65\sqrt{N} + 100{,}000 \times C + 12{,}000 \times S + 800 \times Mn - 4{,}000 \times P$$

Upper limits $C = 0.0085$ $S = 0.05$ $Mn = 0.20$ $P = 0.05$

Calculation of Hysteresis Loss

In order to ascertain further the validity of the above formulas, a number of samples of commercial 4 per cent Si steels treated in various ways so as to give a variety of compositions and structures were analyzed chemically and microscopically. The first set of samples marked "A" in Table III were remelted in vacuum, forged and machined into test rings (⅜ in. cm. thick). Two of these were annealed at 900 deg. and two rings at 1100 deg. in a current of air at reduced pressure resulting in carbon contents of 0.03 per cent and 0.003 per cent, respectively. The second set, marked "B", consists of samples made from regular sheet bars, that had been more or less decarbonized by annealing them in iron oxide at 1000 deg. cent. at reduced pressures. The machined rings were annealed at 1000 deg. in vacuum for 20 hours, the final carbon contents varying from 0.002 to 0.023 per cent. The third set, marked "C", consists of samples made from sheets rolled to various gages, 0.35—9.5 mm. (14—375 mils,) by the commercial rolling mill. The samples were prepared by punching rings 4.5 cm. × 3.2 cm. from the rolled sheets, except in the case of the first sample that was machined from the sheet bar. The samples were annealed at 1000 deg. for two hours in vacuum. The carbon contents in this case varied from 0.013 to 0.058 per cent. All the samples were cooled slowly after being annealed and were then tested and analyzed by sampling the test pieces themselves. The results, as far as hysteresis loss is concerned, are given in Table III. The actual losses are

22. The variation from the smooth curve for high carbon contents is probably due to variation in the relative amounts of carbon precipitated as $Fe_3\,C$ and as graphite.

given in the column next to the one giving the calculated losses and the difference given in ergs and per cent in the last two columns. While the maximum errors are $\pm$ 10 per cent it will be noted that the algebraic mean errors for the three sets are − 0.5 per cent, + 1.6 per cent and 0 per cent, respectively, and the mean error for all the sets is only + 0.43 per cent, showing that by taking the mean for a few samples, the individual errors due to analysis are eliminated and very accurate results are obtained.

Third and Fourth Series: 2 Per Cent Silicon and 5-6 Per Cent Silicon

Note: These two series were not investigated as fully as the previous two series, thus the effects of S, P and Mn on the magnetic properties were not investigated separately but assumed to be the same as for 0 and 4 per cent silicon, respectively. Furthermore, only a few samples of the 2 per cent series were inspected for grain structure and none of the fourth series. While the final calculations, therefore, are based on a number of assumptions, a close examination will show that the errors involved should be well within $\pm$ 5 per cent. These two series are included in the paper for the sake of correlating all the information available at the present time.

Third Series: 2 Per Cent Silicon

The effect of carbon on the magnetic properties of 2 per cent iron-silicon alloys.

Two sets of alloys were made, one using Carborundum Co. 95 per cent ferro-silicon and the other using Goldschmidt-Thermit Co. 91 per cent ferro-silicon. No investigation of the effect of S, Mn and P was made for 2 per cent Si, but based on the results obtained for 0 and 4 per cent Si, the error in using the constants for 0 per cent Si cannot be appreciable. The effect of P and Mn—being present in only minute quantities (Mn—0.01 per cent, P—0.003 per cent) is therefore disregarded and the effect of sulphur is assumed to be

$$W_h = 18{,}000 \times S.$$

On this assumption the hysteresis loss for pure Fe-Si-C alloys containing 1.75—2.25 per cent Si has been calculated and plotted in Fig. 25.

On account of the large deviation from the curve in

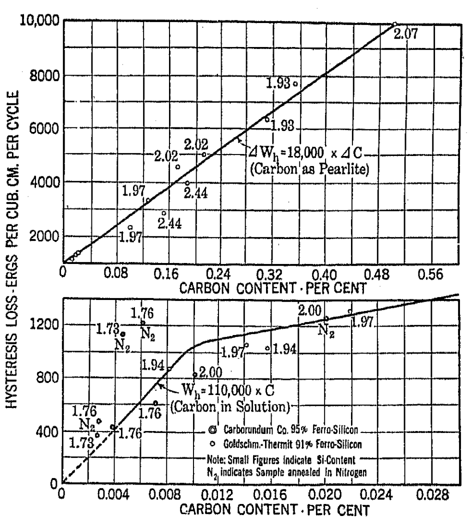

Fig. 25—Hysteresis Loss vs. Carbon Content for 2 Per Cent Fe-Si Alloys (1.73 − 2.44 per Cent Si). Effect of Grain Size not Eliminated

the case of two of the rings (carbon contents 0.0044 per cent and 0.0060 per cent, respectively) the grain structure was suspected, and two rings having nearly the same carbon content (0.0044 and 0.0026 per cent) but one having a high loss and one a low loss were inspected under the microscope and photographed (see Fig. 26). The result confirmed the suspicion, one ring having 48 grains per sq. mm., while the other had less than 0.5

grains per sq. mm. or 100 times as large grains as the former. Applying the same formulas as derived for 0 per cent and for 4 per cent Si, namely,

$W_h = 65 \times \sqrt{N}$ for 0—0.008 per cent C

the effect of the grain size on the hysteresis loss is 10 times as great in the one case as in the other, being 450 ergs to 45 ergs, which is sufficient to account for the difference in the total hysteresis loss. No cementite is visible in either case, showing that carbon is in solution.

A few more samples were analyzed for grain size and the effect on the hysteresis loss eliminated in accordance with the equations deducted for 0 and 4 per cent silicon.

The result has been plotted in Fig. 27. Based on the

FIG. 26A—2 G 201 $L \times 100$, C – 0.0026 PER CENT. $W_{10} = 576$. $N < 0.5$ GRAINS PER MM.²

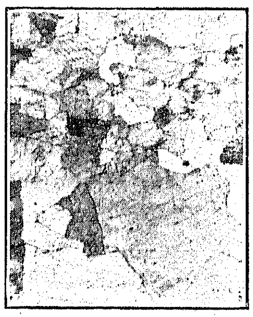

FIG. 26B—2 G 202 $L \times 100$, C – 0.0044 PER CENT. $W_{10} = 1216$. $N = 48$ GRAINS PER MM.²

combined magnetic and microscopic results the conclusion is that for carbon contents of less than 0.0085 per cent carbon is in solution, as in the case of 0 and 4 per cent Si, the effect of carbon being expressed by the equation,

$$W_h = 105{,}000 \times C \quad \text{for } C < 0.0085$$

Carbon in excess of 0.0085 per cent is precipitated as pearlite. This is in contrast to the cases for 0 per cent and 4 per cent Si in both of which cases carbon in the region 0.008—0.09 per cent is precipitated as Fe_3C unassociated with iron. As a consequence, the total effect of precipitated carbon is greater for 2 per cent Si than for 0 and 4 per cent Si, being expressed by the equation:

$$W_h = 105{,}000 \times C + 16{,}120\ (C—0.0085)$$

Upper limits	$C = 0.0085$	$C = 0.50$
	C in solution	C as pearlite

but the rate of increase is practically the same as for pearlitic carbon for 0 per cent silicon, (16,120 vs. 16,700). On the other hand, due to the silicon, the normal grain size is so much larger for 2 per cent silicon alloys with low carbon contents that the actual hysteresis loss is less than for 0 per cent Si up to a carbon content of about 0.04 per cent.

Minimum reluctivity curves for the 2 per cent Si alloys will be found in Appendix 3 Fig. 33, indicating that carbon may go into solution to some extent up to 0.02 per cent as in the case of 0 and 4 per cent Si.

FOURTH SERIES: 5-6 PER CENT SILICON

The effect of carbon on the magnetic properties of 5-6 per cent iron-silicon alloys.

The effect of S, P and Mn was not determined separately for these alloys but was assumed to be the

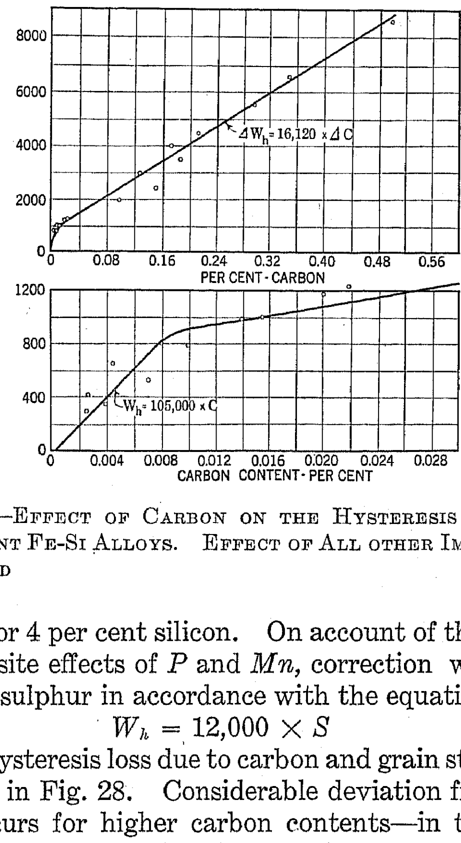

FIG. 27—EFFECT OF CARBON ON THE HYSTERESIS LOSS OF 2 PER CENT FE-SI ALLOYS. EFFECT OF ALL OTHER IMPURITIES ELIMINATED

same as for 4 per cent silicon. On account of the slight and opposite effects of P and Mn, correction was only made for sulphur in accordance with the equation:

$$W_h = 12{,}000 \times S$$

The net hysteresis loss due to carbon and grain structure is plotted in Fig. 28. Considerable deviation from the curve occurs for higher carbon contents—in the case of the samples made with Goldschmidt-Thermitt ferro-silicon—probably due to variation in the grain structure. Based on the results obtained for the 4 per cent Si alloys in regard to grain size the hysteresis loss has been reduced in accordance with the equation:

$$W_h = 3\,N$$

(where N = no. grains per sq. mm.) resulting in the horizontal curve in Fig. 28 for carbon contents in excess of 0.007 per cent. From these results it can be concluded that for Fe-Si alloys containing 4.7 per cent Si and above, carbon is in solution up to 0.007 per cent

and carbon in excess of this amount is precipitated as graphite. The effect on the hysteresis loss is

$$W_h = 100{,}000 \times C + 0\ (C - 0.007)$$

Upper limits $C = 0.007$ $C = 0.50$
C in solution Graphite

i. e., there is no further increase due to carbon percipitated as graphite. The reason for the increase in the *total* hysteresis loss is probably to be found in the decrease in the grain size due to the disturbance caused by the graphite with the consequent increase in the amount of the intercrystalline material. One might say, of course, that the primary cause of this increase is carbon and write the equation.

$$W_h = 100{,}000 \times C + 700\ (C - 0.007)$$

Upper limits $C = 0.007$ $C = 0.50$

but as it is possible to vary the grain size even with a high carbon (graphite) content it would be preferable to write the equations:

$$W_h = 65\sqrt{N} + 100{,}000 \times C \qquad \text{for } C < 0.007$$

and

$$W_h = 3\,N + 700 \qquad \text{for } C > 0.007$$

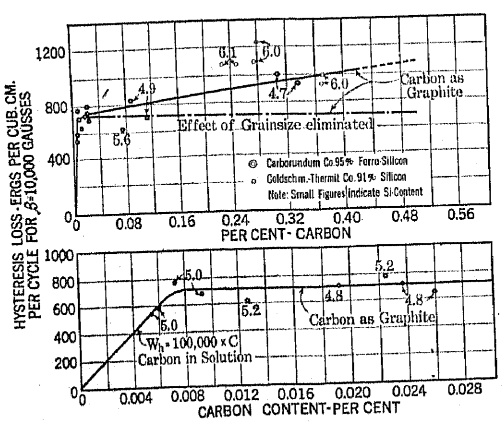

Fig. 28—Hysteresis Loss vs. Carbon Content 5-6 Per Cent Alloys

Minimum reluctivity curves for the 5 and 6 per cent alloys will be found in Appendix 3 Fig. 34.

The Question of Grain Size and Intercrystalline Impurities

The question naturally arises: Why should the grain size affect the magnetic properties? There must be something that increases as the grain size decreases, and upon which the hysteresis loss partly depends, or, in other words, that causes an increase in the hysteresis loss over and above that due directly to carbon and other impurities. As far as is known at present there is only one material that increases, as the grain size decreases, and this is the amorphous inter-crystalline cement, so called. It is, therefore, logical to conclude that there is a definite relation between the amount of this material and the hysteresis loss. It has been shown that the hysteresis loss per unit volume for alloys with carbon in solution is proportional to $\sqrt{N}$. It can also be shown that the amount of the inter-crystalline material per unit volume is proportional to $\sqrt{N}$[23]. It follows, therefore, that the hysteresis loss is directly proportional to the amount of the inter-crystalline cement, and that the latter acts just like any other inter-crystalline impurity, such as $Fe_3\,C$, pearlite, $Fe\,S$, etc.

Another question that remains to be answered is in regard to the mechanism by means of which these inter-crystalline impurities increase the hysteresis loss. Does the loss occur in the impurities themselves—or do they increase the loss in the ferrite grains by disturbing the uniformity of the flux distribution? Or, do they act merely as inert material, like graphite or air, having relatively speaking, no capacity for conducting a magnetic flux? In favor of the first suggestion speaks the fact that pure pearlite, consisting of $Fe_3\,C$ and ferrite, has a maximum permeability of 1000 and a hysteresis loss of about 15,000 ergs., 13,500 of which is due to $Fe_3\,C$ as pearlite (the remainder being due to carbon in solution). This is nearly 15 times the loss for iron saturated with carbon in solution (0.006—0.008 per cent C). Now, pearlite consists of about 13.5 per cent $Fe_3\,C$ and 86.5 per cent ferrite, and it is difficult to conceive how a reduction in the amount of active ferrite of only 13.5 per cent can possibly increase the flux density in any part to such an extent as to increase the hysteresis loss to 15 times the original value. On the other hand, how can we account for the difference in the effect on the hysteresis loss of $Fe_3\,C$ as free cementite and of $Fe_3\,C$ associated with ferrite as pearlite, the ratio of the former to the latter being as 1 to 7. Furthermore the permeability of $Fe_3\,C$, even at 1000 gauss (it saturates at less than 3000 gauss)[24], is so extremely low compared with that of ferrite with 0.008 per cent C at 10,000 gauss that the amount of flux passing through the $Fe_3\,C$ would be very small, unless the $Fe_3\,C$ formed a more or less continuous barrier across the flux path.

The only conclusion we can arrive at is, therefore, that there must be a hysteresis loss in the intercrystalline impurities, including in this term the amorphous inter-crystalline cement, and that the more or less continuous films formed by these impurities force the flux to pass through them, and furthermore, that more flux passes through the cementite when it occurs in the finely divided form of pearlite than when it occurs unassociated with the ferrite. It follows from this that the hysteresis loss of $Fe_3\,C$ must be approximately

$$13{,}500/0.135 = 100{,}000 \text{ ergs per cu. cm. per cycle.}$$

23. Assume that the grains are cubes and that the number of grains per $m\,m^2$, N, is the same in every direction. Let the thickness of the cement be "t" $m\,m$. No. grains per $m\,m^3$ = $N^{3/2}$ and each grain has a volume of $1/N^{3/2}\ m\,m^3$. Each grain is bounded by 6 faces of $1/N\ m\,m^2$.

Assign one-half the thickness of the intercrystalline cement to each grain, then the volume of cement per grain is one-half x 6 x $t \times 1/N = 3\,t/N\ m\,m^3$. Vol. of cement per cu. mm. = $3\,t/N\ N^{3/2} = 3\,t\,\sqrt{N}\ m\,m^3$ or vol. of cement per unit volume = $3\,t\,\sqrt{N}$ units.

24. Honda & Murakauri: Spec. Magnetism of Cementite. Tohuku University. *Sci. Repts.* 6 p. 23-29, 1917.

If Fe_3C saturates at a flux density of less than 3000 gauss, as stated by Honda, the flux density in the Fe_3C with 10,000 gauss in the pearlite (obtained by a magnetizing force of 15 gilberts) would be considerably less than 3000 gauss. Supposing, for the sake of calculation, that it is 2500 gauss in the Fe_3C, corresponding to a loss of 100,000 ergs. Applying Steinmetz' coefficient 1.6, the hypothetical loss corresponding to 10,000 gauss would be

$W_{10} = W_{2.5}(10/2.5)^{1.6} = 100{,}000 \times 4^{1.6} = 913{,}000$ ergs.

Now, by regarding Fe_3C as 6.67 per cent carbon dissolved in iron, and applying the formula for dissolved carbon, namely,

$$W_h = 100{,}000 \times C$$

the loss for pure Fe_3C for $B = 10{,}000$ gauss should be

$$W_{10} = 100{,}000 \times 6.67 = 667{,}000 \text{ ergs.}$$

While these two results differ considerably (25 per cent) it is interesting to note that by these two different methods of approach, we can arrive at figures for the loss of Fe_3C that are of the same order of magnitude, and that the hysteresis loss of Fe_3C would approach 1,000,000 ergs for a flux density of 10,000 gauss if such a flux density could be reached.

Summary and Conclusion

1. The effect of sulphur, phosphorus and manganese on the magnetic properties, as represented by the hysteresis loss (ergs per cu. cm. per cycle for $B = 10{,}000$ gauss) can be expressed by the equations:

For 0 per cent *Si* alloys,

$W_h = 18{,}000 \times S + 1000 \times Mn + 13{,}000 \times P + 0(P - 0.015)$

Upper limits $S = 0.10$ $Mn = 1.0$ $P = 0.015$ $P = 0.14$

For 4 per cent *Si* alloys,

$$W_h = 12{,}000 \times S + 800 \times Mn - 4000 \times P$$

Upper limits $S = 0.50$ $Mn = 0.16$ $P = 0.05$

2a. Carbon in amounts up to 0.007—0.008 per cent exist in solid solution (martensite) in iron and in all iron-silicon alloys, even after long annealing and very slow cooling, and has an exceedingly detrimental effect on the magnetic properties:

$$W_h = 100{,}000 \times C$$

b. Carbon goes into solution to some extent up to 0.02 per cent, the extent probably depending upon the annealing conditions.

3. In amounts greater than 0.007—0.008 per cent carbon occurs in one or more of three forms (1) graphite with practically no effect, (2) Fe_3C (cementite) with the effect $\Delta W_h = 2250 \times \Delta C$ or (3) pearlite with the effect $\Delta W_h = 16{,}500 \times \Delta C$. The effect of the latter two is in the ratio of 1:7.4 or in the same ratio as the per cent of carbon containing constituents of the two materials for the same actual carbon content.

4. With 0 per cent *Si*, as carbon increases, it changes from solid solution through Fe_3C to pearlite; in 2 per cent *Si* alloys, the change is directly from solid solution to pearlite; in 4 per cent *Si* alloys the change is from solid solution through Fe_3C to graphite, and in 5-6 per cent *Si* alloys the change is directly from solid solution to graphite. These changes are shown graphically in Fig. 29.

5. In addition to the ordinary impurities, it has been found that the magnetic properties depend to a large extent upon the grain structure, in particular upon the inter-crystalline amorphous cement. Denoting the number of grains per sq. mm. by N, it has been shown that for low carbon contents (for carbon in solution) the effect of grain size on the hysteresis loss may be expressed approximately by the formula,

$$W_h = 65\sqrt{N},$$

whereas for precipitated carbon the effect may be expressed more nearly by the formula,

$$W_h = 3\,N$$

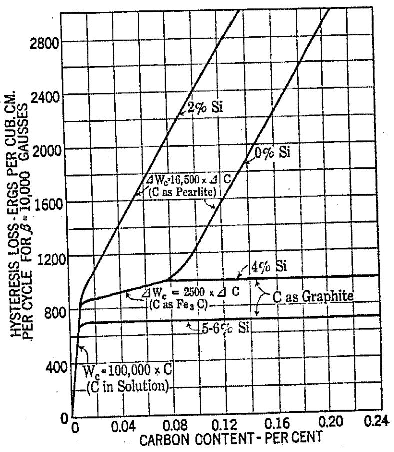

Fig. 29—Effect of Carbon on the Hysteresis Loss of Iron-Silicon Alloys. All other Impurities and Effect of Grain Size Eliminated

6. The hysteresis loss of any *Fe-Si-C* alloy, containing the ordinary impurities, *S*, *P* and *Mn* in small amounts, as for instance commercial electrical steels, can be calculated with a good degree of accuracy by means of the relationships given, using for this purpose one set of constants for 0 and 2 per cent silicon and a second set for 4-6 per cent silicon.

Thus, for carbon in solution, the hysteresis loss is,[25]

For 0—2 per cent *Si*:

	$W_h = 65\sqrt{N} +$	$100{,}000 \times C$	$+ 18{,}000 \times S$	$+ 1000 \times Mn$	$+ 13{,}000 \times P$
Upper Limits		$C = 0.006$	$S = 0.10$	$Mn = 0.60$	$P = 0.015$

For 4—6 per cent *Si*:

	$W_h = 65\sqrt{N} +$	$100{,}000 \times C$	$+ 12{,}000 \times S$	$+ 800 \times Mn$	$-4000 \times P$
Upper Limits		$C = 0.008$	$S = 0.05$	$Mn = 0.16$	$P = 0.05$

25. N = No. grains per sq. mm.

C, S, Mn and P are the percentages of these elements, respectively. The upper limits given are the values of the elements (in per cent) above which the constants either do not hold or have not been investigated.

For precipitated carbon the equations vary more with the silicon content, thus:

	Form of Precipitated Carbon			
	Fe_3C	Pearlite	Graphite	
For 0 per cent Si:				
$W_h = 3N + 800$	$+ 2250 (C - 0.008)$	$+ 16{,}500 (C - 0.09)$		$+ 18{,}000 S + 1000 Mn + 13{,}000 P$
Upper limits........	$C = 0.09$	$C = 0.90$		$S = 0.10 \quad Mn = 0.60 \quad P = 0.015$
For 2 per cent Si:				
$W_h = 3N + 800$		$+ 16{,}500 (C - 0.008)$		$+ 18{,}000 S + 1000 Mn + 13{,}000 P$
Upper limits........		$C = 0.50$		$S = 0.10 \quad Mn = 0.60 \quad P = 0.015$
For 4 per cent Si:				
$W_h = 3N + 800$	$+ 2250 (C - 0.008)$		$+ 0 (C - 0.08)$	$+ 12{,}000 S + 800 Mn - 400 P$
Upper limits........	$C = 0.08$		$C = 1.0$	$S = 0.05 \quad Mn = 0.16 \quad P = 0.05$
For 6 per cent Si:				
$W_h = 3N + 700$			$+ 0 (C - 0.007)$	$+ 12{,}000 S + 800 Mn - 4000 P$
Upper limits			$C = 1.0$	$S = 0.05 \quad Mn = 0.16 \quad P = 0.05$

7. The evidence obtained is to the effect that the increased hysteresis loss due to carbon and other impurities that are precipitated combined with iron is caused by the inherent hysteresis loss of these precipitated impurities.

8. As it is found that the hysteresis loss (for carbon in solution) is proportional to the amount of intercrystalline amorphous material, it is concluded that the latter can be regarded as belonging to the same class as the precipitated impurities, and that the increased hysteresis loss due to decreased grain size consequently is caused by the inherent hysteresis loss of this amorphous material.

9. Regarding the tremendous effect of carbon in solution it is suggested that this is due to the entering of carbon, into the more or less stable equilibrium arrangement of the ferro-magnetic structure, and upsetting this equilibrium arrangement.

10. An attempt has been made in this investigation to separate the various factors influencing the magnetic properties. On account of the large number of factors involved and the large number of separate steps required to obtain the data for the various sets of samples, the conclusion may in some individual case be based on what may seem insufficient evidence. However, if the results are viewed as a whole it will be seen that evidence in one part of the investigation can be used to strengthen evidence in other parts that may seem rather scant if taken by itself. The writer does not wish that the results be considered as final in regard to the various factors affecting the magnetic properties, but it is believed that they are qualitatively correct and that they have opened a new path in the unexplored region of magnetism that may be of service in the further exploration of the same.

Acknowledgements

The alloys were prepared partly by Mr. E. F. Long, partly by Mr. A. A. Frey and partly by the writer; the annealing has been attended to largely by Mr. D. C. Mayne; the carbon analysis has been done partly by Mr. A. L. Shields and partly by Mr. D. C. Mayne.

The magnetic testing has been done under the direction of Mr. Thomas Spooner; the chemical analysis, other than the carbon analysis, under the direction of Mr. C. J. Rodman; and the micro-analysis under the direction of Mr. N. B. Pilling.

All of the above work has been done in the Research Laboratory under conditions insuring great accuracy and the results are therefore believed to be as reliable as is possible with the time and money available. The writer feels greatly indebted to all the above colleagues and takes this occasion to express his appreciation for their valuable cooperation.

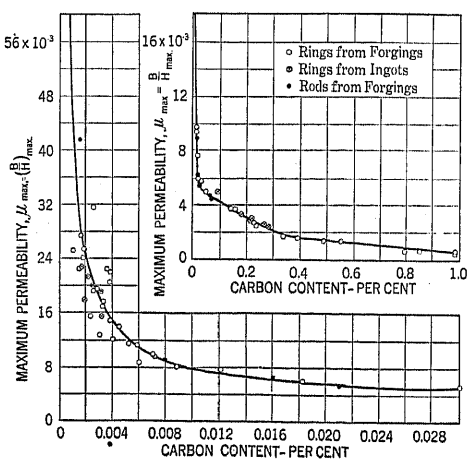

Fig. 30—Maximum Permeability vs. Carbon Content 0 Per Cent Si. No Correction made for Incidental Impurities of Grain Size

Appendix I

Magnetic Testing

In the previous work reported by the writer test pieces was used in the form of round or rectangular bars and these were tested by the Burrow's compensated double-bar and yoke method. For low permeabilities and for uniform bars this method is very accurate, but with high permeabilities and in case of bars of non-uniform permeability, it became evident that the results were far from reliable.[26] In order to get definite data

26. See Eng. Exp. Sta. Univ. of Ill., Bull. No. 83 & 95, 1915 & 1917.

in regard to this method, Mr. Thomas Spooner had test pieces prepared that could be tested both as bars by the Burrow's method and as rings, the ring method being regarded as the ultimate method of reference. His results[27] show that the Burrow's method falls down for maximum permeabilities above 10,000 and becomes increasingly inaccurate as the permeabilities increase. It was, therefore, decided for the purpose of the present investigation where accuracy was a prime factor, to rely altogether on the ring method.[28] While the results obtained with bars in the early part of the investigation were tabulated in a few cases, only the results obtained with rings have been plotted and used as a basis for drawing conclusions.

Appendix II

Apparatus, Materials, Test Pieces and General Procedure

The alloys were all prepared in an Arsem type vacuum furnace by melting together under a pressure of about 2 mm. $H\,g$, electrolytic iron, ferro-silicon, and Acheson graphite in the desired proportions, making 2-kg. ingots.

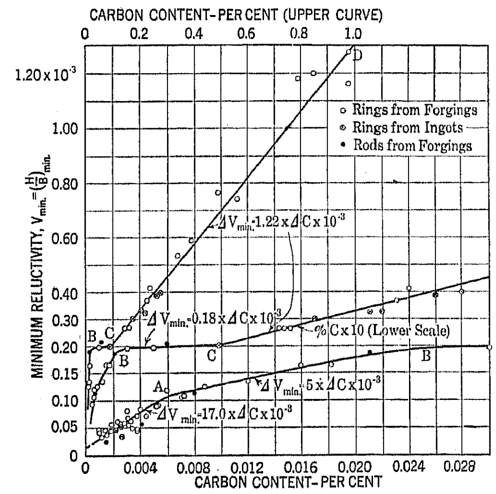

Fig. 31—Minimum Reluctivity ($= 1/\mu_{max}$) vs. Carbon-Content for 0 Per Cent Si. Effect of Incidental Impurities and of Grain Size not Eliminated

Analyses of the electrolytic iron gave the following impurities:

S—0.001—0.005 per cent
P—0.003—0.005
Mn—0.001
C—0.010
Cu—Trace
Si—0.01—0.02
Al—0.01—0.02

Total 0.035—0.061

Total........	99.60	99.06

*Not Reliable

The ingots, after being allowed to cool in the furnace,

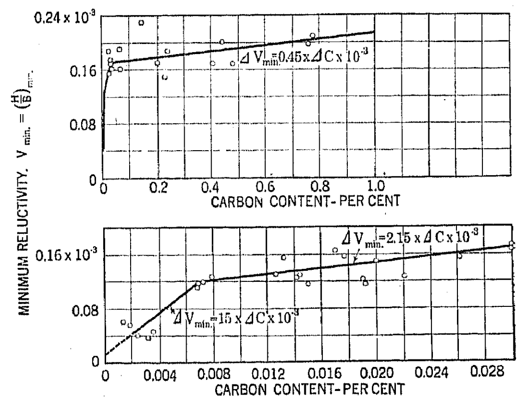

Fig. 32—Minimum Reluctivity ($= 1/\mu_{max}$) vs. Carbon Content for 4 Per Cent Si. Effect of Incidental Impurities and of Grain Size not Eliminated

were forged into bars 3.18 cm. (1¼ in.) dia. from which the test rings were machined 2.46 cm. (31/32 in.) × 1.83 cm. (23/32 in.) × 1 cm. (⅜ in.) or 2 cm. (¾ in.) long. In a few cases rings of different dimensions were used and in the early part of the investigation rods were used but the conclusions are based on results obtained with rings only. The shavings from the machining of the rings were used for chemical analysis for S, Mn and P. The samples were annealed at various temperatures in a closed silica tube under a pressure of < 1 *m m. H g.* In some cases a stream of air 120 cc. per min. at 12 mm. pressure was used in order to reduce the carbon content. The annealed rings were tested magnetically, the B-H curve and the hysteresis loop for $B = 10{,}000$ being obtained in every case. One half of each of the tested rings was then cut up into fine shavings and analyzed for C by the liquid-air-vacuum method and in a large number of cases the other half was examined microscopically to determine the grain size and other structural characteristics.

Appendix III

Permeability and Reluctivity

In the body of this paper only the hysteresis loss has been considered, because the hysteresis loss can be used as a criterion of magnetic quality. As it is desirable, however, for certain purposes to have actual figures in regard to permeabiilty the following curves have been prepared. The maximum permeability

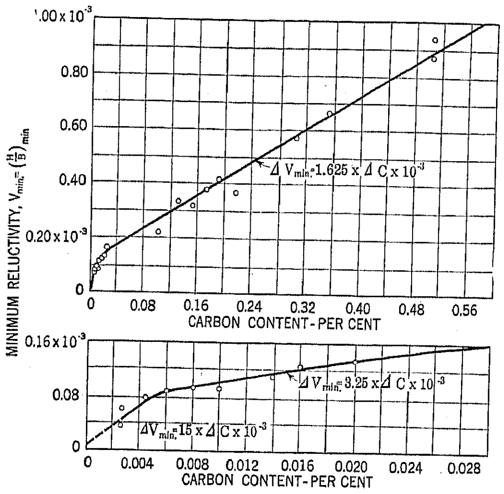

Fig. 33—Minimum Reluctivity ($= 1/\mu_{max}$) vs. Carbon Content for 2 Per Cent Si. Effect of Incidental Impurities and of Grain Size not Eliminated

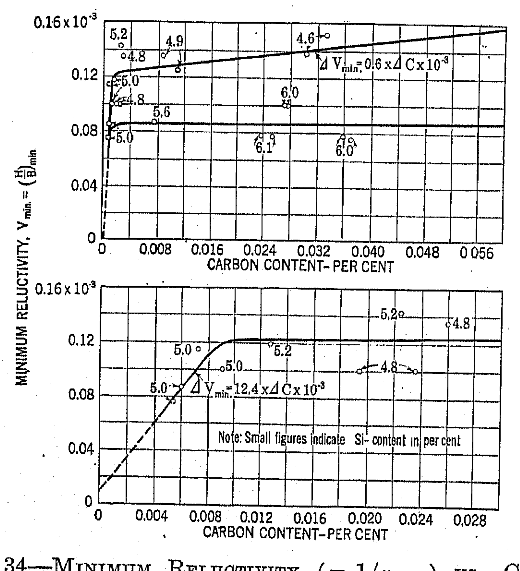

Fig. 34—Minimum Reluctivity ($= 1/\mu_{max}$) vs. Carbon Content for 5-6 Per Cent Si. Effect of Incidental Impurities and of Grain Size not Eliminated

of the Fe-C alloys (0% Si) is plotted in Fig. 30. No attempt has been made in this case to correct for the incidental impurities. The general form of the curve for low carbon contents is seen to be that of a rectangular hyperbola, *i. e.* $\mu_{max} \times C =$ constant. Therefore, by plotting minimum reluctivity, ν_{min} ($= 1/\mu_{max}$), instead of μ_{max} a straight line will be obtained: $1/\mu_{max} = \nu_{min} = C \times$ const. In Fig. 31, ν_{min} has been plotted against per cent C and it will be seen that the shape of this curve is almost identical with that of the curve for hysteresis loss (Figs. 14 and 15). As a matter of fact the ratio of the slopes of the various parts of the curve, OA:BC:CD is 94.5: 1:6.78 or nearly the same as for the hysteresis loss (98:1:7.40) and for the coercive force (100:1:6.76), Fig. 19.

It must therefore be concluded that these three quantities: minimum reluctivity, hysteresis loss, and coercive

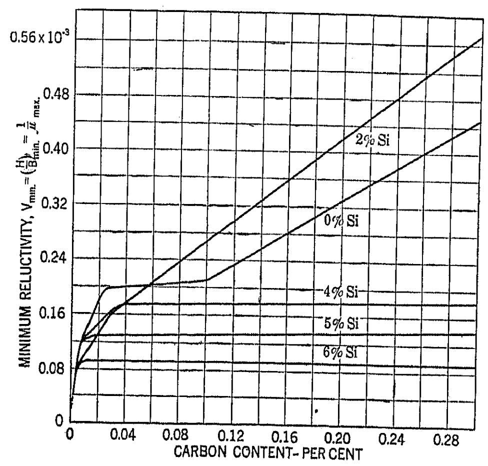

Fig. 35—Minimum Reluctivity ($= 1/\mu_{max}$) vs. Carbon Content for Fe-Si Alloys. No Correction made on Account of Incidental Impurities and Grain Size

force are all identical functions of the carbon content and of the state in which carbon exists.

In Figs. 33, 32 and 34 the minimum reluctivity data have been plotted for 2 per cent, 4 per cent and 5-6 per cent Si respectively, and in Fig. 35 all the curves thus obtained have been redrawn for comparison. While there are certain minor differences between these

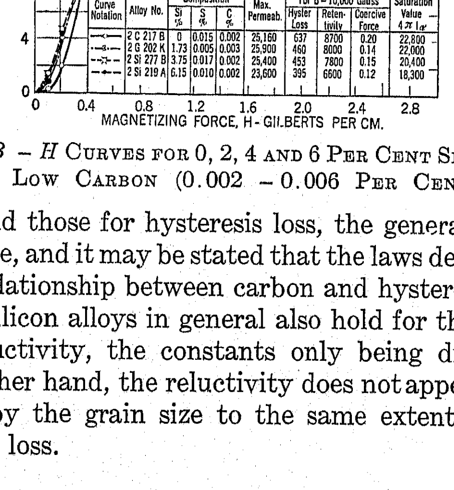

Fig. 36—$B - H$ Curves for 0, 2, 4 and 6 Per Cent Si Alloys. All Low Carbon (0.002 – 0.006 Per Cent)

curves and those for hysteresis loss, the general shape is the same, and it may be stated that the laws developed for the relationship between carbon and hysteresis loss for iron-silicon alloys in general also hold for the minimum reluctivity, the constants only being different. On the other hand, the reluctivity does not appear to be affected by the grain size to the same extent as the hysteresis loss.

In Fig. 36 will be found representative *B-H* curves and other data for 1, 2, 4 and 6 per cent *Fe-Si* alloys with low carbon contents (0.002-0.003 per cent), uncorrected for incidental impurities and for grainsize. The maximum permeability is practically the same for all of them, 25,000, but the high induction permeability and saturation value decreases in proportion to the silicon content. The hysteresis loss and coercive force are seen to be higher for the 0 per cent *Si* than for the other alloys on account of the smaller grainsize. Data un regard to the electrical resistance will be found in Appendix 4.

Appendix IV

Electrical Resistance

1. Fe-C, Fe-Mn, Fe-S & Fe-P alloys

The data tabulated in Appendix VI in regard to electrical resistance have been plotted in Fig. 37, giving the following results:

1. Pure *Fe* has a resistance of 9.6 michroms per cu. cm. at 20 deg. cent.
2. With addition of *Mn*, $\rho = 9.6 + 7 \times Mn$.
3. With addition of *S*, $\rho = 9.6 + 12 \times S$.
4. With addition of *P*, $\rho = 9.6 + 60 \times P + 3.5 \times (P—0.015)$.
   Upper limits.................. $P = 0.015$ per cent $P = 0.12$ per cent
5. With addition of *C*, $\rho = 9.6 + 82.5 \times C + 4.5 \times (C—0.02)$
   Upper limits.................. $C = 0.02$ per cent $C = 0.85$ per cent
   C in Sol. *C* as Fe_3C and pearlite

For iron containing small amounts ofll a of these impurities the electrical resistance will therefore be:

$$\rho = 9.6 + 7\,Mn + 12\,S + 60\,P + 82.5\,C$$

Upper limits $Mn = 1.0$ $S = 0.1$ $P = 0.015$ $C = 0.02$

Thus, for iron containing 0.01 per cent each of *Mn*, *S*, *P* and *C* the resistance will be:

$$\rho = 9.6 + 0.07 + 0.12 + 0.60 + 0.83 = 11.22 \text{ microhms per cu. cm.}$$

In regard to the effect of *C* the curve obtained from Gumlich's formula[29]

$$\rho = 10.5 + 3 \times C + 2\,x\,C^2$$

has been drawn in Fig. 37. This formula was deduced from results obtained by means of materials prepared by two commercial firms (Phoenix and Lindenburg) and contained only a few hundredths of a per cent of *S* and *P* but "relatively high percentages of *Si* (up to 2.4 per cent) and *Mn* (up to 0.52 per cent), the latter being "frequently disturbingly noticeable in the measurements", and "could only partly be taken into consideration."

It is, therefore, believed that our values are the more reliable, our alloys containing only about 0.015 per cent *S*, 0.02 per cent *S i* 0.0015 per cent *Mn* and 0.003 per cent *P*, and that the discrepency is due to the necessity in Gumlich's case of making large and uncertain reductions because of impurities. Another point to be noted is that Gumlich's formula is based on samples, the lowest carbon content of which is 0.07 per cent, and he therefore was unable to detect the important part of the curve below 0.02 per cent *C*.

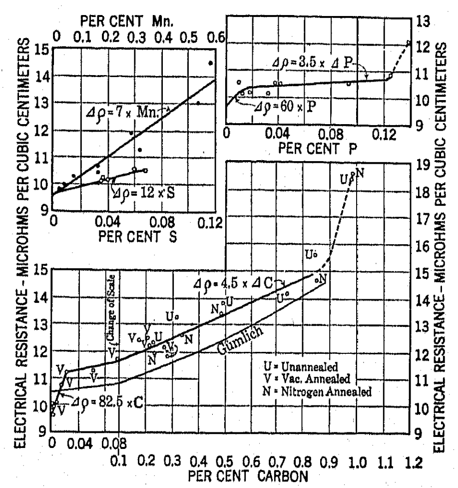

Fig. 37—Electrical Resistance of Fe-C, Fe-Mn, Fe-S and Fe-P Alloys

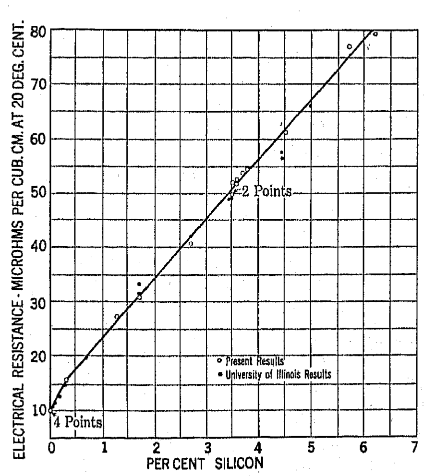

Fig. 38—Electrical Resistance of Iron-Silicon Alloys

Whether the sudden rise above 0.85 per cent (the eutectoid point) is real or due to an experimental error can not be stated, because 1.0 per cent *C* was the limit of the carbon content. This same statement must be made in regard to the sudden rise in the curves for *Fe-P* alloys for $P > 0.12$ per cent. With these excep-

29. *E. T. Z.* July 3, 1919 pp. 325-8.

tions these curves for electrical resistance in general check those for hysteresis loss as shown in Figs. 13, 14 and 15, and thus serve the useful purpose of confirming the conclusions in regard to the relationship between carbon and iron.

2. Fe-Si Alloys

The results obtained for 0–6 per cent *Si* are shown in Fig. 38.

This curve can be expressed in the form of an equation:

$$\rho = 9.6 + 18.4 \times Si + 11.1 \times (Si - 0.35)$$

Upper limits $Si = 0.35$ per cent $Si = 6$ per cent

that is, the curve is composed of two straight lines with a slight bend at $Si = 0.35$ per cent[30].

30. The solid points were obtained by the writer at the University of Illinois in 1915. (See Bull. No. 83 Eng. Exp. Sta.).

Gumlich[31] gives the following equation for the resistance of *Fe-Si* alloys up to 4 per cent *Si*.

$$\rho = 9.9 + 12 \times Si$$

but accompanies this by a statement, that this can not be regarded as accurate, because his curve is slightly concave toward the x-axes. His curve checks the writer's results fairly closely. Thus for 1, 2, 4 and 6 per cent *Si* the following results are obtained.

Per cent *Si*	Gumlich Equation	Gumlich Curve	Writer Equation	Writer Curve
0	9.9	9.9	9.6	9.6
1	21.9	23.0	23.3	23.0
2	33.9	36.0	34.4	34.2
4	57.9	57.5	56.6	56.5
6	81.9	75.0	78 8	78.7

*Deducting 12,000 × % S from the total Hysteresis Loss. †Ring Broken.

Discussion

Thomas Spooner: In conversation recently with an engineer of a large public service company, I asked what the value would be to his company of reduced core losses in transformers. Without any hesitation, showing that he had previously given this matter careful consideration, he told me that core losses were worth to his company approximately $800 per kilowatt for distributing transformers and from $300 to $400 for power transformers.

Taking these figures and applying them to certain standard distributing transformers, by simple calculation, I found that for a 5 kv-a. transformer, a reduction of twenty per cent in core loss would make it possible for a customer to pay approximately eight cents a pound more for the core material. For a 200-kv-a. transformer, this figure was approximately twenty cents a pound. This is on a basis of no re-design of the transformers.

The improved electrical sheet, made by the methods outlined by Mr. Yensen, would of course cost considerably more to manufacture. I think though there is no question but what progressive customers who know how to get the most for a dollar, would be very willing to pay the increased cost of this material in order to obtain transformers of improved quality.

M. G. Newman: The most interesting and vital point that is brought out is the effect of carbon. If there is carbon even in very small quantities, as Mr. Yensen points out, it is very detrimental, and silicon, while really it does not affect the magnetic properties of the material itself, does do something to the carbon there.

Most of our magnetic sheet steel, however, is used in alternating-current machinery in very thin laminations, and silicon does help out there, of course, in increasing the electrical resistance and decreasing the eddy-current losses. That brings up one question I would like to ask Mr. Yensen. Will it be possible to roll this material into sheets and obtain the same curves he has presented to us, and if not, what will be the effect on the material when rolled into sheets where it is finally used?

J. B. Whitehead: We know that the basic laws of the electrostatic field, and those of the magnetic field all take their beginnings from very much the same character of fundamental physical principles; but we also know that the parallel which exists between electrostatic phenomena and magnetic phenomena cannot be carried very far.

The increase in electrostatic flux density which follows the introduction of a dielectric, is called "electrostatic induction" just as the increase in flux density in magnetic material following the introduction of iron is called "magnetic induction." However our parallel cannot be carried any further. We find the dielectric constant of the material is really a constant so far as we can determine all the way up to breakdown, whereas the permeability of magnetic materials as we know departs very markedly indeed from a constant value, very early in the increase of magnetic induction. So while we have always hoped that some day we would be able to tie together in some fundamental way the behavior of magnetic materials, and the behavior of dielectric materials, and in a way which could be traced back to our fundamental relations, where they are of the same character, we have never yet I think come so near to it, as we seem to be doing in some of the results that are obtained by Mr. Yensen. I refer particularly to the initial portions of these curves in which he speaks of the carbon as being in solution with the iron, and his showing there that the losses that occur are the direct result of the combination, in the form of solution of these two materials.

Now, wherein does the parallel lie? I think it lies in this: That so far as the losses in dielectric are concerned, about the only safe starting point we have is the suggestion of Maxwell, that dielectric losses are really to be attributed to the mixtures of different materials. We are still uncertain as to whether we can say absolutely that dielectric absorption is present at all in pure materials, but the suggestion of Maxwell, and those who have followed after him in the study of dielectric hysteresis, is that the loss itself is largely due to the mixture of two different materials. Mr. Yensen now shows that magnetic hysteresis loss is also due to a combination of materials.

T. D. Yensen: In regard to the question raised by the first speaker about phosphorous: Of course, this curve does not mean that if you start with the material of zero hysteresis loss, that is, with all the impurities eliminated and of infinite grain size, and then add phosphorous to it, that a material of negative hysteresis loss will result. It means that in connection with other impurities and in connection with material having a finite grain size, phosphorous seems to be beneficial to the magnetic properties of four per cent silicon steel. As a matter of fact, this effect is so very small anyhow, as compared with the effect of sulphur and carbon, that it does not make very much difference whether the curve is drawn as shown or horizontal. In other words, the effect of phosphorous on *Fe-Si* alloys can be regarded as negligible.

In regard to Mr. Newman's question as to whether these same relationships hold for sheets, I can say that as far as we know they do. There is one factor that we have not yet considered, that we have not studied systematically, and that is, the effect of oxidation. In heavy materials, in big samples, the effect of oxidation is not very great, but the thinner the material becomes, the greater will be the effect of surface oxidation, and great precautions must be taken to prevent excessive oxidation when this material is rolled into sheets.

As far as actual results are concerned, I might add this: by taking special precautions we have been able to get material in sheet form with a loss considerably less than one watt per kilogram for 10,000 gausses at sixty cycles. Those of you who are familiar with magnetic materials will realize that this is quite an advance, because the ordinary materials that you have been using in transformers up to the present time have a loss of one and a half watts per kilogram or more. Better than this has been obtained during the last few years, but that is an average figure, so you will see that if you can reduce the loss to less than one watt per kilogram, you will have obtained an improvement of over fifty per cent. Mr. Spooner mentioned the fact that if we could decrease the loss by twenty per cent, we could afford to pay twenty cents a pound for the material, and by decreasing it fifty per cent, we might be able to place iron-silicon alloys in the same class as iron, nickel and other semi-precious materials.

Haakon Styri (by letter): I find two points which would be of great interest to have explained; one is the probability of having the second term of the hysteresis loss corresponding to free cementite continued to higher carbon contents when the steel has been prepared in such manner as to produce granular pearlite instead of lamellar pearlite. Such condition of the steel can readily be obtained by quenching at high temperature, followed by proper drawing.

The other question which to me particularly is of great interest, but which would probably mean a large amount of work, is to find by the same kind of magnetic analysis, how the saturation point for solid solution of carbon varies with temperature. I would believe that by increasing temperatures the amount of carbon going into solution, should increase.

If variation of magnetic properties with temperature could be determined, this would certainly throw some light on whether it was proper to consider the carbon in solution either as cementite or as free carbon, and whether the influence of carbon on the magnetic properties might be due to dissociated ionized carbon. It can certainly not be possible that carbon could have such influence on the magnetic properties if only mechanically dissolved.

T. D. Yensen (by letter): Replying to Dr. Styri, my conclusion in regard to the slopes of the hysteresis loss vs. carbon for 0% Si between A and C and C and D (Fig. 15) was that the hysteresis loss in both cases is due to the inherent hysteresis loss of Fe_3C, but that the actual flux passing through the Fe_3C is much greater in the case of pearlite (for $C > 0.1\%$) than in the case of free Fe_3C $(0.01 < C < 0.1)$. It is my opinion, therefore, that the actual hysteresis loss will, in any given case, depend upon the relative distribution of Fe_3C and ferrite. If granular pearlite gives a distribution whereby the magnetic flux will tend to avoid the Fe_3C more than in the case of lamellar pearlite, then the slope of the $C - D$ part of the curve should become less. However, as the concentration of Fe_3C becomes greater I should venture to say that the slope should increase and approach the slope $C - D$ shown in Fig. 15. To test this out experimentally would be somewhat difficult, as we should have to introduce another variable due to the heat-treatment, apart from the effect on the Fe_3C, and this might screen the effect due to the difference between granular and lamellar pearlite.

The second question brought out by Dr Styri, namely; whether the saturation point for carbon in solution (0.006 — 0.008 for 20 deg. cent.) increases with increase in temperature, is a very interesting one, and I hope to be able to investigate this point at some future date. It would be natural to assume that the solubility should increase with the temperature; on the other hand, we know that Fe_3C all goes into solution at the A_1 transformation point which may or may not harmonize with a gradually rising solubility curve between 20 deg. and the A_1 point.

Whether carbon in solution (martensitic) exists as Fe_3C or as free carbon apparently is a question not yet answered to everybody's satisfaction. Reference might be made to arguments of Jeffries (*Chem. & Met. Eng.*, Vol. 24, p. 1057, 1921 and Vol. 26, p. 250, 1922 which are in favor of the free carbon hypothesis. Westgren at first opposed this view, but later admitted that Jeffries' conclusion probably is correct (*Jour. Iron & Steel Inst.*, Vol. 95, p. 241, 1922, No. 1.)

The tremendous effect of carbon in solution is, to my mind readily explained either by the substitution theory, whereby one atom of a foreign element is capable of replacing one of the solvent atoms and thereby distorting the entire original space lattice, or on the assumption that the carbon atoms enter the interstitial spaces between the Fe and Si atoms. (See Walter Rosenhain: Solid Solutions, A. I. M. E. preprint No. 1250 N, June 1923). Dr. Styri has just called my attention to a paper by Dr. Westgren (*Jernkontorets Annaler* 1923) where he proves that the latter view is the correct one.

E. Gumlich (by letter): I was pleased to note that Mr. Yensen, by means of much better basic materials, perfected analytical methods and plentiful support, has succeeded in going much further than I could in my own investigations. Twenty years ago when most of my test pieces were prepared, the standards in regard to purity of iron were much lower than now, when we have available for the preparation of alloys an almost pure base, *viz.* electrolytic iron; it is therefore the more gratifying that our results, at least in general, coincide. For instance, the fact, observed by Mr. Yensen, that in the region of C-content between 0.006 per cent and 0.09 per cent, free iron carbide, Fe_3C, affects the magnetic properties and electrical resistance much less than Fe_3C in solution or in the form of pearlite. This is in agreement with the observation made by me in many cases, that the effect of carbon on the electrical resistance as well as the coercive force and the saturation value is much less pronounced for alloys with C-content in excess of 0.9 to 1 per cent, than for alloys with less than this amount of carbon, whether the material is slowly cooled or quenched; in other words, whether the carbide grains, precipitated in hypereutectoid alloys, is embedded in a pearlitic or a martensitic base.

The corresponding diagrams can be found in full only in my complete article in Wissenschaftlichen Albandlungen der Ph. Tech Reichsanstalt, Vol. IV, Part 3, and only partially in an abstract published in E. T. Z., 1919.

I consider very important the fact, found by Mr. Yensen and perfectly well established, that carbon to the extent of at least 0.006 per cent, remains in solution even after very slow cooling and, therefore, has a correspondingly large effect. This phenomenon was naturally overlooked by me, because of my much less pure material and less exact method of C determination. At that time these factors were of no practical importance, while today, when the manufacture of entirely pure iron and the investigation of its magnetic and electric properties is our goal, these factors come to assume greater and greater importance. (In Fig. 14, there seems to be a mistake in that the C-content plotted as abscissas only refers to the lower, not to the upper curve; for the latter the abscissa values should be multiplied by about 20; also in the table entitled "Form of Precipitated Carbon" in the section for 4 per cent Si there seems to be a misprint; it should be"—4000 P" instead of "—400 P.")

Of particular interest to me was Mr. Yensen's demonstration in regard to the relationship between the grain size and the magnetic properties, which has often been mentioned, but never definitely established.

On the other hand, according to our measurements I cannot consider the data on saturation values for pure iron to be correct; using field intensities at our disposal, (6-7000 gauss), we have always obtained by various methods $4\pi I = 21{,}600$, while the values given in the paper are 23,000 and over. We cannot believe that the comparatively small amount of impurities in our electrolytic iron can noticeably affect the saturation value. It is, therefore, probable that the method used in obtaining the saturation value (not described in the paper) may be responsible for the discrepancy.

Finally, quoting the motto "Qui tacet, consentire videtur," I should like to correct one point in the article, which concerns me personally. In the first paragraph of the introduction it is stated that the discovery of the advantage of silicon steel as compared with ordinary iron was made by Sir Hadfield. Strictly speaking this is not incorrect, since Messrs. Barrett, Brown and Hadfield found that magnetic properties of many Si and Al alloys were better than their basic materials (their article in the *Sc. Trans.* Roy Dublin Soc. VII, 1900); but absolute values for these new alloys were in no way exceptional and did not reach those for rolled iron or good ingot iron. This is clear from the fact that the first sample of Hadfield's Si-iron, which was sent by Fr. Krupp Co. to the Reichsanstalt for magnetic test, had a coercive force of 1.45 and a hysteresis loss of 12,300; at the same time the best grades of iron at that time had a coercive force of between 0.6 and 1 gauss and a hysteresis loss of between 4900 and 10,000, and the director of the Krupp Co. told me personally, that his factory had no interest in this new material at all. This interest was only aroused after it had occurred to me to utilize the high resistivity of the Si-alloys for lowering the eddy-current loss in transformer and generator sheets and after I had communicated this idea personally not only to representatives of metallurgical works and rolling mills, but also to ETZ in 1901 and 1902. Thus it happened, that at the end of 1903, when Sir Hadfield obtained his first patent in England, in Germany the manufacture of silicon sheet steel, started by my activities, was in full swing and could not be restricted by foreign patents. Whether Sir Hadfield, independently of me, came to the idea of using Si-alloys in sheet form for construction of transformers is unknown to me; anyhow, I can insist upon my priority, because the first publication by Barrett, Brown and Hadfield, by which I had been moved to my activities, gives no reference to the possibility of utilizing the high resistivity. The best proof of the correctness of my contention can be found in the fact that I could open my address in the Faraday Society of London in 1912, under the presidency of Sir Hadfield, with the following words:

"When in 1900 Messrs. Barrett, Brown and Hadfield published the results of their interesting researches on the magnetic properties and the electric resistance of iron-aluminum alloys and iron-silicon alloys, I had the idea to utilize the high specific resistance of the silicon alloys for the diminution of the eddy currents in transformer and dynamo sheet metal. The P. T. R. therefore requested some prominent German firms to produce transformer sheets out of silicon alloys, and began itself to make experiments with the new material. It resulted in the course of these experiments that more had been attained than had been expected; for not only were the eddy currents weakened in accordance with the higher specific resistance, but also the hysteresis loss was often smaller, and the permeability in low fields was higher than in the usual dynamo iron. Thus the so-called "legierte Blech" could not fail almost entirely to replace the usual material within a short time, in spite of the initial difficulty of production and of the much higher price, and German electrical engineers are much indebted to Messrs. Barrett, Brown and Hadfield for the researches which supplied the foundation for this great improvement in transformer material."

This presentation of the matter has not been corrected by Sir Hadfield; I therefore consider myself justified, in claiming the credit for being the first to have conceived and realized the idea of the application of silicon sheet steel to transformer construction.

T. D. Yensen (Communicated): Replying to Dr. Gumlich's communication, I note that he is in substantial agreement with my results in regard to the relative effect on the magnetic properties of C in the form of free Fe_3C, pearlite, and martensite. He states in his discussion that "Carbon in excess of 0.9—1.0 per cent has a much smaller effect on the electrical resistance, the coercive force, and the saturation value, than carbon contents below this value, whether the samples have been slowly cooled or quenched, *i. e.*, whether the carbide grains in these hypereutectoid alloys are embedded in a pearlitic or martensitic base." I believe this statement, to make the facts clear, should be modified by specifying that the quenching be done from a temperature sufficiently low to permit the free hypereutectoid Fe_3C to be precipitated, *i. e.*, from just above the A_1 point. If the quenching is done from a higher temperature, then obviously carbon is not precipitated at all (or only partially) but remains in solution with the corresponding effect on the physical properties. This is well illustrated in Fig. 8 of Dr. Gumlich'spaper in *ETZ* of July 3, 1919, page 328. By quenching from 900 and 1000 deg. the curves have no breaks in them at $C = 1.0$ per cent because the quenching temperatures lie above the A_3 point for all the alloys. In the case of the 1.8 per cent C alloy quenched from 900 deg. there may be a slight amount of precipitated Fe_3C but most of the carbon will remain in solution. By quenching at 800 deg. however, the carbon above about 1.2 per cent will have a chance to be precipitated as Fe_3C and he consequently obtains the break shown. It is interesting to note that the slope of the upper part of the curve ($C > 1.0$ per cent) for the 800 deg. quenching in Fig. 8 is 2.5 or identical with the slope obtained by me for the coercive force in the region $0.01 < C < 0.1$, *i.e.*, where C occurs as free Fe_3C. This consistency is most gratifying, because it shows that we have found relationship that can be depended upon. It also answers a question asked by Dr. Haakon Styri as to whether the relationship given for the region $0.01 < C < 0.1$ holds for higher C contents whenever carbon occurs as free Fe_3C. I believe the evidence given in Fig. 8 of Dr. Gumlich's paper is sufficient to answer this in the affirmative.

Dr. Gumlich's remark in regard to Fig. 14 "that the abscissa values only hold for the lower curve, not for the upper" is correct. This is taken care of, however, in the chart as it will be noted that the upper curve is marked "Percent $C \times 10$." There is, however, a misprint in the table entitled "Form of Precipitated Carbon" in the equation for 4 per cent Si. The constant for P should be "—4000" instead of "—400." Another mistake has been made in the abscissa values for the upper part of Fig. 34. These should all be multiplied by 10; *i. e.*, they should be 0.08 to 0.56.

In regard to the saturation values, it is possible but not probable that Dr. Gumlich's value is correct. Our values were obtained by plotting $\rho = \dfrac{H}{B - H}$ vs. H for values of H up to 500 gilberts per cm. for the rod samples. As the curves were apparently straight lines for $H = 300$ to 500 we used the reciprocal of the slopes for this region as the saturation value. This is a method extensively used in the past and has been regarded as reliable. (See J. D. Ball "The Reluctivity of Silicon Steel as a Linear Function of the Magnetizing Force" *Gen. Elec. Review* 15, page 750, 1913, and "Some Notes on Magnetization Curves" *Gen. Elec. Review*, Jan. 1915) but it is possible to get values that are far off if the plotting is done carelessly. My colleague, Mr. Thomas Spooner, has recently conferred with the Bureau of Standards in Washington in regard to this matter, and finds that the saturation value for pure iron reported by the Bureau varies from 21,200 to 21,900, the most reliable value being regarded as 21,600, which checks Dr. Gumlich's value. On the other hand, Mr. Spooner has obtained actual values of $B - H$ for some of our rod samples that exceed 21,600. For example, for $H = 600$ he obtained in one case 21,890 after making all proper corrections for air space. The calculated saturation value in this case was 23,200. These results were obtained with an apparatus that checks the Bureau of Standards results within one per cent. To be doubly certain of our values, we recently sent the rods to the Bureau for checking our results for high values of H. The values obtained by the Bureau are appoximately one per cent *higher* than ours. As far as we know now, therefore, the saturation values reported in the paper are correct within a few per cent. They also check the value obtained by Dr. E. H. Williams at the Univ. of Ill. for vacuum fused electrolytic iron in the form of elipsoids (See *Gen. Elect. Rev.* 18, p. 881, Sept. 1915), the value obtained being 22,800.

As far as the values for the ring samples are concerned the writer regrets to have to report that all values of B are 3.5 per cent too high, due to an error just discovered, in the formula for calculating the cross section.

Finally, as regards the credit for the benefits that have resulted from the use of silicon steel in transformers, I think Dr. Gumlich states the matter very clearly in the introduction to his lecture before the Farraday Society in 1912 when he ends by saying:"———and the German electrical engineers are much indebted to Messrs. Barrett, Brown and Hadfield for the researches which supplied the foundation for this great improvement in transformer material." Dr. Gumlich, undoubtedly deserves great credit for having seen and understood the importance of the results obtained by his English colleagues, and for having pushed the application thereof in Germany and thereby in the rest of the world, and I think Sir Hadfield would be the last man to deny that this credit is due him. On the other hand, the world is indebted to Sir Hadfield and his colleagues for having laid down the foundation upon which the present magnificent structure has been built.

E. Gumlich (Communicated): Mr. Yensen is of course perfectly correct, when he states that the effect of free iron carbide in a base of martensite will be observed only when the quenching temperature is sufficiently low, or the carbon content sufficiently high, so that the carbon at the temperature in question will not all go into solution. While this is quite obvious to experts in this particular field, it will perhaps make things clearer if the statement is made as follows:

The effect of carbon, etc., is much less for alloys with more than 0.9 per cent—1 per cent carbon than for alloys with less than this amount, no matter whether we deal with slowly cooled alloys (in which the precipitated free carbide is embedded in a pearlitic

base) or with alloys that have been quenched from a sufficiently low temperature (so that the precipitated free carbide is embedded in a martensitic base).

E. A. Smith (by letter): Within the last 10 years, many investigations have been carried on to improve alloys, for use in transformers and generators. Some of the authors covered various phases of iron and steel alloys, yet, many difficulties were still to be encountered due to the hysteresis effects and only lately the improvements have progressed fairly well. The papers that I am referring to, have been published by the German Electro-Technical Societies, The Faraday Society, Imperial Academy of Sciences of Germany and Austria, The German Iron and Steel Institute and the German Society of Engineers. I have also compared Mr. Yensen's Bulletins in 1915 and 1916 published by the University of Illinois Experiment Station, with those of the above Institutions covering ironsilicon alloys and found them all to check closely in their respective tests.

In my estimation, the present paper of Mr. Yensen seems to be fairly accurate with the magnetical properties of alloys as described and further investigations will result in many improvements to the construction of electrical apparatus.

In most metals and alloys more or less impurities exist and the grain size affects the magnetic properties and the hysteresis losses considerably, therefore, a special annealing process is being worked out at the present time by one of the manufacturing companies in Germany.

The best results can be obtained by eliminating the carbon and other impurities which appear to affect the magnetic flux much more than the grain structure. The maximum permeability of the individual alloys cannot be changed, but the resistance and reluctance can be altered, by the removal of the impurities. The numerical coefficients for the effect of the carbon on the hysteresis losses can be calculated if the structural and composition characteristics possess fixed constants or factors.

While the analysis of different alloys shows varying factors in their physical states it proves from actual conditions that many of the factors can be improved upon by the introduction of changes in their grain structures and compositions.

Alkali Vapor Detector Tubes

By HUGH A. BROWN and CHAS. T. KNIPP

HUGH A. BROWN, Assoc. A. I. E. E., Associate, Department of Electrical Engineering

CHAS. T. KNIPP, Member, A. I. E. E., Professor of Experimental Electricity

Both of the University of Illinois

Review of the Subject:—*This paper describes unusual and very desirable results that are obtained on priming tungsten filament three-electrode vacuum tubes with an alloy of potassium and sodium when such tubes are used as detectors of radio frequency currents in receiving circuits.*

The method of preparing the tubes and of introducing the alloy is described in some detail.

Data obtained for these alkali vapor tubes are shown in the form of curves. They show the static characteristics of the tube, the operation characteristics when used as detectors, also the effect of filament temperature increase upon their performance.

The results obtained when the tubes are used as detectors include—lower optimum plate voltage (5 to 10 volts), less critical adjustment of plate voltage, steady action, considerably greater sensitiveness to weak signals than for gas content tubes, and no distortion in detector action.

CONTENTS

I. Introduction

ABOUT two years ago the authors of this paper completed an experimental investigation on the effect of various residual gases in three-electrode vacuum tubes upon the characteristics of the tubes and upon their performance as detectors and demodulators. It was found that the introduction of certain gases improved to some extent the sensitivity of the tubes as detectors.[1] Argon at a pressure of 0.005 mm. of mercury gave the best results. The most important result of this earlier investigation was the effect of gases upon the critical characteristics of detector tubes. The data relating to these are summarized in the form of curves in Fig. 1. The curves show how critical the adjustment of plate voltage becomes for air, nitrogen, neon, etc., when the pressure within the tube is increased. Helium, having a higher ionizing potential than the gases just mentioned, causes a detector tube to function best at a corresponding higher plate voltage. It should be noted also that mercury vapor, due to its lower ionizing potential, causes a tube to function best at correspondingly lower plate voltages. However, at the same time the allowable per cent variation of plate voltage for mercury vapor with no change in audibility was found to be greater than for the other gases except helium. Furthermore, if the pressure of the residual gas is increased the plate voltage required for the best audibility of signal response, which will be called the "operating voltage," was found to vary as shown in the curve of Fig. 2. Hence it was concluded that if a gaseous medium possessing an extremely low ionizing potential could be provided the tube would function as a detector on a minimum plate voltage.

The characteristic of mercury vapor shown in Fig. 1 indicates that a metallic vapor possessing a very low ionizing potential would not only operate on low plate potentials but also would not be critical as regards plate voltage adjustments. Vapors of certain alkali metals, and also of certain alloys of these metals, have very low ionizing potentials. Notable among these is the alloy of potassium and sodium, the vapor of which

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

1. *Phys. Rev.*, 19, (2), No. 3, 1922.

has an ionizing potential of 4 volts or less. Accordingly, a small amount of this material was introduced into several vacuum tubes by methods described presently. Curve *E* of Fig. 1 is typical of the results obtained. Curves similar to this one will be shown later. In addition to this other results were obtained, which were entirely unexpected, and will be described in due course.

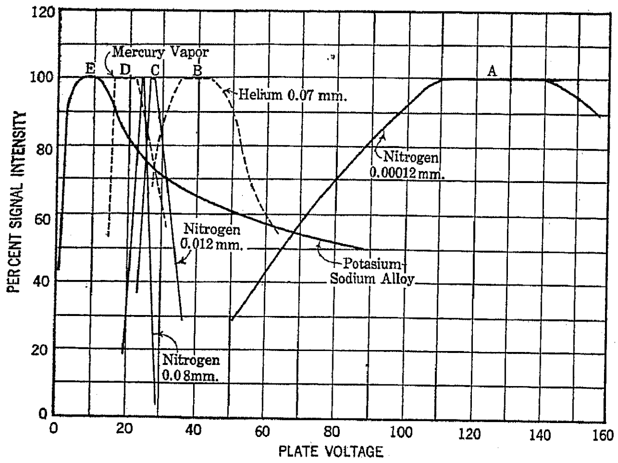

Fig. 1

II. Method of Priming Tubes

Standard types of detector and amplifier tubes, and also special forms made in this laboratory, were primed with a molecular alloy of potassium and sodium. This alloy which at ordinary temperatures is a fluid resembles mercury in appearance though its density is less than one. The potassium-sodium alloy was contained in an evacuated glass supply tube *A*, Fig. 3. Two or more

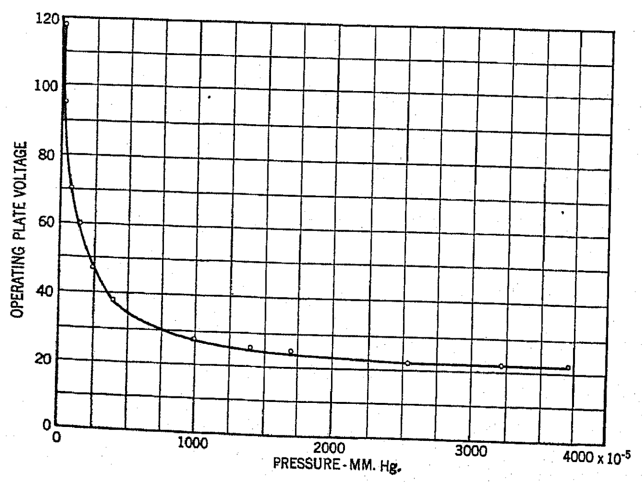

Fig. 2

three-electrode tubes were fused in a vertical position onto a horizontal manifold as shown in the figure. This manifold was connected through a *T*-tube, one branch of which, *B*, led to the evacuating system, and the other to the *K-Na* alloy supply tube *A*. The evacuating system consisted of a charcoal tube in liquid air, a phosphorous pentoxide tube, a mercury vapor trap also immersed in liquid air, a McLeod gage, a mercury condensation pump, and a rotary supporting oil pump. The supply tube, *A*, had a number of branch outlets, each branch being drawn down into a slender tube *D*, and also provided with a constriction, for the introduction of the alloy into the manifold and for subsequent sealing off. Connection between the outlet tube and manifold was made by heavy walled rubber tubing lubricated with rubber cement and tightly wired down, as shown in the figure.

When the pressure was of the order of 10^{-4} mm. of mercury the tip at *D*, which was previously nicked with a file, was broken off by bending sharply the rubber tubing. The evacuation was continued and in order to completely as possible outgas the tubes the filaments were kept incandescent, and also 150 volts were applied to the plates. This outgassing process was continued until the electron tubes (having been previously con-

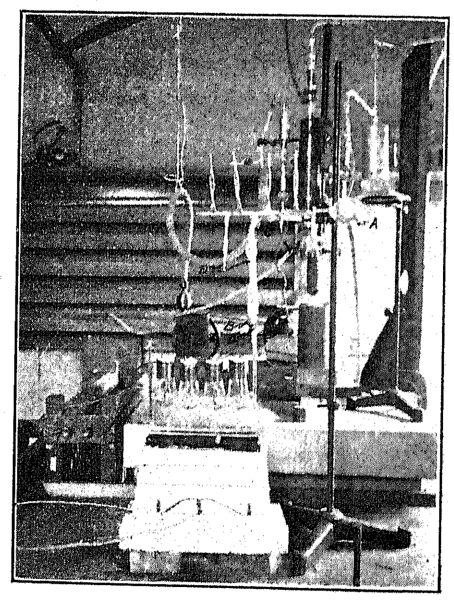

Fig. 3

nected to receiving circuits) functioned best as detectors with 60 to 80 volts on the plates. This test indicated that the tubes were fairly well outgassed. The supply-tube *A* was now tilted up and a little of the alloy was allowed to run down into the manifold, after which tube *A* was sealed off at *C*. To guard against possible leaks, due to the rubber connecting tube, another seal off was made at *E*.

The oil bath with its electric heater attached was now raised so that the horizontal manifold was immersed in the oil. The bath was gradually heated, with the pumps going, and ultimately the temperature was pushed to about 230 deg. cent., at which temperature the alloy was fully vaporized. The vapor passing through the capillary tubes connecting the manifold to the electron tubes was condensed on the colder walls of the latter forming a thin film, at first of varied purplish hues but shortly becoming silvery white, when

viewed on the inside as the deposited film became thicker. Heat coming to the bulbs by reason of being mounted vertically over the oil bath was intercepted by strips of cardboard and by turning on an electric fan. The filaments were kept incandescent at nearly normal filament current during this distillation process,

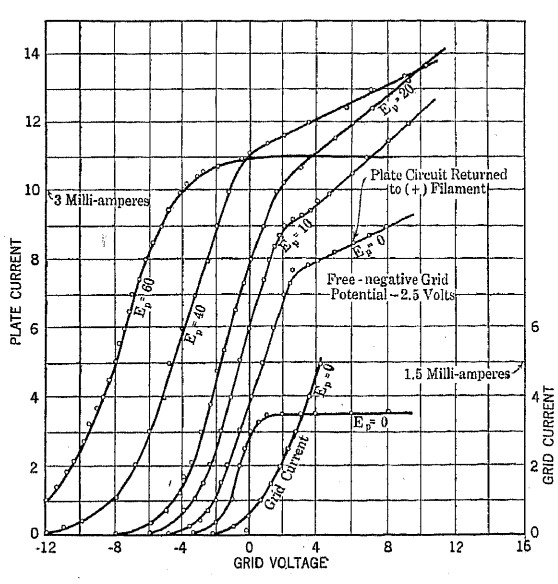

FIG. 4

thus preventing a deposit of the alloy on the inner metal parts of the tube, as well as aiding in the process of outgassing. After the inner walls of the bulb were well covered with the alloy the oil bath was removed, and the tubes sealed off. The pressure throughout the

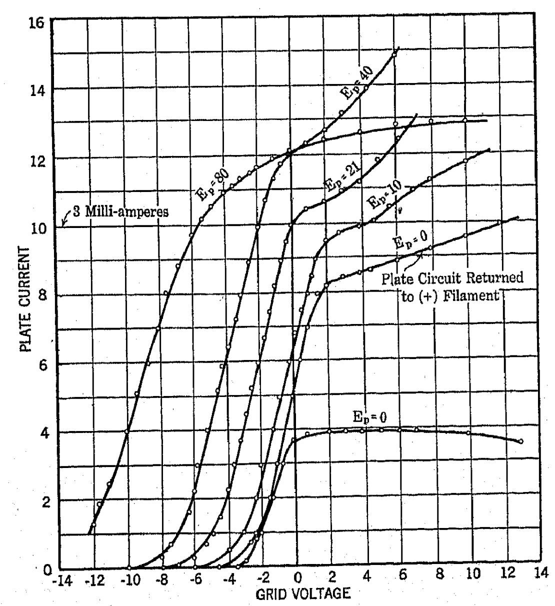

FIG. 5—K-NA VAPOR TUBE NO. 7

final stages of priming was easily maintained at approximately 0.00004 mm. mercury. The presence of the alloy within the tube will "clean up" the remaining traces of air and hence the vacuum improves with time.

It is extremely important to clean all glass and rubber tubing with "aqua regia" and distilled water, otherwise the alloy will stick to the walls of the tubing. The writers preferred to construct new manifolds rather than attempt to clean the used ones, also to use fresh rubber tubing each time. In order to facilitate distillation into the electron bulbs the sealing off strictures should be fairly large—about 1 to 2 mm. inside diameter. Any of the alloy condensed in the stricture should be evaporated gently before attempting to seal off, as excessive heat will burn the alloy giving it a brown color.

The potassium-sodium alloy was prepared by putting potassium and sodium into a glass tube in proportion to their atomic weights, *i. e.*, 39 to 23, the tube was then quickly closed by fusing and the pumps started. Heat was then slowly applied, but not in sufficient quantities to melt the metals until the gage showed a vacuum of the order of 0.001 mm. mercury. The heating was

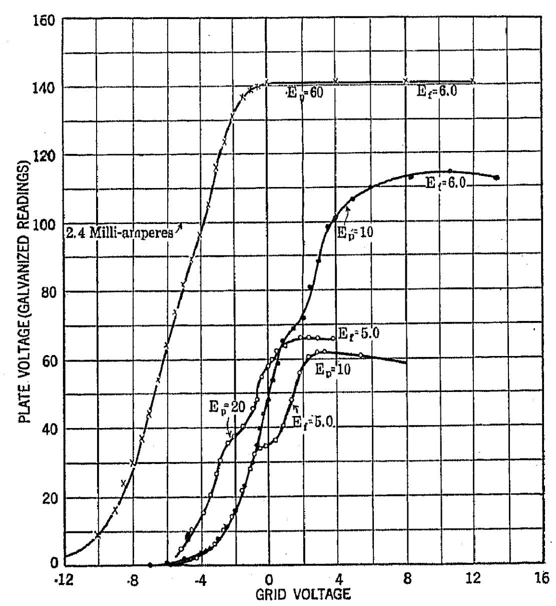

FIG. 6—K-NA VAPOR TUBE NO. 20, POORLY EVACUATED

then continued until the metals were melted and thoroughly mixed, after which the flame was removed, the connection to the pumps sealed off, and when cool the mixture was poured through small funnel-like strictures into the previously attached glass supply tube *A*, which in turn was sealed off, thus providing a store of potassium-sodium alloy for future use. The alloy must never be exposed to the air.

III. CHARACTERISTIC CURVES

All data and curves shown, with one exception, were obtained with standard Radiotron UV 201 amplifier tubes primed with potassium-sodium alloy vapor. This type was used because the stock tubes as purchased came with the electrodes carefully freed of gas and hence they required a minimum amount of time in subsequently out gassing. Note is made on all curves, the data for which were obtained for other types of tubes. Figs. 4 and 5 show conventional charac-

teristic curves for different tubes containing potassium-sodium alloy vapor. The vapor pressure in each tube corresponds to the temperature of the coolest portions of the walls. The most remarkable curves are those obtained for zero plate voltage when the plate circuit return was connected to the negative filament terminal, thus making the plate actually negative to a portion of the filament, yet plate currents as high as one milli-ampere flowed from plate across the vacuum to the filament. This action is the same as though a positive external potential was applied to the plate. These currents at zero plate voltage were 50 to 100 times as great as those obtained for the conventional vacuum

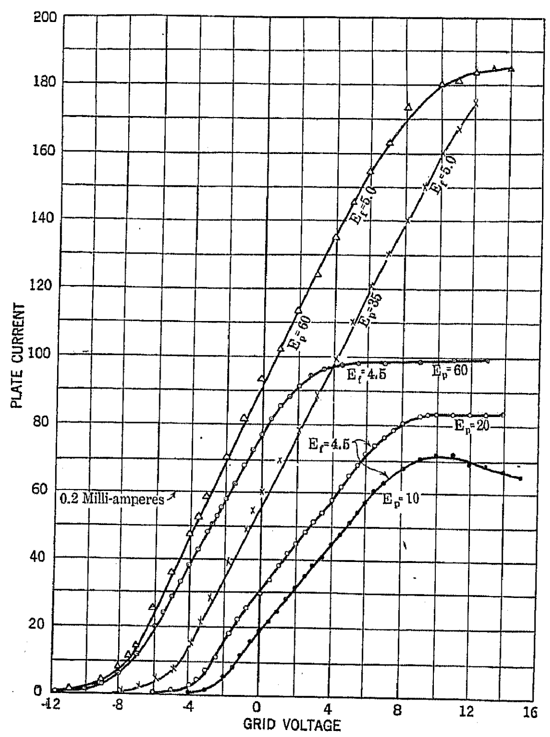

FIG. 7—K-NA VAPOR TUBE NO. 22

or gas content tubes now in use. It should also be noted that the curves are smooth and straight for negative grid voltages, when plotted against plate voltages, and that when a certain plate voltage is exceeded the curves approach a saturation point at negative grid potentials.

If the tube contains a large amount of gas the characteristic humps of gas content tubes are present, however, if the filament temperature is substantially increased these humps disappear and the saturation points are not reached until the grid voltages approach positive values. These results are shown in Figs. 6 and 7. With the filament voltage increased from 4.5 volts to 5 volts the curve for 60 volts on the plate remains straight up to 7 volts positive grid potential. In Fig. 8 this same tube was used with the filament voltage increased to 5.5 volts, and with 100 volts plate potential. This indicates that increased filament temperatures make the alkali vapor more active and effective and also that vacuum tubes containing alkali vapor at high vapor pressures possess the characteristics of high vacuum amplifier tubes. At the same time the considerable plate currents that are obtained at low plate voltages, and the steep slope of these low-voltage curves, indicates that the tubes will function as detectors at low plate potentials. This point will be dwelt on later. It was found that to obtain tubes with smooth characteristic curves at normal filament tem-

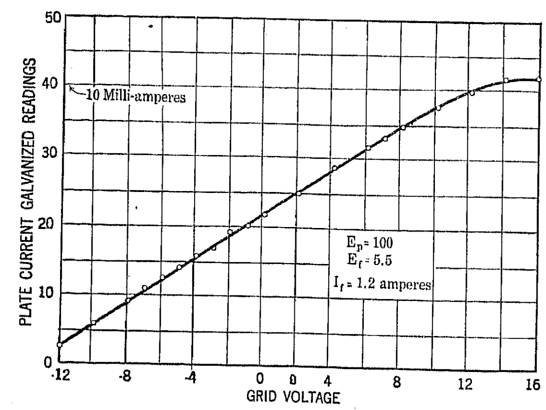

FIG. 8—K-NA VAPOR TUBE NO. 22

peratures, and lower, the evacuation must be made as complete as possible, just as in the preparation of high vacuum amplifier tubes.

Grid current curves and emission curves for sample alloy vapor tubes are shown in Figs. 9 and 10, respectively. The high degree of assymetry of the grid-current curves at about 2 volts negative grid potential should be

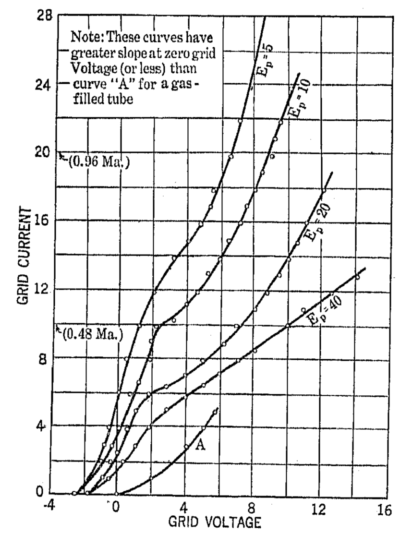

FIG. 9—GRID CURRENT, GRID VOLTAGE CHARACTERISTICS, K-NA VAPOR TUBE NO. 1

noted. Fig. 11 shows plate voltage-grid voltage curves at constant plate currents for three of these tubes. Curves A and B are typical for gas content tubes and for amplifier tubes and are given for comparison. The slope of these curves is a measure of the amplification constant of the tube. The slope for the alkali vapor tubes is steeper than that for the vacuum amplifier tubes, and the curves of the former are parallel straight lines.

The amplification constants of several tubes were measured for varying plate voltages by an audio-frequency a-c. method described on page 203 of Van der Bijl's "The Thermionic Tube." The results are shown

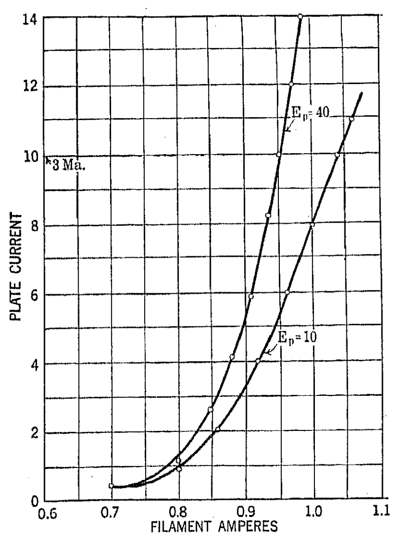

FIG. 10—K-NA VAPOR TUBE NO. 7
$E_g = 0$

in Fig. 12. It is not certain whether or not the high values obtained at low plate voltages were due to extra sensitiveness of the tubes, or to some discrepancy in the method when working at such low plate voltages.

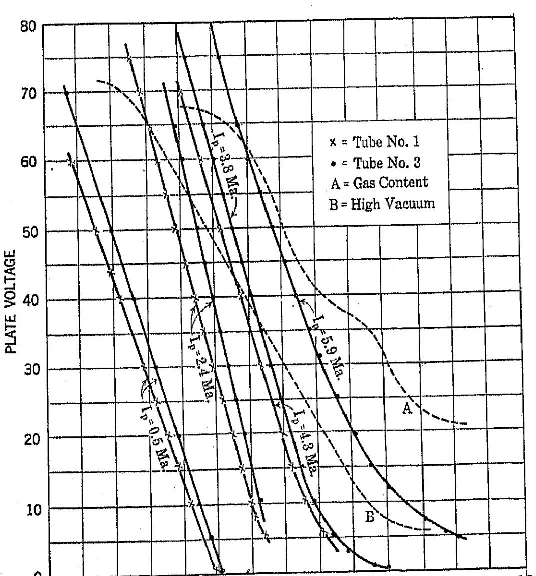

FIG. 11—K-NA VAPOR
x = TUBE NO. 1
• = TUBE NO. 3
A = GAS CONTENT
B = HIGH VACUUM

In the measurements the impressed 1000-cycle e. m. f. and the negative grid potential were varied, but no marked change in results occurred. It should be noted that the amplification constant falls off as the plate voltage is increased, and in Curve A, Fig. 13, it falls to zero at about 140 volts. However, increasing the filament current has the effect of keeping the curve from falling to zero, at least not until a considerably higher plate voltage is reached. In Curve B it is seen that the value of μ does not fall below 9.0 at 225 volts plate potential. In Fig. 14 are plotted values of mutual conductance for varying plate voltages, showing that the variation of this constant is much more gradual than it is for the case of gas content detectors.

IV. DETECTOR AND AMPLIFIER PERFORMANCE

One of the most important features of a detector tube is the degree of critical adjustment of plate voltage and filament current. It is known that low vacuum tubes, containing nitrogen, air, etc., (see Fig. 1) are quite critical. The alkali vapor tubes have been found to be much less critical in spite of the low plate voltages necessary for best efficiency, hence careful tests were made on several tubes used as detectors in laboratory receiv-

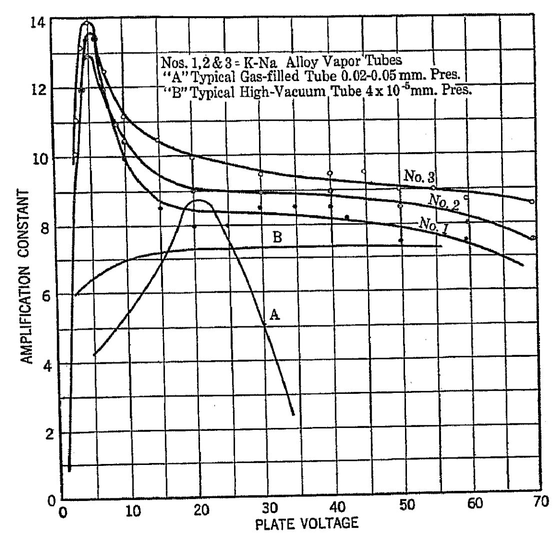

FIG. 12—VARIATION OF AMPLIFICATION CONSTANT WITH PLATE VOLTAGE

ing circuits, receiving modulated undamped waves from a small loop transmitter. Measurements on the intensity of response in the telephones were made by matching the intensity of the received signal with another signal which could be attenuated in definite proportions from which per cent comparative audibilities could be calculated.[2] The results are shown in Fig. 15. Curves for low and high-vacuum tubes are shown for comparison. Not only are the alkali vapor tubes much less critical than the conventional gas content tube, but the tests showed several of the former to be more than three times more sensitive than are the latter on weak signals, *i. e.*, three times as loud signal response. It is regretted that space does not permit a detailed discussion of the method of making the tests and the precautions[3] that are necessary.

2. Van der Bijl's "The Thermionic Tube," pp. 337 and 347.
3. See paper by the authors, *Proc. I. R. E.*, Vol. 10, No. 6, pp. 460-3.

Another very interesting effect of filament temperature was here noted.

The value of μ, the amplification constant, and also the audibility, vary with the filament current in a manner similar to that of a high vacuum amplifier tube. These quantities increase from zero to full value rapidly as the filament current increases from 75 per

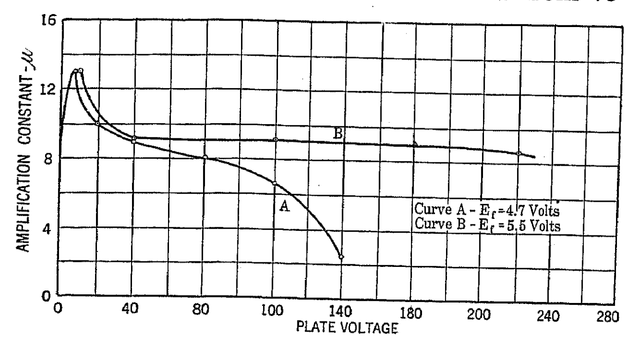

Fig. 13—K-Na Vapor Tube No. 23

cent to 90 per cent normal rated value, and they remain practically constant as the filament current increases to full value and on to 10 per cent above normal. Above this value the amplification constant falls off gradually.

If a tube contains considerable gas in addition to the alkali vapor the performance curve will be that of curve

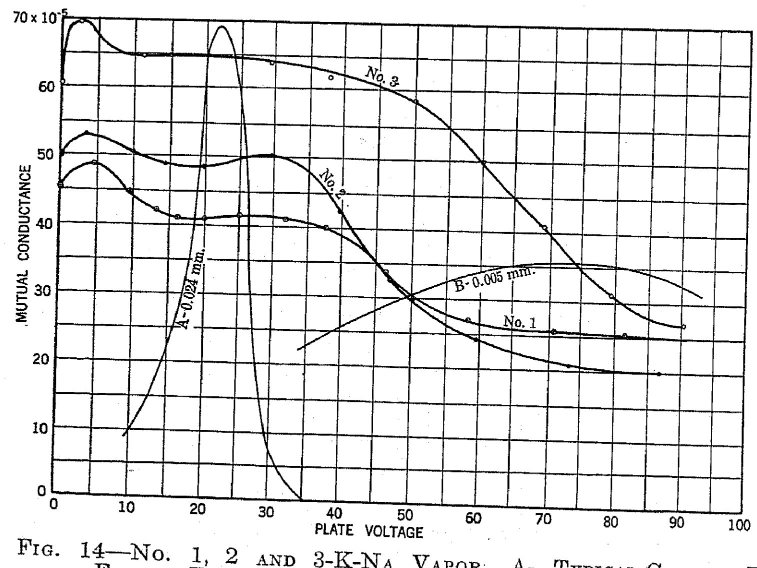

Fig. 14—No. 1, 2 and 3-K-Na Vapor. A—Typical Gas-Filled Tube; B—Typical Vacuum Amplifier

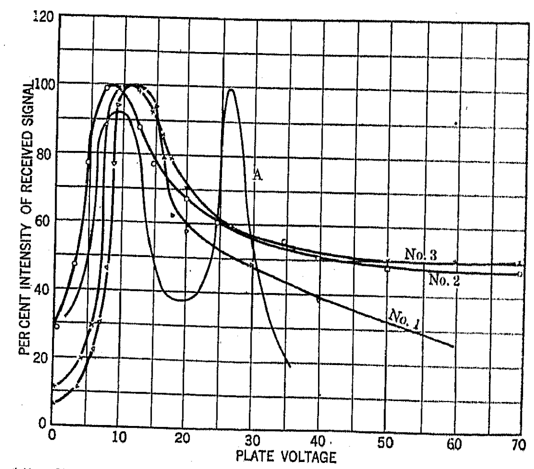

Fig. 15—Detector Performance, K-Na Vapor Tubes

A, Fig. 15, having a second peak in the region of the ionizing potential of the residual gas. If now, the filament current is increased, say, from 0.97 ampere to 1.02 amperes, the second peak will entirely disappear, and the curve will be similar to one of those shown in the figure, say for tube No. 1. These results, in addition to the mentioned effect of increased filament temperature on the amplification constant at high voltages, and the results showing effect on the characteristic curves, indicate that the heat of the filament makes the alkali vapor more effective in producing desirable characteristics that overcome the well known effects of the residual gas in tubes.

The quantitative results obtained indicate that potassium-sodium vapor tubes should be efficient and practical detectors. Actual use of these tubes has proved such to be the case to a surprising degree. The best plate voltage to use is about 8 or 10 volts. With this voltage users in this vicinity (Urbana-Champaign, Illinois) report excellent results. When using only the positive filament drop, with no additional "B" battery, the writers have often received broadcasting stations in Kansas City, Atlanta, Schenectady and Pittsburgh, using a variometer type of regenerative receiver with an antenna 12 ft. above the ground and 40 ft. long, and with *no* amplifier. The reception from the above stations was fairly loud and very distinct. Again, using an antenna 40 ft. high, and with *no* external "B" battery, broadcasting stations in Los Angeles, Cal., were received fairly loud. The above stations could even be heard faintly with the plate circuit return connected to the negative filament lead, and with no "B" battery. With these conditions the tubes were also used as beat receivers of the autodyne type receiving the high-power stations on the coasts, when using the negative filament drop as plate potential. In addition to their high degree of sensitiveness the tubes have exhibited a remarkable degree of selectivity when functioning as detectors, especially in zero beat reception. They also give reception absolutely free from distortion which is not the case of many gas content tubes. In listening to piano music, for instance, every note in the runs was received perfectly lear and distinct.

When used in receiving circuits the tubes do not function efficiently until the filament has produced enough heat to render the alkali vapor active. This requires from 20 seconds to 1 minute. In most tubes the filament current can be maintained 10 to 20 per cent lower

than for gas content tubes. Some of the alkali vapor tubes prepared in the laboratory have been used intermittently for 8 months, and no deterioration of the filaments has been noted. It is known that potassium and sodium can form alloys with tungsten, but it is very improbable that, owing to the filament temperatures, any alkali metal remains in contact with the filament. Another peculiar effect studied qualitatively is the ability of the tube to function most efficiently as a detector at a certain definite wave length. The wavelength of the transmitted signal was varied and the receiver tuned to receive it. The maximum audibility occurred at about 650 meters. Vacuum amplifier tubes did not show this effect when used in the same receiver.

V. Effect of Variation in Spacing of Electrodes

The foregoing data and discussion apply to the standard Radiotron U. V. 201 tubes, and also to a few tubes of different makes having nearly the same electrode spacings. To determine the effect of various spacings upon tubes primed with potassium-sodium alloy vapor was also undertaken. For tubes with slightly greater or slightly smaller spacings than those previously studied there was found no marked difference in the characteristics. When the spacings were increased to 6 mm. and 8 mm. from filament to grid, and to plate respectively, the amplification constant was found to pass through a maximum value for a plate voltage of 50 volts as the latter was varied. When the tube was used as a detector the audibility of the received signal was also maximum at this plate voltage, and passed through a maximum value for a filament current of about 50 per cent of the normal rated value as the latter was varied. Some of the results are shown in Fig. 16, and are typical for several tubes tested. Some of these tubes were extremely sensitive detectors under the above conditions, low filament current and high plate voltage and in the testing circuits gave approximately 10 times louder response than did those of normal spacing, but their action seemed erratic and unsteady. The response at zero plate voltage was very weak. The characteristic curves of the tubes having large spacings proved to be similar in shape to those shown in this paper. The results of these tests indicate that in order to obtain the low plate voltage characteristics the spacings of the electrodes must be small.

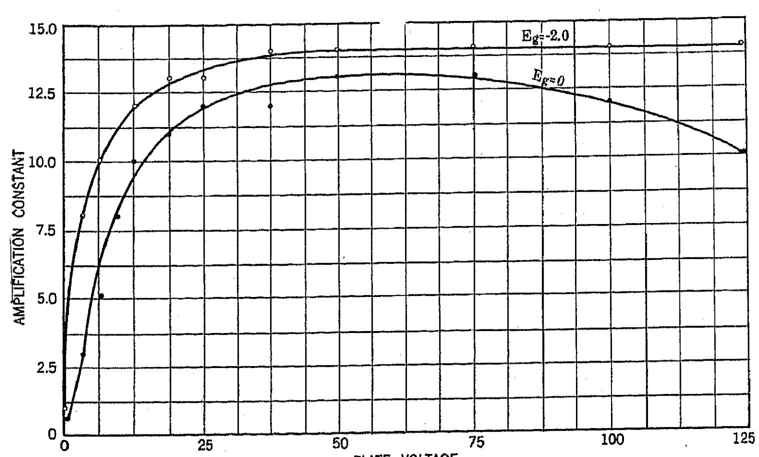

Fig. 16—K-Na Alloy Vapor Tube with Large Electrode Spacings, 50 Per Cent of Arted Filament Current

VI. Oxide Coated Filament Tubes

The effect of potassium-sodium alloy in oxide coated filament tubes is very peculiar. Several of the "dry cell" types of vacuum tubes were filled with the alloy and proved to have extremely high plate resistance with normal filament current flowing. The measured *d-c.* plate resistance was upwards of a million ohms. The tubes were insensitive as detectors below filament currents that were 100 per cent above normal. This shows that for low temperatures the alkali vapor actually opposes the emissive power of the cathode, and it is only when the latter becomes so hot as to set the alkali vapor into very violent agitation that the plate current flows. Other effects such as contact potential, photo sensitivity, and ionizing action, probably combine in a complicated way to produce the results obtained. It should be mentioned that the Western Electric type VTI tubes primed with potassium-sodium alloy functioned fairly well as detectors at low plate voltages and normal filament current due to the considerable heat produced by the oxide coated filament in this type of tube. The application of heat externally improves their action. Characteristic curves obtained for such a tube are shown in Fig. 17. Due to the large increase in plate current when the voltage was raised from 10 to 20 it was necessary to lower the

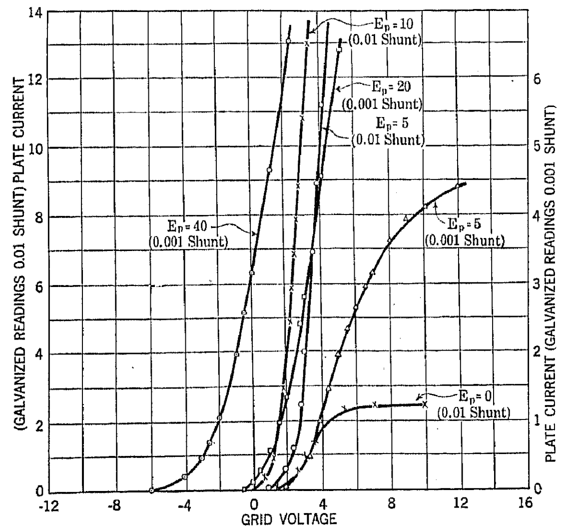

Fig. 17—Western Electric V. T. I. Tube, Containing K-Na Alloy Vapor, Normal Rated Filament Current

VII. Summary

Three electrode tubes containing potassium-sodium alloy vapor, and probably other alkali metal vapors, were found to be very sensitive detectors in radio

receiving circuits at low plate voltages. This sensitivity is due to the low ionizing potentials of these vapors, and probably also to other characteristics of such vapors, as photo-sensitivity, contact potential, etc. These tubes are much less critical than are gas content detectors. They are steady in their action, needing no frequent adjustments of filament current or plate voltages. The electrode spacings must be small to obtain the low plate voltage characteristics. Curves and measurements show excellent amplifier characteristics especially at higher filament temperatures. value of the shunt across the galvanometer that read plate currents, hence the two sets of coordinates. These curves are extremely steep and that they are shifted to the right of the zero grid voltage line as compared to the tungsten filament tubes is significant. The effect of residual gas on the detector and amplifier characteristics is nullified by raising the filament temperature from 10 to 15 per cent. For sensitive detector operation the filament temperature necessary to make the alkali vapor active is a little lower than the rated value for that type of tube.

Credit should be given Dr. Jakob Kunz who recommended the alkali metal vapors in response to an inquiry as to what gases possessed the lowest ionizing potentials. The writers are also obliged to Mr. Orlando Whelan for valuable assistance.

Discussion

G. D. Robinson: Will the authors please state what decrease or increase of filament life is found to accompnay the use of the alkali vapor?

Referring to Mr. Knipp's discussion of Figs. 4 and 5, where he states that plate current flows with the "plate actually negative to a portion of the filament," it appears that the plate is actually negative with respect to all active parts of the filament.

Alexander Nyman: The first curve, I believe, shows the sensitivity of the detector. As a rule, it is a very difficult thing to measure the sensitivity, and I would like to know how it was measured in this case. I believe several curves show amplification constants. That is another doubtful thing in the tubes. There are two ways of measuring amplification constants; one is the amplification constant on open circuit, and the second, is with full current on the plate circuit. The easiest way to get the second is by simply having a family of plate-current and grid-voltage curves, and computing the ratio of voltages from these series of curves. I would like to know which particular amplification constant is used.

With regard to the application of this tube, it seems that if it can meet all the qualifications of a detector and amplifier, it ought to make quite a good commercial product.

There is one factor that hasn't been discussed and that is the stability of this tube as an oscillator. In other words, if you have a regenerative circuit, and you are adjusting for the most sensitive conditions, unless the tube is a fairly stable oscillator, the signal will swing from non-oscillatory conditions to an oscillatory condition and distort the signal.

Hugh A. Brown: Replying to Mr. Robinson's question, no accurate data on the effect of the alloy on the life of the filament have been obtained. However, some of the tubes have been in use intermittently for nearly two years and the filament resistance has changed very little. It seems as if the presence of the alloy is not nearly so serious a factor on the filament life as is the presence of the argon and helium in the conventional gas content detector tubes. This is probably due to the fact that the alkali vapor tubes function at about 10 per cent lower filament current than do the former. It is known that potassium and sodium can form an alloy with tungsten under proper conditions, but it may be true that the alloy of these two metals is not so active. This is true in the case of glass, the separate metals will crack glass in time, but the alloy seems to have no effect.

Replying to Mr. Nyman's questions, the curve he refers to was obtained principally for the purpose of showing how critical the tubes are with varying plate voltages. The method of testing is described very briefly on page 4, of the paper. A more detailed description of the measuring apparatus can be found in the I. R. E. paper by the authors referred to on page 5. The tubes were used as "plain" detectors on a weak signal which showed 5 to 7 "times audibility" on a standard *J* tube used as a detector. The amplification constants were measured by an a-c. method described in Van der Bijl's book, "The Thermionic Tube," and which method the authors understand is used by the Western Electric Company in rating amplifier tubes. It is a "no load" amplification constant, but plate current flows during the measurement. The methods of measuring both "no load" and "full load" amplification constants are described in Morecroft's "Radio Communciation." The tubes are exceedingly stable oscillators, especially in the weakly excited condition and are thus excellent for "zero beat" reception.

Transient Performance of Electric Elevators

BY DAVID L. LINDQUIST

and

E. W. YEARSLEY
Member, A. I. E. E.
Otis Elevator Company, New York, N. Y.

Review of the Subject.—*The investigation of transient conditions is vitally important in elevator engineering, both electrical and mechanical. In no other method of human transportation are traveled distances so short and speeds and loads so frequently varied. Passengers must be hoisted and lowered safely and expeditiously. Landings must be accurately made. The elevator is consequently a machine that is very sensitive to transient effects and the entire apparatus must therefore be designed on the basis of transient analysis.*

Pure mathematical determination of elevator transients is evidently both difficult and laborious. In some cases it is impossible because the functions are unknown. Graphic methods of analysis lead to a much clearer understanding of the reasons for transient conditions, thus considerably aiding development.

Interdependent mechanical and electrical transients of a hoist system are first developed in the following. Then separate mechanical and electrical transients are considered. Finally, temperatures of the electrical apparatus, resulting from elevator operation in service are determined.

The basic method of transient determination used in this paper is to plot one or more curves representing integrals which each contain a single variable and which, when integrated, will give the desired solution. These integrals are evaluated between limits by measurement of the areas defined by these curves.

Methods of determining elevator transients of speeds, distances, currents, voltages, powers, forces and fluxes, are developed in this paper by means of this system of graphic integration.

* * * * *

TRANSIENT PERFORMANCE AS A MEASURE OF ELEVATOR QUALITY

TO determine the quality of elevators, including general efficiency and ability to supply service, it is necessary to study their transient performance. Predetermination of elevator transients is often desirable, and it is the purpose of this paper to describe comparatively simple means for obtaining transients from data that are available from the usual tests of electric elevator apparatus.

For maximum transportation, it is not only essential that an elevator have a full speed as high as can be advantageously utilized, taking into account the height of the building, the service required and the apparatus available; but it is also necessary to accelerate and retard as quickly as practical, and always to make and maintain accurate landings.

Quantity and quality of transportation are both essential considerations, particularly where elevator service is intensive, which is almost always the case in high buildings. The practical height for a building is dependent upon the service that can be obtained from available elevator equipment. The hatchway and hall space required for elevators capable of giving the required service, is the principal factor in determining how high a building is commercially practical for a given plot. Elevator equipment that will give maximum service is invariably justified for high buildings.

Changes in torque, with accompanying changes in speed, acceleration, and retardation, must proceed properly in order to secure satisfactory elevator operation. Shocks must be avoided for safety considerations and to prevent objectionable sensations of passengers. Constancy of acceleration and retardation, with all loads within the allowable capacity moving in either direction, is very desirable. When acceleration and retardation change, as they must at starting, at coming to constant speed, at the beginning of retardation, and at stopping, the changes must be gradual, tending toward constancy of rate of change of acceleration and retardation. These considerations are necessary even though the elasticity of the human body allows these changes to be made in fractions of a second.

Transient conditions near the stop are important as affecting the accuracy of the stopping point. Accuracy, expediency, and smoothness in making landings have a considerable effect on both quantity and quality of transportation.

The fitness of an elevator for providing a required amount of transportation is dependent upon the rapidity, smoothness and constancy of its transient performance, and the story of this performance is definitely written by the curves of transient speeds, forces, powers, currents, voltages and temperatures resulting from its operation.

ANALYSIS OF TRANSIENT PERFORMANCE

A detailed technical analysis of the transient performance of elevators is useful for preliminary investigations, for definite determination of satisfactory operation, for locating the causes of unsatisfactory operation, for checking performance stated to be the result of tests, and for definite comparisons of different apparatus.

It is important to study transient performance both by means of direct tests, usually made with curve drawing instruments, and by development of theory to the extent that the necessary values for plotting performance curves can be calculated from basic data. Most of the necessary data can be obtained from the characteristic test records of the electrical apparatus employed.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

Theoretical Methods of Predetermining Performance

By comparatively simple methods, it is possible to predetermine performance with sufficient accuracy for practical purposes. This paper describes methods of determining transient performance which avoid seriously involved mathematics and which enable calculations to be made, when the equations of functions are unknown, when functions are discontinuous, and when both conditions exist. An example of a solution readily made by the method described, but which is impossible on a strict mathematical basis, is that of the determination of variation of flux with time through a coil having a magnetic core. The saturation curve is known, but its equation is unknown. Even if an approximate equation is assumed to represent the saturation curve, complete mathematical treatment is seriously involved and the results obtained are too inaccurate to be of practical value.

Complete treatment of all the problems of transient electric elevator performance has not been attempted here, but it is believed that sufficient cases have received consideration to enable the process to be extended to solve any practical transient problems of electric elevators.

General Equations

In general, we have the differential equation:

$$\frac{d\,v}{d\,t} = f/M \tag{1}$$

From which for a hoist system

$$f_1\,d\,t = M\,d\,v \pm F\,d\,t \pm f_2\,d\,t \tag{2}$$

f_1 = the variable driving force
v = the variable velocity of the load
f_2 = the friction force, which may be variable
M = the constant equivalent mass of the system
F = the constant net load hoisted or lowered.

M, which is the equivalent mass of the moving system reduced to speed v, must be determined.

The process of calculating M is laborious and likely to be inaccurate, so that it is best to determine it by test. Various test methods for obtaining this value are described, and finally that giving the most accurate results.

To Determine the Kinetic Energy and Equivalent Mass of a System Including Rotating and Translating Masses

1. The times in which the system stops against friction from various velocities are known, and the power necessary to overcome friction at a single velocity is also known.

Plot the curve of time t to stop from velocity v. See Fig. 1.

Then if P_1 = the known friction power at speed V_1
and F_1 = friction force at speed V_1

$$F_1\,V_1 = P_1$$

and $$F_1 = P_1/V_1$$

Referring to the curve, we have

$$\frac{d\,v}{d\,t} = \tan\alpha = f/M$$

and $$\frac{d\,V_1}{d\,T_1} = P_1/V_1\,.\,1/M = \tan\alpha_1$$

in which $\tan\alpha_1$ may be obtained by drawing the tangent to the curve at point T_1, V_1.

Therefore $$M = P_1/V_1\,.\,\frac{1}{\tan\alpha_1}$$

Thus, by determining the tangent and substituting the power and velocity values, the equivalent mass M may be determined. Consequently the kinetic energy at any speed v is $1/2\,M\,v^2$.

This method is subject to error both in drawing the tangent and in determining the friction power at a single velocity.

Note: In calculating transients it is necessary to know the friction at various velocities, but it is often difficult to measure the friction power at various velocities. With the speed-time curve and the friction power at one velocity, known, as above, the friction power-time curve may be determined as follows.

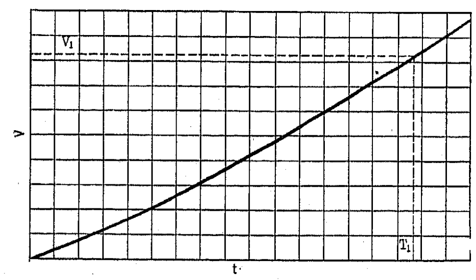

Fig. 1

We have $\tan\alpha = 1/M\,.\,p/v$

Therefore $p = M\,v\tan\alpha$

Substituting $M = P_1/V_1\,.\,\dfrac{1}{\tan\alpha_1}$

We have $p = \dfrac{P_1}{V_1\tan\alpha_1}\,v\tan\alpha$

By drawing tangents to various points on the curve (Fig. 1) and substituting the corresponding values of v, we can obtain the corresponding values of p and thus draw the Friction Power-Velocity Curve.

Any errors that there may be in the determination of the friction power P_1 and the $\tan\alpha_1$ still exist, and the curve so constructed is subject to these errors.

2. The Friction-Power at various velocities and the time required to come to rest from a single velocity are known

From equation (1)

$$t = M\int 1/f\,d\,v$$

This integral cannot be directly integrated since f is a mathematically unknown function of v.

If we draw a curve (Fig. 3), plotting various values of $1/f$ against corresponding values of v, we have Evidently the area of this curve is $\int 1/f\, d\, v = \times B$

It is therefore only necessary to take the area up to any velocity with a planimeter, to determine the time corresponding to this velocity.

$$\int_0^{V_1} 1/f_1\, d\, v = B_1$$

$$T_1 = M\, B_1 \text{ and } M = T_1/B_1$$

and $T_2 = M\, B_2$ etc. and $M = T_2/B_2$

Taking the area (as B_1) corresponding to a velocity (in this case V_1) and taking T_1 corresponding to V_1, we determine M.

This method of drawing a curve in such a manner that it defines an area which represents a certain integral, then measuring the area by means of a planimeter, is a simple method of solving differential equations. It avoids both the mathematical solution of the integral and the determination of constants of integration.

This solution is subject to any error there may be in the measurement of the time required to stop from a single velocity.

3. If the times required for the machine to come to rest against friction, from various velocities, and the friction-powers at various velocities are known.

a. Run the balanced hoist system at various velocities and, cutting off power, allow it to stop opposed only by friction, noting the time required to stop from each velocity.

b. Plot the speed-time curve, Fig. 4.

c. Drive the system at various speeds, noting the friction power required at each speed.

d. Plot the friction-power-velocity curve, as shown in Fig. 2.

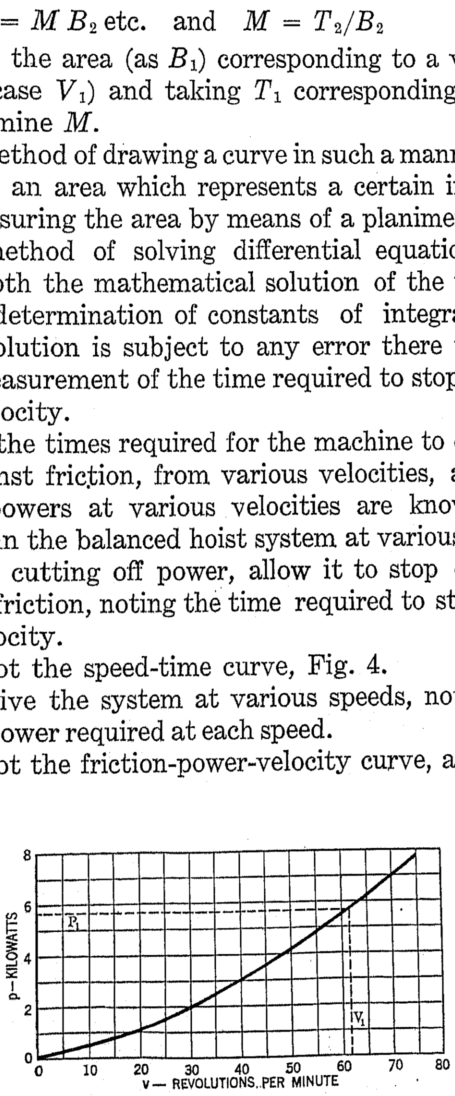

FIG. 2

e. Plot a friction power-time curve, taking the power and time from Figs. 2 and 4, for the same values of velocity.

The area of this curve, which may be obtained by a planimeter, is

$$f\, v\, d\, t = \int p\, d\, t = 1/2\, M\, v^2 = A$$

Taking area A_1 for a velocity V_1

$$M = \frac{2\, A_1}{V_1^2}$$

Note that it is necessary to use proper multipliers in determining actual values from the above.

This is an accurate method of obtaining equivalent mass and kinetic energy, since all test points are averaged in the result. It is only necessary to employ an ammeter, voltmeter, stop-watch and tachometer, instruments usually available and which may be used without difficulty, to obtain the value of the equivalent mass M of the hoist system.

Mathematical Treatment

Proceeding now to the consideration of elevator transients, having shown a simple and accurate method

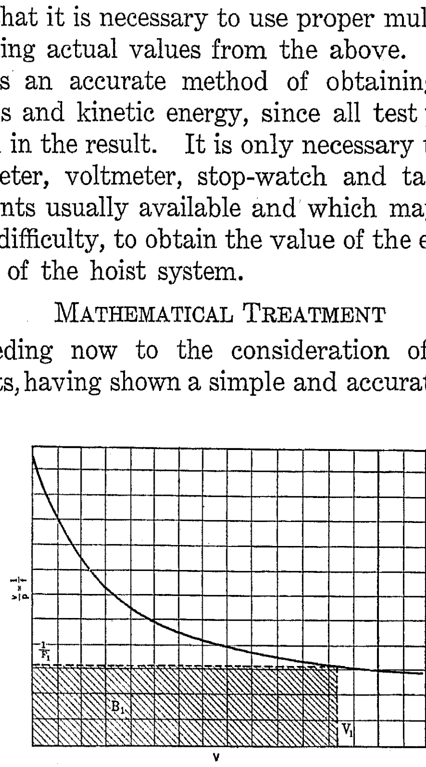

FIG. 3

for obtaining the value M to be used in the equations, we may first investigate pure mathematical treatment. A simple case will serve to demonstrate that pure mathematical method is complicated and often impossible.

Taking a very simple example, we have a direct-current motor having a constant field, operated on constant e. m. f. A constant field has been assumed to simplify the problem. Such a condition is, however, seldom, if ever, met with in elevator practise. To further simplify this case, we shall neglect the effect of armature reaction, which is to reduce torque by weakening the field. The effects of core losses and armature circuit inductions are also neglected. The friction force is assumed constant.

Elevator Speed-Time Curve

Direct-Current Motor with Constant Field.

E = Constant line voltage

R = Constant resistance of armature circuit, including external and armature resistance

e = the variable counter e. m. f.

i = the variable current in the armature.

We have $e\, i\, d\, t = M\, v\, d\, v \pm F\, v\, d\, t + F_1\, v\, d\, t$

In this equation the plus sign is used with F when the load is being driven by the elevator machine and the minus sign when the load is driving the machine.

t = the variable time

v = the variable velocity

M = the constant equivalent mass of the moving system at speed v

F = the constant hoist load, positive or negative
F_1 = the friction load (assumed constant)

Assuming with constant field that

$e = K v$ where K is a constant.

Neglecting the induction of the armature circuit, we have

$$i = \frac{E - K v}{R}$$

Substituting these values in the differential equation, we have

$$d t = M R \frac{d v}{(E K - F R - F_1 R) - K^2 v}$$

Integrating and substituting the constants of integration, we have the equation of the speed-time curve:

$$t = \frac{M R}{K^2} \log \epsilon \frac{E K \mp F R - F_1 R}{E K \mp F R - F_1 R - K^2 v}$$

also $$v = \frac{E K \mp F R - F_1 R}{K^2} \left(1 - \epsilon^{-\frac{K^2}{MR} \cdot t}\right)$$

To obtain the equation of the current-time curve, we have

$$e = E - R i$$

$$v = \frac{E - R i}{K}$$

$$d v = - R/K \, d i$$

From which we have, by substituting in the differential equation:

$$d t = - \frac{M R}{K} \cdot \frac{d i}{K i \mp F - F_1}$$

Integrating, we have the equation of the current-time curve

$$t = \frac{M R}{K^2} \log \epsilon \frac{F_1 \pm F - K I}{F_1 \pm F - K i}$$

where $I = E/R$, the initial current admitted to the armature.

Note again that it is necessary, in determining actual values, to insert the proper conversion multipliers to make the energy equation read in the same units on both sides.

In plotting the speed-time and current-time curves, the resistance of the armature circuit changes with every step of resistance, so it is necessary to change the value of R in the equation for every controller step.

This mathematical solution is made possible by assuming, for the sake of simplicity, conditions that are seldom, if ever, encountered in elevator practise. In some cases the armature reaction must be taken into account, and in almost all cases there is a variable field.

With the usual variable field it is impossible to get algebraic equations for the transients, because the equation of the saturation curve is unknown. If an equation is assumed to represent the saturation curve, the result, in the case of elevator motor fields, is too inaccurate to be of practical value. For low saturations, the flux will be approximately directly proportional to the magnetizing force and the equations

$$i = E/R \left(1 - \epsilon^{-\frac{R}{L} t}\right) \text{ for an increasing field}$$

and $i = I \epsilon^{-\frac{R}{L} t}$ for decreasing field may be used. Since high saturations are used in the accelerating and retarding periods of elevators, the actual saturation curve must be taken into account. Secondary currents must also be considered.

In his work on "Transient Phenomena," Dr. Steinmetz has treated the cases of combined mutual and self-induction where the magnetism is assumed directly proportional to the magnetizing force and also self-induction alone, using Froehlich's formula for the saturation curve. He notes that the equations obtained are only approximately correct for low saturations.

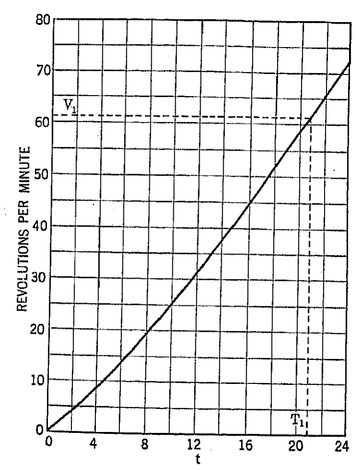

FIG. 4

By a simple graphical method, the flux and current in the case of highly saturated variable fields, such as are generally used with elevator motors, may be taken into account with sufficient accuracy for all practical purposes. By the graphical method described in this paper, we have treated the cases of self-induction and also mutual induction, neglecting primary and secondary leakage, in both cases taking the actual saturation curve into account. Mutual induction, including primary and secondary leakage, is an involved problem, but it is possible by combining the methods we employ, with the Steinmetz method, to obtain a step-by-step solution of actual fluxes and currents, taking the actual saturation curves into account to any degree of saturation.

Before considering the field problem, we shall take up the determination of speed-time and distance-time elevator curves when the speed-torque curve of the motor and the speed-friction curves of the elevator are known.

Graphical Treatment

It is evident, if all the variables are to be taken into account, that it is practically impossible to determine electric elevator transients by pure mathematical methods.

If we attempt to deduce the equation of the speed-torque curve of a motor, we must take into account a large number of variables. In some cases theory has not been sufficiently developed to enable us to consider the variables mathematically. Even if theory were available that would make it possible for us to determine the equation of the speed-torque curve of a motor, taking all the variables into account, it is evident that the resulting equation would be too cumbersome to be of any practical value in determining actual transients.

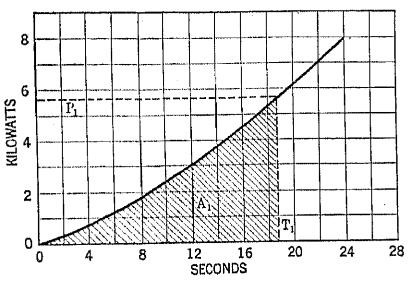

Fig. 5

The speed-torque curve of an electric motor can always be obtained from simple tests and the necessary test data are usually available from standard tests made to determine the motor characteristics. This curve takes all the variables into account, but its equation is unknown; that is, the torque is a mathematically unknown function of the speed.

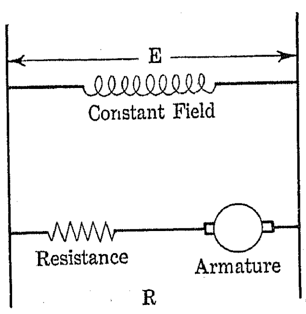

Fig. 6

Graphically, however, this function is known, since it is exactly expressed by the speed-torque curve.

In determining elevator transients it is evidently necessary to take the correct speed-torque curve into account. As this is only known graphically, some graphical method must be employed for using it in calculations of elevator transients. The method described in the following is easily applied to practical problems, and employing no approximations and being based on the actual speed-torque curve, gives correct transient values. The accuracy is only limited by the accuracy of the instruments used in making the speed-torque tests, and the accuracy of their observation.

To Determine the Speed Time Curve when the Force Causing Speed Change Varies with Velocity.

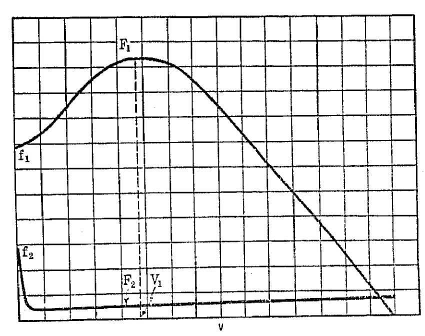

Fig. 7

Given: The Curves (Fig. 7) representing the speed-torque characteristic of the motor as determined by the usual tests and the change in friction force of the elevator with velocity.

Obtaining f_1 and f_2 from the test curves above plot, the curve (Fig. 8).

From the differential equation (2), we have

$$t = M \int \frac{1}{f_1 - f_2 \mp F} \, d v$$

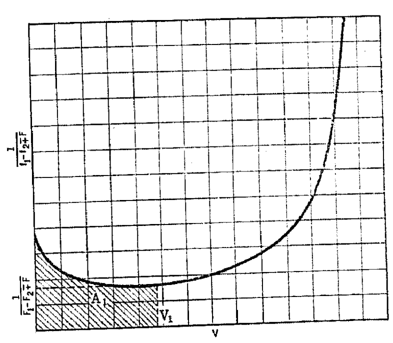

Fig. 8

Therefore $\quad T_1 = M A_1$

Since A_1 (which is the area up to point V_1)

$$= \int_0^{V_1} \frac{1}{f_1 - f_2 \mp F} \, . \, d v$$

Also $\quad T_2 = M A_2$

$T_3 = M A_3$, etc.

To find the time corresponding to a speed V_1, take the area of the curve up to V_1 (shown shaded) using a planimeter. Multiply this area by M (the equivalent mass) and the result is the time T_1 corresponding to velocity V_1.

In this case we have two mathematically unknown

functions, the speed-torque curve and the speed-friction curve. By the very simple graphical method using a planimeter, we are able to determine the speed-time curve of a hoist system with an accuracy only limited by the accuracy of the instruments used and the average accuracy of observation.

To Determine the Distance-Time Curve of an Elevator

If the speed-time curve (Fig. 9) has been determined,

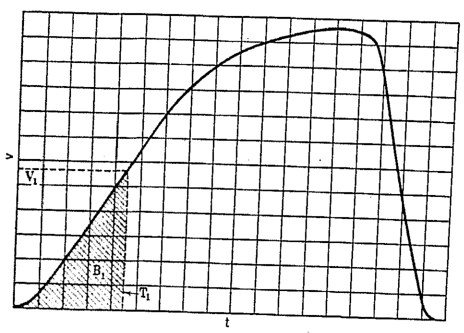

FIG. 9

the distance-time curve may be obtained by integrating this curve by means of a planimeter.

We have $\dfrac{d\,s}{d\,t} = v$

and $s = \int v\,d\,t$

At time T_1 $S_1 = B_1$ where B_1 = shaded area

At time T_2 $S_2 = B_2$ etc.

To Determine the Speed-Distance Curve of an Elevator

We have, as before $\dfrac{d\,v}{d\,t} = \dfrac{f_1 - f_2 \mp F}{M}$

Also $\dfrac{d\,s}{d\,t} = v$

Therefore $d\,s = M \dfrac{v\,d\,v}{f_1 - f_2 \mp F}$

Then $s = M \int \dfrac{v\,d\,v}{f_1 - f_2 \mp F}$

Plot the curve (Fig. 10)

Then

$$S_1 = M\,C_1$$

$$S_2 = M\,C_2 \text{ etc.}$$

Take the area to V_1 by planimeter, and this area multiplied by M is the distance traveled to speed V_1.

To Determine the Speed-Time Curve when the Force Causing Speed Change Varies with Distance

The curve plotted in Fig. 11 is known:

f = force causing speed change

s = distance traveled while speed is changing

$$\int_0^{S_1} f\,d\,s = \text{work done} \Big/_0^{S_1} = \text{Area } D_1$$

This work is converted into kinetic energy.

If V_1 is the velocity at distance S_1. Then at B_1 we have

$$D_1 = 1/2\,M\,V_1^2$$

$$V_1 = \sqrt{\frac{2\,D_1}{M}}$$

$$V_2 = \sqrt{\frac{2\,D_2}{M}}$$

We have $\dfrac{d\,s}{d\,t} = v$

Therefore $d\,t = \dfrac{d\,s}{v}$

and $t = \int 1/v\,d\,s$

If we plot curve (Fig. 12)

Obtaining values for $1/V_1$ from $V_1 = \sqrt{\dfrac{2\,D_1}{M}}$

and for $1/V_2$ from $V_2 = \sqrt{\dfrac{2\,D_2}{M}}$ etc.

We have $T_1 = B_1$ for distance S_1

$T_2 = B_2$ for distance S_2 etc.

Areas B_1 and B_2 are obtained by the planimeter. This solution is applicable to elevator buffer problems.

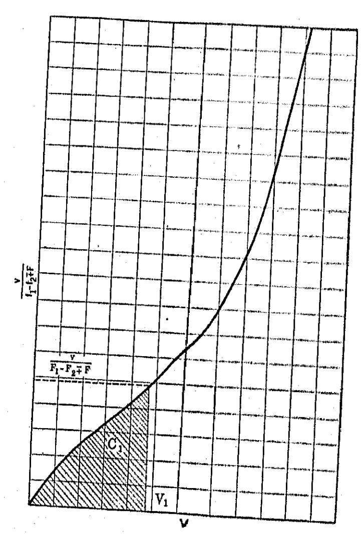

FIG. 10

Having obtained the speed-distance curve, tangents may be drawn to various points on it, determining

$$\frac{d\,v}{d\,s} = \tan \alpha.$$

Then $v \dfrac{d\,v}{d\,s}$ = the retardation, and by plotting the curve of retardation against distance, the maximum retardation of the buffer may be obtained.

The force causing change of speed is the algebraic sum of the forces acting to accelerate and retard the mass of the system.

Elevator Buffers

When an elevator buffer operates, it is necessary to know the retardation and the stresses in the mechanical structures, under all conditions. The human body can only withstand retardations below a certain maximum. The mechanical structures can only withstand limited stresses.

Some elevator buffers apply a retarding force varying only with distance. The following example gives the solution for transient retardation when a traction elevator runs into a buffer having a retarding force varying in a graphically known relation to distance.

The sheave is turning so as to cause the elevator car to descend, at the time that the buffer is struck, and continues to turn in the same direction, the ropes slipping on the sheave.

f_s = Buffer retarding force
s = Distance buffer is compressed
g = Acceleration of gravity
a = Acceleration or retardation

$$T_2 = W_2\,(1 + a/g) - f_s$$

$$T_1 = T_2\,(\epsilon^{\mu\alpha})$$

$$T_1 - T_2 = [W_2\,(1 - a/g) - f_s\,(\epsilon^{\mu\alpha} - 1)\,]$$

When driving sheave is rotating and ropes are slipping over it.

$$W_1 - W_2 + f\,s - (T_1 - T_2) = M\,a$$

$$a = \frac{W_1 - W_2\,\epsilon^{\mu\alpha} - f\,s}{M = W_2/g\,(\epsilon^{\mu\alpha} + 1)} = K_1 - K_2 f\,s$$

$$\frac{d\,v}{d\,t} = \frac{v\,d\,v}{d\,s} = K_1 - K_2 f_s$$

$$v\,d\,v = (K_1 - K_2 f_s)\,d\,s$$

$$1/2\,v^2 = \int (K_1 - K_2 f_s)\,d\,s$$

Plot Curve of s against $K_1 - K_2 f_s$ (Fig. 14).

$$\tfrac{1}{2} v^2 = A$$

$$V_1 = 2\,A_1$$

$$V_2 = 2\,A_2 \text{ etc.}$$

Plot curve between v and s (Fig. 15).

$$\frac{d\,v}{d\,s} = \tan\alpha$$

Plot curve of $v \tan\alpha$ against s to determine the retardation at any point.

Speed-Time and Distance-Time Curves of Elevators

The methods described enable these transients to be easily determined under all conditions of operation, no matter what kind of control is used. If acceleration and retardation are regulated by speed, the speed-torque curve is drawn from the characteristic curve data. Fig. 16 is a curve of this type, the steps occurring where the controller changes at certain velocities.

The curve of $\dfrac{1}{f - f_1 \mp F}$ against v, which is drawn from the above, may be directly integrated to determine corresponding time and speed.

If time control of acceleration and retardation is employed, the speed-time curve is determined up to the time when the controller changes and then the speed-torque curve corresponding to the controller change is used to determine the corresponding portion of the speed-time curve.

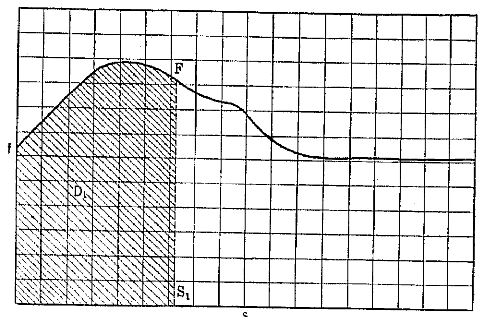

Fig. 11

If acceleration and retardation are controlled by distance, the controller change point is determined from the distance-time curve, shifting to the new speed-torque curve at the specified distance.

Speed-time curves may be determined with any kind of control of acceleration or retardation, for example, current or voltage control, by the comparatively simple methods described.

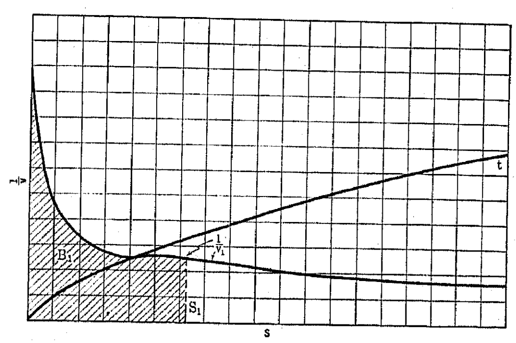

Fig. 12

Varying Fluxes

When fields vary, as they frequently do in elevator operations, the corresponding flux must be taken into account, in determining the torque at any instant. Fields are operated at high, as well as at low saturations, so that it is necessary to use the correct saturation curve in making calculations. By the method employed here, it is comparatively easy to determine fluxes and field currents, including the effect of secondaries, which are usually present in direct-current elevator fields. Since

the correct saturation curve, the equation of which is mathematically unknown, is taken into account by this graphical method, the results are correct for all saturations.

In addition to determining the transient flux of motor fields, it is also important to determine the transient flux of brake and controller magnets used with elevators, and the same method is applicable to these cases. Magnet time constants have an important effect on operation and it is essential to be able to definitely determine this effect.

Rise of Flux and Current with Time in an Inductive System Consisting of a Coil with a Core of Magnetic Material, when a Constant Direct-Current Electromotive Force is Applied, Assuming no Secondary Current

The saturation curve of current and corresponding flux is first plotted.

Let φ = the variable flux
and i = the variable magnetizing current
N = the number of turns in the coil
R = the resistance of the coil
E = the constant impressed d-c. electromotive force
t = variable time

We have first the electromotive force equation:

$$E = R\,i + N\frac{d\,\varphi}{d\,t}$$

According to the saturation curve

$$\varphi = f\,(i)$$

Then
$$d\,\varphi = f'\,(i)\,d\,i \quad \frac{d\,\varphi}{d\,i} = f'\,(i) = \tan\alpha$$

$$d\,\varphi = \tan\alpha\,d\,i$$

$$t = N\frac{d\,\varphi}{E - R\,i} = N\frac{\tan\alpha}{E - R\,i}\cdot d\,i$$

If now we take a number of points of the saturation curve and draw tangents to these points, these tangents will be $\tan\alpha$.

If we now plot a curve of $\dfrac{\tan\alpha}{E - R\,i}$ against i, and take the area of this curve up to the value of i, we obtain t from the above equation. Assuming as an example a direct-current motor field of six poles having 1200 turns per pole, the total field resistance being 36 ohms, we have

$$t = 7200/10^8\,\frac{\tan\alpha\,d\,i}{E - R\,i}$$

The saturation curve is shown as Fig. 16. Tangents have been drawn to points on this curve and plotted against i, in Fig. 17.

The curve $\dfrac{\tan\alpha}{E - R\,i}$ plotted against i, is shown as Fig. 18. Taking areas of this curve, with planimeter the curve Fig. 19 has been drawn, plotting t against i. In this case the flux is simultaneous with the current. (See Fig. 20.)

Rise of Flux and Current with Time in an Inductive System Consisting of a Primary Coil Connected to a Constant Direct-Current Electromotive Force, and a Secondary Assuming the Same Flux Passing through Primary and Secondary

We have previously developed the current and flux time curves without secondary currents, and as the next step, we are developing the current time and flux time curves with short-circuited secondary, including the leakage both of primary and secondary magnetism.

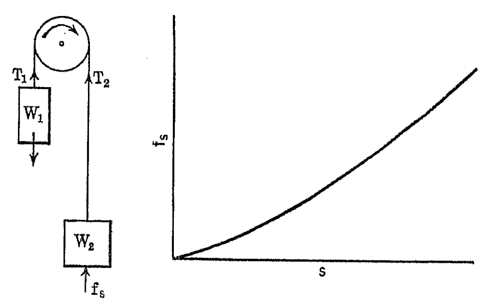

Fig. 13

In this case
Let R_1 = Primary resistance
R_2 = Secondary resistance
i_1 = Primary current
i_2 = Secondary current
N_1 = Turns in the primary coil
N_2 = Turns in the secondary coil

Electromotive Force Equations:
$$\begin{cases} E = R_1\,i_1 + N_1\dfrac{d\,\varphi}{d\,t} \\[2ex] O = R_2\,i_2 + N_2\dfrac{d\,\varphi}{d\,t} \end{cases}$$

$$i_1 = 1/R_1\left(E - N_1\frac{d\,\varphi}{d\,t}\right)$$

$$i_2 = -\,1/R_2\left(N_2\frac{d\,\varphi}{d\,t}\right)$$

$$i_0 = i_1 + N_2/N_1\,i_2 = 1/R_1\left(E - N_1\frac{d\,\varphi}{d\,t}\right) - 1/R_2\left(N_2\frac{d\,\varphi}{d\,t}\right)N_2/N_1$$

$$i_0 = E/R_1 - \frac{d\,\varphi}{d\,t}\left(N_1/R_1 + \frac{N_2^2}{N_1 R_2}\right)$$

$$d\,t = \left(N_1 + \frac{N_2^2 R_1}{N_1 R_2}\right)\frac{\tan\alpha\, d\, i_0}{E - i_0 R_1}$$

$$\text{and } t = \left(N_1 + \frac{N_2^2 R_1}{N_1 R_2}\right)\int \frac{\tan\alpha\, d\, i_0}{E - i_0 R_1}$$

if $R_1 = R_2 = R$ and $N_1 = N_2$

$$d\,t = 2N\frac{\tan\alpha\, d\, i_0}{E - Ri_0}$$

$$t = 2\,N\int\frac{\tan\alpha\, d\, i_0}{E - R\, i_0}$$

Therefore, in this case, if the secondary has the same copper section as the primary, the time for a given flux

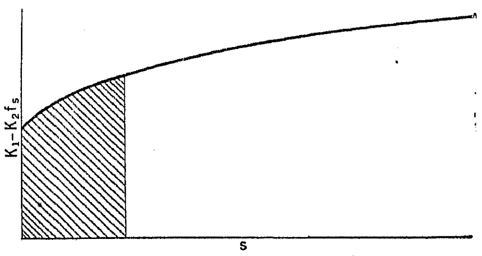

FIG. 14

is doubled. If the secondary has half the copper section of the primary, the time for a given flux is increased 50 per cent.

i_0 in this case represents the magnetizing current which is the combined primary and secondary currents.

We first plot the curve of i_0 and time, obtained as above. See Fig. 21.

Referring then to the saturation curve, we obtain the fluxes corresponding to the various values of i_0.

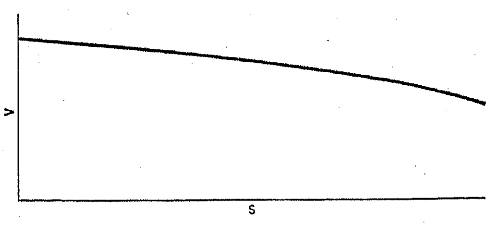

FIG. 15

The flux time curve can then be plotted. See Fig. 22.

If primary and secondary currents are wanted, we have

$$i_1 = 1/R_1\left(E - N_1\frac{d\,\varphi}{d\,t}\right)$$

and

$$i_2 = -\,1/R_2\left(N_2\frac{d\,\varphi}{d\,t}\right)N_2/N_1$$

and

$$i_0 = i_1 + N_2/_1N\, i_2$$

Drawing tangents to the flux-time curve, we obtain the values of $\frac{d\,\varphi}{d\,t}$ corresponding to various values of i_0. See Fig. 17.

Substituting these values in the above equations, we obtain the primary and secondary current-time curves. See Fig. 21.

Fig. 23 shows primary, secondary and magnetizing currents when there is mutual induction with primary and secondary magnetic leakage.

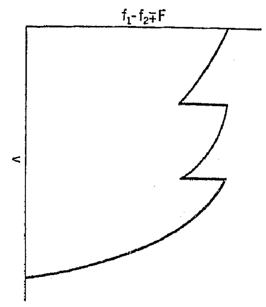

FIG. 15A

Temperature Resulting from Cyclic Operation of Elevator Motors

It is often desirable to determine the maximum temperatures attained by elevator motors in cyclic operation as in actual service. The heat generated in the running period, with a given load, is a function of velocity, and the temperature rise depends on the dissipation of heat, which is dependent on two factors; first, the difference in temperature between the radia-

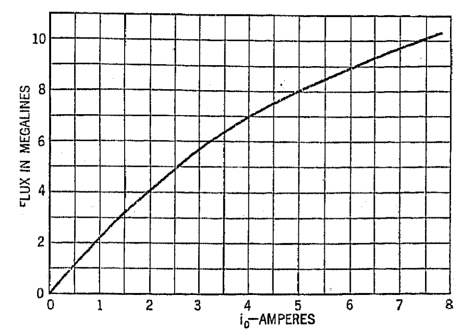

FIG. 16

ting surface and the surrounding air, and second, the ventilation, which is a function of velocity and temperature.

In this case, the motor, if suitable for the work, must have its maximum temperatures limited to proper values, and must therefore finally reach a temperature where the heat dissipated in a cycle equals the heat generated.

When the working cycles are of short duration, as they always are with elevators, it is evident that the elevator motor will not change its temperature materially during the cycle, when heated to the final balanced

condition. It is therefore practically correct to assume that the temperature of the motor is constant during the final cycle.

The following method of calculating final temperatures of elevator motors in service is based upon the above substantially correct assumption, which considerably simplifies the problem.

To Determine the Heating of the Driving Motor Resulting from Cyclic Operation

Let T_1 = final temperature rise at $t = \infty$

" T = temperature of the motor after time (t)

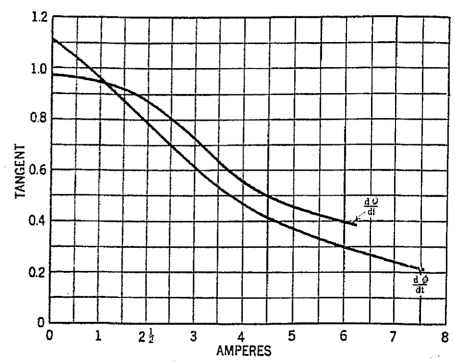

Fig. 17

" R = radiation of the motor per degree rise in temperature

" M = mass of the motor

" L = specific heat of the motor

" W = watts loss of the motor

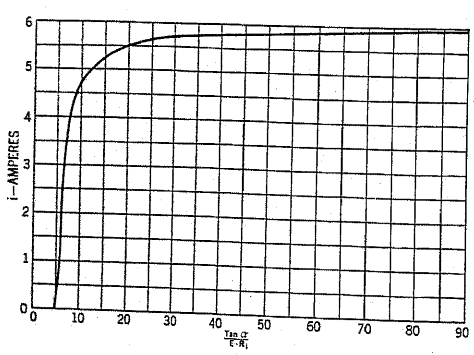

Fig. 18

Then,

$$\int_0^t W\,d\,t = \int_0^t R\,T\,d\,t + M\,L\,T \qquad (1)$$

$\int W\,d\,t$ = energy required to heat the motor to T temperature

$\int R\,T\,d\,t$ = energy radiated by motor

$M\,L\,T$ = Absorption of heat by motor

It is evident that if the motor is run until final temperature is reached, or in other words, if the above equation is integrated between O and ∞ the term $M\,L\,T$ will be comparatively small and may be neglected. Then the above expression reduces to:

$$\int W\,d\,t = T_1 \int R\,d\,t$$

or

$$T_1 = \frac{\int W\,d\,t}{\int R\,d\,t} \qquad (2)$$

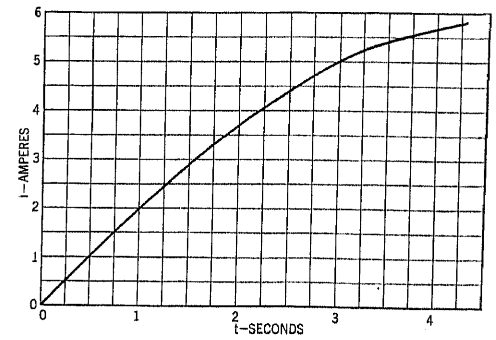

Fig. 19

Below are derived formulas for both numerator and denominator of expression (2) in terms of known values of the motor.

$$\int R\,d\,t = \int a\,[c_1 + c_2 f\,(n)\,]\,d\,t$$

Where a = radiating surface of the motor in square inches

" $f\,(n)$ = some known function of n

" C_1 and C_2 are constants depending upon the construction of the motor

" n = speed of motor in revolutions per second

$$\int R\,d\,t = \int a\,c_1\,d\,t + \int a\,c_2 f\,(n)\,d\,t$$

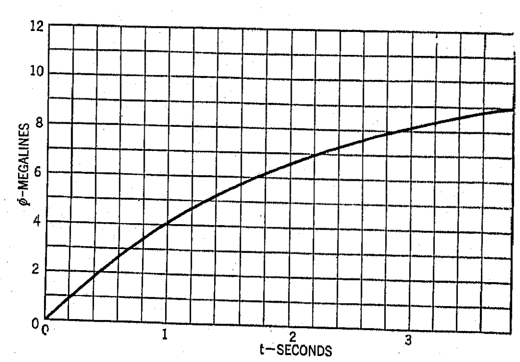

Fig. 20

But

$$d\,t = \frac{M\,K}{Q}\,d\,n$$

Where M is the equivalent mass, K is a constant and Q is the net torque of the motor, causing speed change.

Then

$$\int R\,d\,t = \int_{n_1}^{n_2} \frac{a\,c_1\,M\,K}{Q}\,d\,n + \int_{n_1}^{n_2} \frac{a\,c_2\,M\,K\,f\,(n)\,d\,n}{Q}$$

Or $$\int R\,d\,t = a\,c_1 M K \int_{n_1}^{n_2} 1/Q\,d\,n$$

$$+ a\,c_2 M K \int_{n_1}^{n_2} \frac{f(n)}{Q}\,d\,n$$

Or $$\int R\,d\,t = M K a\,[c_1 H + c_2 F] \qquad (3)$$

Where $$H = \int_{n_1}^{n_2} 1/Q\,d\,n \text{ and}$$

$$F = \int_{n_1}^{n_2} \frac{f(n)}{Q}\,d\,n$$

In order to obtain H plot a curve between n and $1/Q$ which are values obtained from test. (See Fig. 24).

The area H (See Fig. 24) between speed n_1 and n_2 is the integral.

$$\int_{n_1}^{n_2} 1/Q\,d\,n$$

In order to determine F plot the ratio $\frac{f(n)}{Q}$ against the speed n. Such a curve is shown in Fig. 25.

The area F (See Fig. 25) between speeds n_1 and n_2 is the integral.

$$\int_{n_1}^{n_2} \frac{f(n)}{Q}\,d\,n$$

Now substituting the value of $d\,t$ in the numerator:

We have $$\int W\,d\,t = \int_{n_1}^{n_2} W \frac{M K}{Q}\,d\,n$$

Or $$\int W\,d\,t = M K \int_{n_1}^{n_2} W/Q\,d\,n$$

Or $$\int W\,d\,t = M K G \qquad (4)$$

Where $$G = \int_{n_1}^{n_2} W/Q\,d\,n$$

In order to obtain G plot the ratio of W/Q against speed n. (See Fig. 26).

The area G (See Fig. 24) between speeds n_1 and n_2 is the integral.

$$\int_{n_1}^{n_2} W/Q\,d\,n$$

Substituting now the known values of $\int W\,d\,t$ and $\int R\,d\,t$ in equation (2).

We have $$T_1 = \frac{G}{a\,(c_1 H + c_2 F)} \qquad (5)$$

c_1 and c_2 can be determined as follows:

Take constant load heat tests on motor at two distinct speeds, n_1 and n_2 until final temperatures T_4 and T_2 respectively are obtained.

Determine the losses W_4 and W_2 on each test.

Substituting these values in the following formula taken from equation (2) for constant values of W and R.

Thus: $$T_1 = \frac{W}{a\,[c_1 + c_2 f(n)\,]}$$

We get $$c_1 = \frac{T_4 W_2 f(n_2) - T_2 W_4 f(n_1)}{a\,T_2 T_4\,[f(n_2) - f(n_1)\,]}$$

and $$c_2 = \frac{T_2 W_4 - T_4 W_2}{a\,T_2 T_4\,[f(n_2) - f(n_1)\,]}$$

Using test results, solve above formulas for numerical values of c_1 and c_2; substitute same in equation (5) together with values of H and F and G previously determined, and determine T_1, the final temperature rise.

Temperature Resulting from Cyclic Operation

In certain cases, where temperatures change rapidly during the final cycle, the assumption made in the previous example is not correct and the temperature change during the final cycle must be taken into account in determining the maximum temperature. Fuses and other high-temperature electrical devices are in this class.

Devices which change temperature rapidly are usually stationary, so that there is no speed element of cooling. The following example refers to stationary devices.

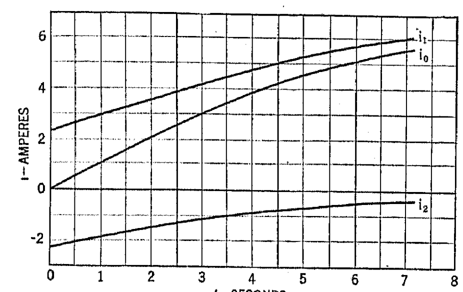

Fig. 21

Temperature Rise due to Input of Power and Dissipation of Heat

Let W = Power input

" R = Radiation constant of body

" A = Absorption constant of body

" T = Temperature of body above surrounding medium at any instant.

The general differential equation is

$$W\,d\,t = R\,T\,d\,t + A\,d\,T \qquad (1)$$

Separating the variables T and t, we get

$$(W - R\,T)\,d\,t = A\,d\,T$$

hence $$d\,t = \frac{A\,d\,T}{W - R\,T} \qquad (2)$$

W, the power input may be constant or variable. We will first consider the case where W is constant.

Case 1: W Constant.

With W constant, equation (2) may be integrated as follows:

$$d\,t = \frac{A\,d\,T}{W - R\,T}$$

$$t = A \int_{T_0}^{T} \frac{d\,T}{W - R\,T}$$

(T_0 = initial temperature)

Let $W - R\,T = Q$, then $d\,T = -\,1/R\,d\,Q$

Substituting, we get

$$t = A \int_{T_0}^{T} -\,1/R \frac{d\,Q}{Q} = -\,A/R \int_{T_0}^{T} \frac{d\,Q}{Q}$$

$$= -\,A/R \log_e Q \int_{T_0}^{T}$$

$$t = -\,A/R\,[\log_e (W - R\,T) - \log_e (W - R\,T_0)\,]$$

$$t = A/R \log_e \frac{W - R\,T}{W - R\,T_0} \qquad (3)$$

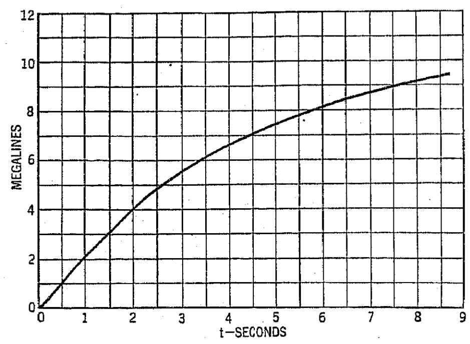

FIG. 22

$$\text{or} \quad -\,t\,R/A = \log_e \frac{W - R\,T}{W - R\,T_0}$$

$$e^{-tR/A} = \frac{W - R\,T}{W - R\,T_0}$$

$$(W - R\,T_0)\,e^{-tR/A} = W - R\,T$$

$$\text{hence} \quad T = \frac{W - (W - R\,T_0)\,e^{-tR/A}}{R}$$

$$= W/R - W/R\,e^{-tR/A} + T_0\,e^{-tR/A}$$

$$T = W/R\,(1 - e^{-tR/A}) + T_0\,e^{-tR/A} \qquad (4)$$

Case 2: W Variable—Expressable Graphically as a Function of t.

Let Fig. 27 represent the known graphical relation between W and t or $W = f\,(t)$.

Required: the relation between T and t, or $T = F\,(t)$. It is evident that this relation can only be known graphically.

Draw the known curve $W = f\,(t)$. Let the curve $T = f\,(t)$ represent the required graphic relation between T and t. Take any interval t, and divide it into n equal increments such that for each increment the input W is constant. In that case, the equations (1) to (4), which were derived for constant input, become applicable for each interval.

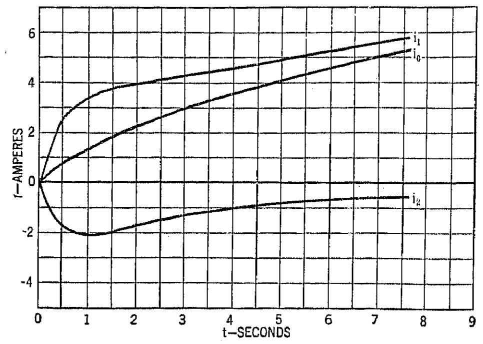

FIG. 23

Let T_0 = Initial temperature
W_0 = Initial rate of input
T_1 = Temperature after 1st interval t_1/n
W_1 = Rate of input after 1st interval t_1/n
T_2 = Temperature after 2nd interval t_1/n
W_2 = Rate of input after 2nd interval t_1/n
etc. (See Fig. 28).

From equation (4) we get

$$T_1 = W_1/R\,(1 - e^{-(t_1/n)\,(R/A)}) + T_0\,e^{-(t_1/n)\,(R/A)}$$
$$= W_1/R\,(1 - E) + T_0\,E$$

where

$$E = e^{-(t_1/n)\,(R/A)}$$

$$T_2 = W_2/R\,(1 - E) + T_1\,E = W_2/R\,(1 - E) + W_1/R\,(1 - E)\,E + T_0\,E^2$$

$$= \frac{1 - E}{R}\,(W_2 + W_1\,E) + T_0\,E^2$$

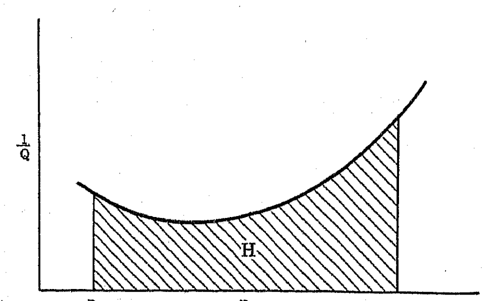

FIG. 24

$$T_3 = W_3/R\,(1 - E) + T_2\,E = \frac{1 - E}{R}\,(W_3 + W_2\,E + W_1\,E^2) + T_0\,E^3$$

accordingly,

$$T_n = \frac{1 - E}{R}\,(W_n + W_{n-1}\,E + W_{n-2}\,E^2 + \ldots\,W_1\,E^{n-1}) + T_0\,E^n \qquad (6)$$

If we let n approach infinity then the terms of the series within the parenthesis may be evaluated as follows:

The 1st term which let us call $y_0 \quad = W_n$

The nth term, $y_n = W_1 E^{n-1} = W_1 e^{-(t_1/n)(R/A)(n-1)}$
$= W_1 e^{-t_1 R/A}$

The $(\frac{1}{4} n)^{th}$ term, $y_{\frac{1}{4}n} = W_{n-\frac{1}{4}n} E^{\frac{1}{4}n} = W_{\frac{3}{4}n} e^{-\frac{1}{4} t_1 R/A}$

The $(\frac{1}{2} n)^{th}$ term, $y_{\frac{1}{2}n} = W_{n-\frac{1}{2}n} E^{\frac{1}{2}n} = W_{\frac{1}{2}n} e^{-\frac{1}{2} t_1 R/A}$

The $(\frac{3}{4} n)^{th}$ term, $y_{\frac{3}{4}n} = W_{n-\frac{3}{4}n} E^{\frac{3}{4}n} = W_n e^{-\frac{3}{4} t_1 R/A}$

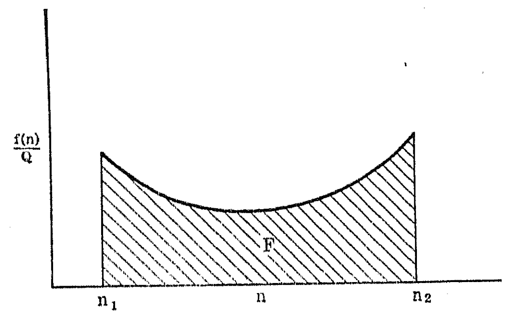

Fig. 25

Similarly, we can obtain the value of any (fraction of $n)^{th}$ term from the value of t_1 and the various values of W.

If the various terms as calculated above are laid out as y ordinates corresponding to the fractional values of t (see Fig. 29), then

$$\frac{\text{area } B}{t_1} = \text{average } y \text{ term}$$

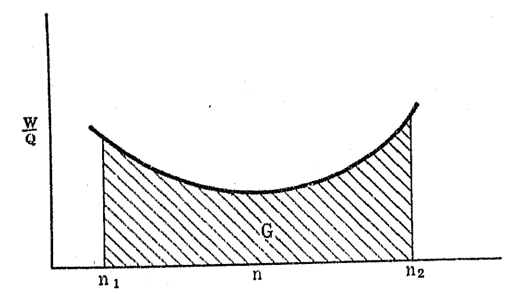

Fig. 26

The average term multiplied by the number of terms n will give the sum of the entire series in (6).

or $\qquad$ Sum of Series $= B\, n/t_1$

Substituting in (6), we get

$$T_n = 1/R\,(1 - E)\, B\, n/t_1 + T_0 E^n$$
$$= 1/R\,(1 - e^{-(t_1/n)(R/A)})\, B\, n/t + T_0\, e^{-(t_1/n)(R/A)n}$$

$$T_n = B/R\,\frac{(1 - e^{-(t_1/n)(R/A)})}{t_1/n} + T_0\, e^{-t_1 R/A} \qquad (7)$$

As n approaches infinity, the quantity

$$1 - \frac{e^{-(t_1/n)(R/A)}}{t_1/n} = \frac{1 - e^{-xR/A}}{x} = 0/0$$

$x = t_1/n = 0$

To evaluate this indeterminate expression, differentiate the numerator and denominator with respect to x:

$$\frac{d\,(1 - e^{-xR/A})}{d\,(x)} = \frac{R/A\, e^{-xR/A}\, d\,x}{d\,x} = R/A\, e^{-xR/A}$$
$$= R/A \text{ when } x \text{ approaches } 0$$

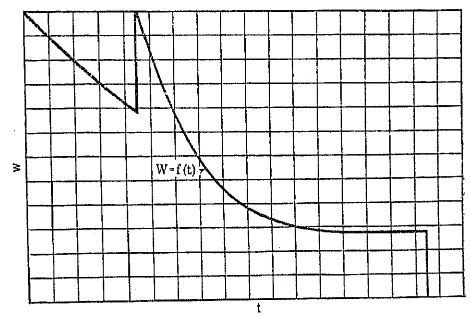

Fig. 27

Substituting in (7), we get

$$T_n = (B/R)\; R/A + T_0\, e^{-t_1 R/A}$$

$$T = B/A + \frac{T_0}{e^{t_1 R/A}} \qquad (8)$$

Combining equation (8) with equation (15), when R/A is known, but not A, we have

$$T_n = \frac{T_f\, R}{W_c}\; B/A\; \frac{T_0}{e^{t_1 R/A}}$$

$$T = B/W_c\, R/A\; T_f + \frac{T_0}{e^{t_1 R/A}} \qquad (8a)$$

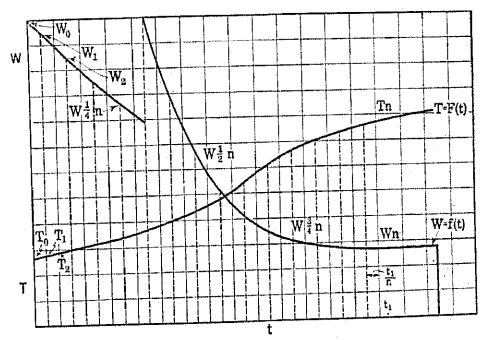

Fig. 28

Final Temperature

Assume a duty cycle of heating and cooling continued indefinitely as shown in Fig. 30. What be will the final temperature?

The final temperature will be reached when equilibrium is established. That is, when the temperature rise during the heating period t_1 is exactly equal to the drop in the temperature during the cooling period t_2 (See Fig. 31).

From equation (8) we get

$$T^1 = B/A + \frac{T_0}{e^{t_1 R/A}} \qquad (9)$$

T''' may be obtained from the differential equation of the cooling curve, as follows:

$$R\,T\,d\,t \;=\; -\,A\,d\,T \tag{10}$$

$$d\,t \;=\; -\,A/R\,\frac{d\,T}{T}$$

Integrating between the limits T' and T''', we get

$$t_2 \;=\; A/R \log_\epsilon T'''/T'$$

$$e^{-t_2 R/A} \;=\; T'''/T'$$

Hence $$T_0 = T''' = \frac{T'}{e^{t_2 R/A}} \tag{11}$$

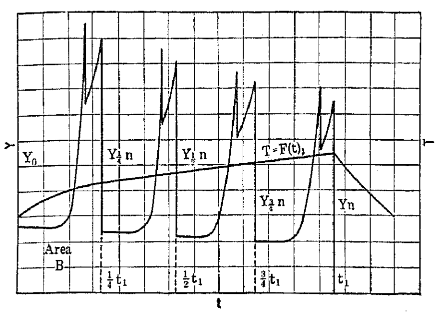

FIG. 29

From equations (**9**) and (**11**), we get

$$T_0 = B/A + \frac{T_0}{e^{t_1 R/A}}\;\frac{1}{e^{t_1 R/A}}$$

$$T_0\,e^{t_2 R/A} - \frac{1}{e^{t_1 R/A}} \;=\; B/A$$

Hence the final $$T_0 = B/A\,\frac{e^{t_1 R/A}}{(e^{(t_1+t_2)R/A} - 1)} \tag{12}$$

and the final $$T' = B/A\,\frac{e^{(t_1+t_2)R/A}}{(e^{(t_1+t_2)R/A} - 1)} \tag{13}$$

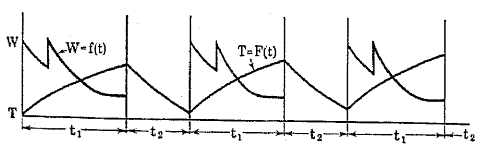

FIG. 30

If the heating cycle is repeated indefinitely *without* any intermediate cooling period, the t_2 in equations (**12**) and (**13**) equals 0.

Hence $$T_0 = T' = B/A\,\frac{e^{t_1 R/A}}{(e^{t_1 R/A} - 1)} \tag{14}$$

If the input is not in cycles but remains *constant* indefinitely then the final temperature is obtained by substituting in equation (**4**) $t = \infty$.

Hence $$T_f = W_c/R$$

or $$\frac{T_f\,R}{W_c} = 1 \tag{15}$$

Where W_c = the constant input to produce the final temperature T_f.

Note: In equations (**12**), (**13**) and (**14**) the value A may not be known. Instead only the ratio R/A may be known. In that case these equations may be combined with equation (**15**) as follows:

$$T_0 = \frac{T_f\,R}{W_c}\;B/A\;\frac{e^{t_1 R/A}}{(e^{(t_1+t_2)R/A} - 1)}$$

$$T_0 = B/W_c\,(R/A)\,\frac{e^{t_1 R/A}}{(e^{(t_1+t_2)R/A} - 1)}\,T_f \tag{16}$$

and $$T' = B/W_c\,(R/A)\,\frac{e^{(t_1+t_2)R/A}}{(e^{(t_1+t_2)R/A} - 1)}\,T_f \tag{17}$$

W_c may be in any units provided only that the same units are employed in obtaining B.

T_0 of equation (**16**) is the final temperature at the beginning of each cycle and T' (eq. **17**) is the final temperature at the end of each cycle. The maximum temperature, however, may occur between these points.

To get the maximum temperature, the entire curve $T = F(t)$ between the final T_0 and T' should be constructed as per Fig. 27.

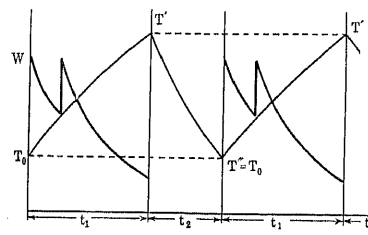

FIG. 31

The methods described in this paper have numerous practical applications. The effects of any kind of control and machine may be definitely predetermined. Different kinds of elevator apparatus may be definitely compared. Test results may be checked. Having determined the power-time curves for various distances, the power consumption of the elevator under all conditions may be accurately calculated. The complete performance of elevator apparatus in all kinds of service may be determined from basic data without special tests. Durability and dependability of apparatus may be forecast. The determination of transients is also of advantage in fixing maximum electrical and mechanical stresses and the variations of these stresses.

Since the transient curves of elevator performance tell the story of the qualifications of the apparatus for the service, any means of calculating them is of value, particularly when the calculations may be quickly and easily made, as by the methods demonstrated.

Discussion

Bassett Jones: It strikes me that the paper by Messrs. Lindquist and Yearsley presents a method of solving a very large class of differential equations of almost any order and complexity involving both continuous and discontinuous functions. The method should prove of inestimable value in mathematical engineering. As the authors have shown, the

method makes *the solution of even an unknown equation,* relating two or more variables, a practical possibility provided only that the actual physical relationship between these variables can be observed and graphically represented. It is not required that the mathematical expression for this relation be known, or if known in abstract form, it does not follow that the detail form of the expression is required.

The method makes it possible for the ordinary man who posesses the necessary instruments to solve real physical problems that lie beyond the reach of any purely analytical method, unless it be a most searching and complicated mathematical treatment. Unfortunately for rigorous mathematical methods, most of our real and pressing day-by-day engineering problems are of this type. If we adhere to the strict rules of the game, no solution is possible, for, as a very great man once said, "most differential equations take refuge in a definite integral and only rarely can these integrals be evaluated." By a very ingenious device, Mr. Lindquist has forced the integrals into the light of day where we can look at them, and measure them, and make an end of them. Heaviside did the same sort of thing by what he called algebraising the differentials. But if the equations are complicated, this method requires marked mathematical agility on the part of the worker.

Mr. Lindquist's method requires merely that the relation between the variables be measurable. To be of any real value, this relation must be measurable. Being measurable it can be properly represented in graphical form. The resulting mechanical integration of such unknown, and generally unknowable functions, will be quite as accurate as the basic data used.

The general method set forth in this paper opens a wide field for investigation that, mathematically speaking, up to the present time has remained either a closed book or subject only to the vaguest sort of approximations.

K. L. Hansen (by letter): Seven years ago the present writer presented a paper before the Institute, entitled "Analysis of Starting Characteristics of Direct-Current Motors" (TRANSACTIONS A. I. E. E., Vol. XXXVI). Although the problems of acceleration discussed in that paper did not refer specifically to elevators, they were nevertheless, in many respects, similar to those discussed by Messrs. Lindquist and Yearsley.

At that time controller engineers appeared to take little interest in analysis of the transient phenomena incidental to acceleration and retardation of electric motors. The feeling seemed to be that rough approximations based on experience and cut-and-try methods were preferable to mathematical analysis. In spite of this sentiment my belief was that interest in the mathematical predetermination of these transients would increase as the requirements became more exact. The paper under discussion indicates that this belief will be justified.

To illustrate the similarity of the problems discussed in the two papers, consider the following formula developed by the authors

$$t = \frac{M\,R}{K^2} \log \epsilon \frac{F_1 \pm F - K\,I}{F_1 \pm F - K\,i}$$

F_1 and F being constants $F_1 \pm F$ may be combined into one constant, T_c, which may be positive or negative. Also writing $\frac{E}{R}$ for its equivalent I. and transforming the equation slightly we have

$$\frac{t\,K^2}{M\,R} = \log \epsilon \frac{T_c - \dfrac{K\,E}{R}}{T_c - K\,i}$$

Expressing this in the exponential form

$$\frac{T_c - \dfrac{K\,E}{R}}{T_c - K\,i} = \epsilon^{\frac{K^2 t}{MR}}$$

and solving for i

$$i = \frac{T_c}{K} + \left(\frac{E}{R} - \frac{T_c}{K} \right) \epsilon^{-\frac{K^2 t}{MR}}$$

By inserting the proper conversion multipliers this formula is readily seen to be identical with formula (10) of my paper. Incidentally it may be remarked that when publishing a formula, which has already been derived in a previous paper, it is customary to make some references to the earlier publication.

However, while the problems discussed in the two papers are similar in many respects, the authors of the paper under discussion have mainly employed a different method of obtaining the solutions. The authors have arrived at useful and valuable results by an ingenious application of the well known method of graphical integration, but have apparently underestimated the limitations of this method and greatly overestimated its accuracy and usefulness as compared with straight analytical methods.

The classes of differential equations, which can be integrated by quadratures, as this method is called, are very limited indeed, being those of first order and first degree, in which the variables can be separated, and those of first order from which one of the variables is explicitly absent. Very few of the differential equations met with in engineering and physics belong in this group. A little reflection will show that the limitations of the method have, in fact, prevented the authors from arriving at the complete solution of the problem they proposed to solve.

To illustrate, consider the motor and elevator having the characteristic curves shown in Fig. 7 of the paper. Assume all conditions to remain unchanged, except that a considerable inductance is inserted in the motor armature circuit. As this in no wise alters the speed-torque characteristic of the motor or the friction curve of the elevator, the same speed-time curve would be arrived at by the authors' method. The fact is that this curve may be considerably modified by an appreciable change in inductance of the main circuit. Indeed, in elevator service such inductance is sometimes employed to limit the current peaks in transition from one controller step to the next, thereby effecting smoother acceleration.

The authors' statement that "the accuracy of their method is limited only by the accuracy of the instruments used in making the speed-torque tests, and the accuracy of their observation" appears therefore to be quite inaccurate. The limitation of the method itself in not being readily extended to take into account the electro-magnetic energy stored in the system is liable to introduce errors greatly exceeding the inaccuracies of observation. The limitation of the method is again illustrated by the necessity of going to a step-by-step calculation in order to take into account the primary and secondary leakage fluxes in the problem of mutual induction.

The authors state that it is comparatively easy to apply the method they describe to determine the speed-time curves when the field currents vary, but the method of procedure in that case is not indicated. It would be of interest to see the method applied, without resorting to step-by-step calculation, to a case of continuously varying field flux, as, for example, to the system of control described by Mr. Bouton in his paper, "Variable Voltage Control Systems as Applied to Electric Elevators."

Step-by-step calculations, like the method described in the paper, are found very useful in many cases when it is impossible to deduce analytical expressions for the variables involved. However, in the vast majority of cases, analytical solutions are preferable, even when certain simplifying assumptions are made in their derivation. That the authors have greatly overestimated the errors that are likely to result from such assumptions, pertaining to these problems, will become apparent by a careful study of the calculated and test curves in Figs. 6, 7, and 8 of my paper.

When the authors state that graphic methods lead to a much clearer understanding of the reasons for transient conditions, is

that statement to be interpreted to mean that they have a better understanding of these problems than one who has deduced the solutions analytically?

The expression "seriously involved" mathematics is obviously a relative term. One is likely to consider mathematics beyond one's own knowledge seriously involved. To some, the elementary calculus used in the paper undoubtedly seems like seriously involved mathematics; while to others, the application of the theory of functions to the solution of differential equations may be a simple matter. As seems to be the case with most mathematical papers, probably very few feel that the authors have used just the kind of mathematics to suit them.

E. W. Yearsley (by letter): The equation referred to by K. L. Hansen was published in the *Proceedings* of the Association of Iron and Steel Electrical Engineers in 1908 as a part of a paper on Electric Motor Drives, by E. W. Yearsley. In this paper the general treatment of systems of electric drives was outlined, both on analytical and practical bases. These equations, which are so simple as to be obvious to those who have even an elementary knowledge of physics and the calculus, were introduced in the present paper for the purpose of leading up to the graphical treatment and to call attention to the difficulties of the analytical method.

It is, of course, impossible to take into account unknown functions such, for example, as the equation of the magnetic or saturation curve in determining transients, unless either a graphical method is used or an empirical equation assumed, which approximates the function. This latter is necessary when purely analytical methods are used and the result is usually very inaccurate.

Dr. Steinmetz, in his work on Transient Phenomena, considers various magnetic problems analytically, and is compelled to resort either to the approximation of Froelich's formula or to confine himself to the basis of magnetism directly proportional to magnetizing force.

The writer has used both Froelich's and Kapp's formulas in analytical investigations of transients as long ago as 1903, but the results obtained were not sufficiently accurate. Those who have read the work of Dr. Steinmetz will appreciate the difficulties of a purely analytical treatment of magnetic transients. The purpose of the paper under discussion was to simplify the treatment of transient problems so that practical solutions could be obtained that would be of advantage in developing satisfactory apparatus for actual service.

To solve all the differential equations of electro-mechanical systems was not within our expectations, but we have obtained practical results by the methods outlined and have had no great difficulty in taking into account continually varying field fluxes.

We have been engaged in the development and investigation of transients of various sorts of electro-mechanical systems, particularly those applied to elevators, for a number of years and have investigated the operation of electric motors under many kinds of control, including the Ward-Leonard System, as described by Mr. Bouton in his paper "Variable Voltage Control Systems as Applied to Electric Motors." This system has recently come into more general favor, particularly on account of the demand for high-speed elevator equipment to be operated on alternating-current supply. It has been found comparatively easy to develop the transients of an elevator system employing this type of control.

Personally, I am interested in mathematics as a means of obtaining practical results. In this connection it does not make much difference what sort of mathematics suits various mathematicians. The means that are simplest are most attractive to those who are developing practical apparatus.

Variable Voltage Control Systems as Applied To Electric Elevators

BY EDGAR M. BOUTON
Assoc. A. I. E. E.
Section Engineer, Westinghouse Elec. & Mfg. Co.

Review of the Subject.—*Low-speed electric elevators, using d-c. motors, came into use about 1890. Later, a-c. motors were employed, but on account of the difficulty of speed control could not be used for the high speeds necessary in tall buildings. Since the height of buildings is dependent upon the elevator system, and in many districts only a-c. is available, the need for high-speed equipments that can be operated from a-c. is evident. A solution to the problem is found in the variable voltage system of control.*

In this system each elevator motor is supplied by an individual generator driven by a motor operating from the a-c. or d-c. supply voltage. The generator's voltage, and hence the elevator motor's speed, are controlled by varying the field of the generator.

The apparatus consists of:

1. *An ordinary shunt-wound d-c. elevator motor.*
2. *A d-c. generator of special design for the elevator motor.*
3. *Control panel for the generator and elevator motor.*
4. *An a-c. or d-c. motor to drive the generator.*
5. *A starting device for the driving motor*

And if the supply is a-c.

6. *A direct-connected exciter for the field, brake and control circuits.*

The control panel (1) makes the proper connections for up and down motion of the car; (2) releases, or sets, the brake; (3) controls the speed; (4) discharges the generator field during retardation, and on stopping (5) demagnetizes the generator and (6) opens the circuit between the armature of the generator and the armature of the elevator motor.

From tests the following conclusions in favor of the variable voltage over the rheostatic control system are drawn:

1. ***Speed.***—*High-speed installations are now possible for any commercial a-c. voltage and frequency.*

2. ***Acceleration and Retardation.***—*The rate of acceleration increases gradually to about half speed, then decreases uniformly until full speed is reached. The time and power required for acceleration are less than with rheostatic control. The time remains practically the same for all loads. The higher rate of acceleration and retardation permits higher speeds, and the smoothness, besides reducing wear and tear on the machinery, makes riding entirely comfortable to passengers. The impression of falling which is often given, under rheostatic control, by a heavily loaded car when descending, is inherently avoided, since the car speed follows the generator voltage which at no time changes suddenly.*

3. ***Speed Control and Regulation.***—*The speed regulation remains flat at as low as one tenth full speed. Consequently it is easier to make an accurate landing, fewer false stops are made the car may be "inched" easily and quickly. In stopping, regenerative braking is set up which brings the car quickly but smoothly to a low speed before the friction brake is applied. Positive speed control enables the limit stops to be made in less time and shorter distances, and without over-travel.*

4. ***Efficiency and Economy of Power Consumption.***—*Less power is required in acceleration and retardation. This saving of power over the rheostatic control is greatest when the number of starts and stops is large. Power is returned to the line while making the limit stops. Power consumption is not increased in making small movements of the car or in running at low speed. During idle periods standby losses may be eliminated by shutting down the motor generator set.*

5. ***Maintenance.***—*Since the switching of major currents is eliminated and they are controlled indirectly, the number of arc rupturing contacts is reduced to a minimum the control as a whole is simpler, less adjustments are necessary and maintenance costs are lowered.*

6. ***Safety.***—*Inherent safety features make higher speeds possible. Limit stops are made accurately and positively. A second independent means is provided for stopping the car in emergencies. On failure of power a dynamic braking circuit closes and a field is maintained, on the elevator motor, making certain the stopping of the car. An overspeed contact on the motor generator set opens the safety circuit independently of the speed governor.*

THE application of electric power to elevators dates back to 1890. The early motors were direct-current machines and were applied to relatively low-speed elevators. Later a-c. motors came into use, both phase-wound and cage-wound secondaries being used. Higher-speed elevators were developed as building heights increased. The modern sky scraper would not be practical except through the use of high-speed elevators. The d-c. motor and its controller were perfected for high-speed work largely because of the difficulty in controlling the speed of the a-c. motor. Until quite recently high-speed elevators invariably required the use of d-c. power.

In the last three or four years a great deal of engineering effort has been put into the problem of developing a high-speed a-c. elevator equipment. These efforts have been very fruitful and a-c. power can now be applied to elevators at as high a speed as can d-c. One of the a-c. systems that has recently been perfected is known as variable voltage. It is this system that will be described in this paper. The development of this system has also greatly improved the operation of all classes of elevators to which it has been applied and because of its superior operation and high economy has frequently been used on d-c. power lines.

During the last few years the cost of buildings and the ground upon which they are built has increased so rapidly that effective use must be made of every available square foot of floor space. The space occupied by the elevators brings in no direct income and should be reduced to a minimum. Higher car speed and reduction of lost time due to better control offer considerable help in solving this problem. Variable voltage control has been used very successfully for elevators running at speeds as high as 700 feet per minute. The system with further refinements in some details will no doubt be used for still higher speeds in the future.

I. Requirements of Elevator Service

It is not the purpose of this paper to discuss all the factors that go to make up elevator service. Elevator

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

service is, however, so affected by the kind of electrical equipment installed that in discussing any particular control system for elevator work, it will be necessary to consider its fundamental requirements. The requirements of elevator service that are affected by the electrical equipment and particularly the control may be enumerated as follows:

1. *Elevator Speeds.* The speed at which cars are run affects the service, and is very largely dependent upon the electrical equipment used and upon the control that can be obtained. Low-speed elevators require relatively simple equipment, while the maximum speed that can be used is limited by the control systems in use at the present time, and increases in speed are probably dependent upon further control developments.

2. *Acceleration and Retardation.* The rate of acceleration and retardation has a very marked effect upon elevator service, not only in so far as comfort to the passengers is concerned, but it also has a direct bearing upon the speed at which cars can be run. It is mostly dependent upon the control system and the ideal control system is one which will accelerate and retard the car at the highest possible rate, and still operate so smoothly as to subject the passengers to no discomfort.

3. *Speed Control and Regulation.* Elevator speeds in the past have increased directly as methods of increasing the speed range over which motors could be controlled have developed. No matter how high a car speed is used, the speed from which the landing can be made will remain more or less fixed. The regulation of the equipment affects elevator service because if the cars slow down too much under load the service is slowed up at the very time when maximum service is demanded.

4. *Efficiency and Power Consumption.* Electrical elevator equipment at the present time has reached a high stage of development and the matter of economy in operation probably receives more attention than in almost any other industry. Electrical elevator equipment to give good service must not only handle passengers as quickly and smoothly as possible, but it must also do it in an economical manner.

5. *Upkeep and Maintenance.* Upkeep and maintenance constitutes a considerable item in the cost of elevator service. It is, therefore, desirable that this item be kept as low as possible. It has an even more important bearing upon the continuity of service. Equipments that are easy to maintain and which are readily kept in good condition are much less subject to shutdown than those which require constant attention to keep them in operating condition.

6. *Safety.* Although this item appears last in the list it is far from being the least in importance. In fact safety is the first consideration in giving good elevator service. Any developments in control systems or apparatus which increase the service must at the same time be absolutely safe in operation, and in no case must the safety of passengers be jeopardized in order to save time or reduce the first cost of installation. Any control system having features which increase the safety with which passengers can be handled is worthy of serious consideration from that standpoint alone.

II. Description of the System

The variable voltage system consists of five main elements, a d-c. motor to drive the elevator, a d-c. generator for each elevator motor, an a-c. or d-c. motor to drive the generator, a control panel for the elevator motor and generator and a starting device for the motor driving the generator. If the supply is a-c., a direct-connected exciter is added. The auxiliary equipment, such as the car master switch, limit switches and magnet brake may be the same as those used for

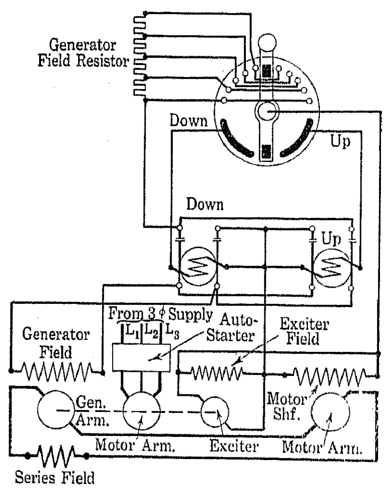

Fig. 1

Elementary diagram showing principal connections of variable voltage control system. The generator is driven by an a-c. motor and the set has a direct-connected exciter.

other well known systems of control. Fig. 1 is a schematic diagram showing how the apparatus is connected together.

1. *Elevator Motor.* The elevator motor requires no special features and is shunt wound which is the accepted elevator practise. No speed adjustment by field control is necessary although it is good practise to strengthen the field during the starting period for applications where high starting torque is required. A constant-speed motor for a given rating will have a lower weight and cost, and better electrical performance than the corresponding adjustable-speed motor.

2. *Generator.* The generator is one of the most important units of the system and is designed almost entirely from the standpoint of its control functions. As shown in the schematic diagram the motor and generator armatures are connected directly together electrically without the use of any resistors. The direction of rotation and the speed at which the elevator motor runs depend upon the direction and value of the generator voltage. The field magnet is excited from a separate source and the field excitation is governed by the controller.

The generator has commutating poles and sufficient commutator capacity to take care of the current peaks that must be handled during the accelerating period. High efficiency and good voltage regulation are incorporated as essential features. Fig. 2 shows the performance curves of a 25-kw. machine that are typical of what can be obtained. The efficiency reaches a maximum of 89 per cent and remains high with overloads so that acceleration is accomplished without excessive generator losses.

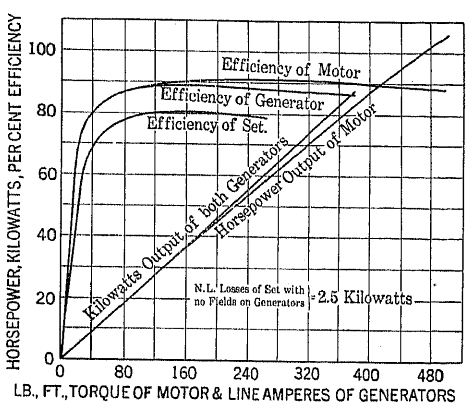

Fig. 2

Performance curves of a double generator motor generator set with an a-c. driving motor.

Fig. 3 shows a test on the rate of building up of a 25-kw. generator designed for variable voltage control service. Full excitation voltage was thrown on the field coils in one step. The machine builds up to 85 per cent of its final voltage in $1\frac{1}{4}$ seconds and in $2\frac{1}{2}$ seconds is generating full voltage. Curve 2 shows the effect of a short-circuited damper winding on the field poles. The damper winding has the effect of increasing the time constant of the field at the early stage of building up but does not materially affect the total time of

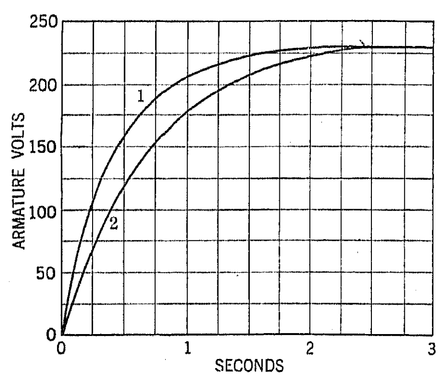

Fig. 3

Curves showing the rate of building up of generator voltage. The curves show the effect of a short-circuited damper winding on the field poles. The maximum rate of acceleration can be adjusted by changing the resistance of this damper winding.

building up. Practical use of this characteristic of the field coils can be made in giving the proper shape to the acceleration curve.

3. *Driving Motor of the Motor Generator Set.* The driving motor of the set may be either a-c. or d-c. depending upon the character of the power supply. Alternating-current motors are cage-wound and designed for low slip and high efficiency. Direct-current motors are shunt wound. It is of particular importance that the no-load or idling losses be kept as low as possible. The motor generator set whose performance curves are shown in Fig. 2 has a no-load loss of 2.5 kw. or 1.25 kw. per elevator.

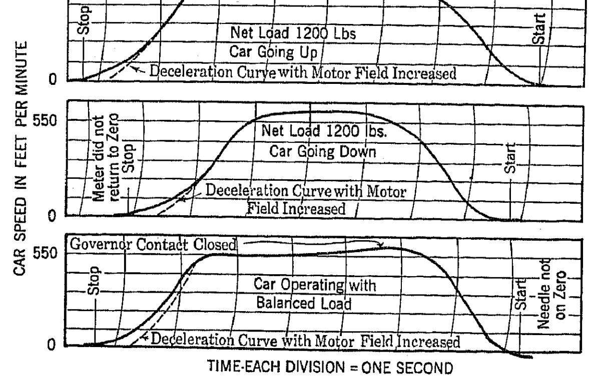

Fig. 4

Speed Time Curves for a Gearless Traction Elevator. Duty 2000 lbs. at 500 F. P. M. The dotted lines show the effect of increasing the motor field during retardation.

4. *Motor Generator Set Starter.* Since the motor generator sets are started infrequently and always start without load a relatively simple automatic starter

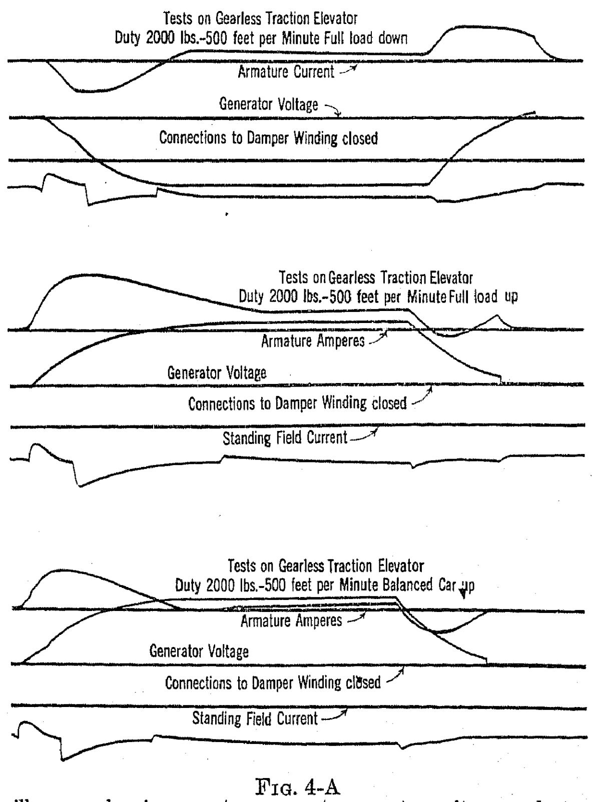

Fig. 4-A

Oscillogram showing armature current, generator voltage, and standing field current.

may be used. For d-c. motors a counter e. m. f. starter with two or three steps of light duty starting resistance is used. The only special feature required

is a counter e. m. f. relay interlocking with the elevator controller to prevent energizing the generator field and brake circuits when the motor generator set is not running or before it has come up to speed. For the a-c. sets a resistance type starter is used. Alternating-current sets have a direct-connected exciter and a switch controlled by the voltage of the exciter is used to short circuit a step of primary resistance when the motor has come up to speed. No interlocking relays are required since there will be no voltage to energize the d-c. circuits unless the motor generator set

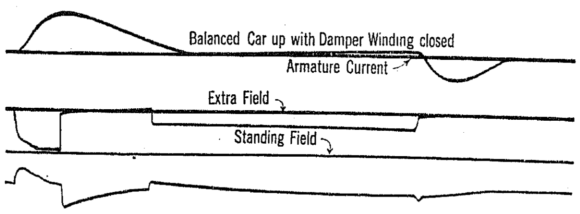

Fig. 5
Oscillogram showing armature current and current in extra and standing motor fields.

is running. Reverse phase protection is inherent in the combination without the use of relays because the exciter being a self-excited machine will not build up its voltage if the motor generator set is started in the wrong direction.

5. *Elevator Controller.* The elevator controller proper carries the contactors and relays to perform the following primary functions:

1. Connect the generator field to the excitation

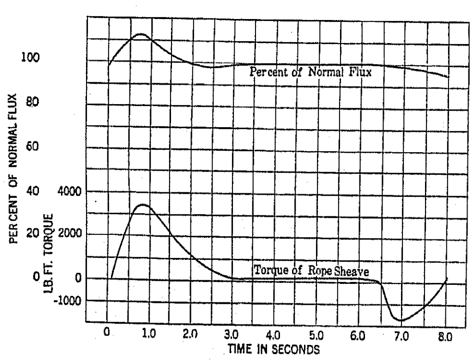

Fig. 5A
Curves showing motor field flux and torque.

voltage in the proper direction for up or down motion of the car.

2. Energize the brake coil. The brake coil is opened on both sides and is fed through the same contactors that energize the generator field.

3. Control the car speed by controlling the excitation of the generator field.

4. Provide the proper discharge circuits for the generator field during retardation.

5. Connect in an extra demagnetizing field on the generator in stopping.

6. Open the connection between the generator and elevator motor after the car has come to rest.

7. Control the setting of the brake by means of its own self induction and so obtain a smooth stop.

There is only one contactor carrying armature circuit current. This contactor is included as an additional safety measure and in normal operation opens only after the car has completely stopped and the brake has set. It also opens immediately when the safety devices, such as the car emergency switch, overspeed governor, etc., operate. In normal operation no current is ruptured by this contactor. The other contacts on the controller handle only field, brake and control circuit currents. When the armature circuit contactor opens its back contacts close a low-resistance dynamic-braking circuit for the elevator motor. This contactor has auxiliary contacts through which the brake coil

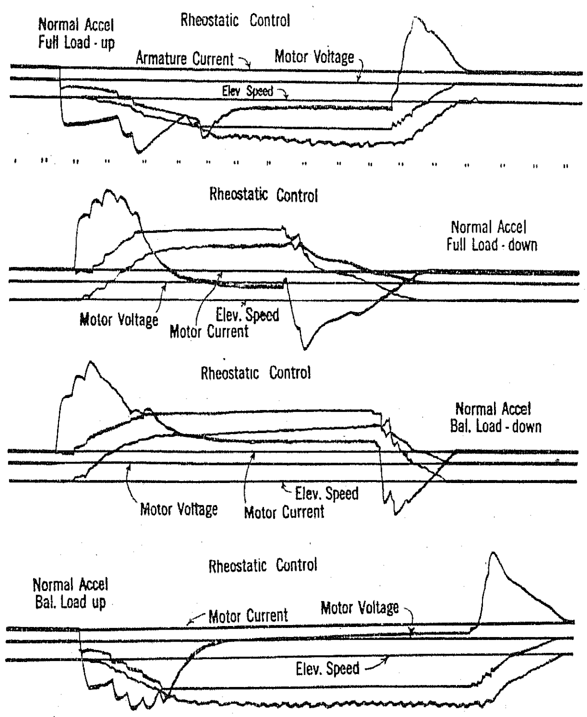

Fig. 6
Accelerating characteristics of a gearless traction elevator with rheostatic control.

current passes so that the brake cannot be released unless the armature circuit is closed.

III. Characteristics and Operation

1. *Acceleration and Retardation.* To obtain maximum service from an elevator car it should be accelerated and retarded at as high a rate as possible without discomfort to passengers. The uncomfortable feeling frequently experienced while riding in high-speed elevators is not due to a high rate of acceleration but to rapid changes in the rate of acceleration. Therefore the rate of acceleration should not change suddenly during the accelerating period.

When a fully loaded car is to be accelerated in the down direction the weight of the unbalanced load alone is sufficient to accelerate the car. Under a system of rheostatic control, if the motor is now connected to the line with a resistance in series with its armature, the

voltage impressed on the armature will be reduced only by a flow of positive current in the resistance current flowing to the motor from the line being regarded as positive; current returned from the motor, acting as a generator, to the line, as negative. This current if it passes through the motor armature would increase the accelerating torque to a value which would be very uncomfortable to passengers. It is therefore customary to connect resistances in parallel with the motor armature so that a voltage drop can be produced in the armature series resistance and retard the acceleration. This is very uneconomical and accomplishes the desired result imperfectly so that it is quite a common experience to ride in cars which give one the sensation of falling when descending heavily loaded.

The acceleration is considerably affected by the load and there is a considerable difference in the shape of the speed-time curves obtained with different loads. With full load up the car accelerates too slowly and with full load down the acceleration increases too rapidly for comfort. The rate of acceleration increases very rapidly when the motor is first connected to the line and when each step of resistance is short-circuited.

With variable voltage control it is possible to obtain more uniform accelerating and retarding characteristics under widely varying load conditions. The generator voltage builds up uniformly, following a fixed law and the car speed follows the generator voltage. The torque developed by the motor may be either positive or negative depending upon the load, but the speed in all cases depends upon the voltages generated by the machines.

If the car is to be stopped from high speed in a minimum of time, the maximum rate of retardation must be maintained during nearly the whole retarding period. When the controller handle is moved to the low-speed point resistance is connected in series and parallel with the generator field. The field shunt or discharge resistance can be adjusted if the generator field has the proper time constant, so as to give the car exactly the right rate of retardation. As the field dies down the generator voltage falls below that of the elevator motor and regenerative braking brings the car to a low speed. The generator voltage falls with absolute smoothness and there are no steps as in the case of rheostatic control. The application of dynamic braking in steps produces peaks in the rate of retardation that tend to cause the cables to slip so that the average rate of retardation must be kept well below the peaks. The absence of these peaks makes it possible to keep the average rate of retardation very high.

Electrical or regenerative braking is used to bring the car to a very low speed from which the final stop can be made with a friction brake. The transition from electrical to friction braking is perfectly smooth as a result of the characteristics of the electrical system and the method of controlling the friction brake.

The friction brake is a very important factor in making a smooth stop. It does not help matters much to have the retardation perfectly smooth if the final stop produced by the brake is rough or if the car slides a considerable distance after the brake sets. Electrical braking will reduce the speed of the car to a low value but except under certain load conditions will not bring it to a complete stop. It is, therefore, only necessary to apply the brake in such a manner that an abrupt change in the rate of retardation is not produced.

The distance that the car will slide when the friction brake sets is given by the formula:

$$d = (K_1 M_1 + K_2 M_2) \frac{V^2}{T_B + T_L} \qquad (1)$$

See appendix for symbols.

Equation 1 shows that the slide of the car when the brake sets varies as the square of the speed and inversely as the net torque exerted by the brake. The net torque developed by the brake is the algebraic sum of T_L and T_B. The torque of the load T_L assists the brake to stop when the load is positive or is being hoisted. It acts against the brake when the load is being lowered and increases the slide. The velocity of the car at the time when electrical braking becomes ineffective, however, has the greatest effect on the distance the car will slide through the brake since the slide varies as the square of the velocity. It is evident therefore that for minimum slide the car speed should be as low as possible before the friction brake is called upon to stop it.

To avoid a jar when the final stop is made there should be a smooth transition from the retardation produced by electrical braking to that developed by the friction brake. To accomplish this result it is necessary to apply the friction brake gradually so that full braking torque is not exerted instantly. The brake must be designed and adjusted so as to stop the car smoothly both when stopping from full speed and when stopping from creeping speed.

When stopping from full speed the brake should not set until the car has been slowed down to a low speed by electrical braking. When stopping from low speed the brake should set in a very short time after the control handle is thrown to the off position but the torque should build up gradually so as not to produce a jar. The most practical means of controlling the setting of a d-c. brake is to utilize the self induction of the brake coil in such a way that the flux is maintained in the magnet cores and retards or opposes the action of the brake spring in developing braking torque.

With rheostatic control in which the motor armature is disconnected from the line in stopping it is difficult to obtain good brake action and very careful adjustment must be maintained. If the time element of the brake is made long enough to make the action smooth with light loads the slide will be excessive with full load down and loads in the up direction may drop back several inches before the brake can take hold and bring the car to rest. With variable voltage control the armature

circuit is not opened immediately in stopping. When the controller handle is moved to the off position the generator shunt field is disconnected from the line and the generator voltage becomes practically zero. Since the line between the generator and motor armature is not broken, sufficient current will circulate to hold the car firmly under control while the brake sets. The control of the flux in the brake core is obtained with suitable contacts on the control panel and on the brake itself. After the brake has set and the car stopped, the contactor in the armature circuit is opened to eliminate circulating currents that might be produced by residual magnetism of the generator.

Tests were made on a gearless traction elevator rated 2000 lb. at 500 ft. per min., equipped with variable voltage control. The motor generator set consisted of an a-c. driving motor, a variable voltage generator, and a direct-connected exciter. The tests were made with the generator voltage adjusted to give a car speed of 550 ft. per min. with balanced load. The car was started by moving the master controller directly to the full-speed position in starting and stopped by moving directly to the off position. Fig. 4 shows the speed-time curves obtained on these tests. The curves were drawn by a graphic meter which recorded the voltage generated by a magnet driven from the shaft of the elevator motor.

Fig. 4A shows oscillograph records of armature current, generator voltage, and current in the standing field of the motor. The motor also has an extra or starting field which is connected to the line for starting. This increases the total field during the first part of the accelerating period, giving a high starting torque. During the last part of the accelerating period, the generator field is overexcited, in order to maintain a high rate of acceleration. The current in the standing field shows rapid changes in value, but due to its self inductance and to the mutual inductance between this field and the extra starting field the resultant change in flux is small and takes place quite slowly. Fig. 5 shows the currents in the two motor fields and Fig. 5A shows the resultant flux and motor torque. The action of these two fields is discussed more fully later.

The torque developed by the motor is proportional to the product of the armature current times the field flux. As shown by the curves the motor current and torque increase at a uniform rate during the first half of the accelerating period and decrease at a uniform rate during the last half. The rate of change of acceleration is proportional to the rate of change of motor torque and is determined by the tangent or slope of the curve. The speed time curves show that the rate of acceleration increases uniformly as the car starts and reaches a maximum at approximately one half speed. Above half speed the rate of acceleration decreases uniformly as the car comes up to speed. The time required to reach full speed is less than two and one half seconds and is practically the same for all loads.

The retardation curves have the same general characteristics as the acceleration curves. The time required to stop from full speed is very nearly the same for all loads. In practise this uniform retardation under all load conditions makes it possible for car operators to gage the stops very accurately in stopping from high speed and so reduce the number of false stops and time lost in making landings. A dotted portion of the retardation curves is added to show the effect upon retardation of increasing the total field by the addition of the extra field.

Fig. 6 shows the results of tests similar to those shown in Figs. 4 and 5 but made on a gearless traction elevator with rheostatic control. The curve of armature current shows notches as the steps of the starting resistance are short-circuited. These changes in the armature current correspond to changes in motor torque and in the rate of acceleration. The same notches are apparent as the dynamic braking resistance is short-circuited. These rapid changes in the rate of acceleration and retardation make it difficult to obtain smooth

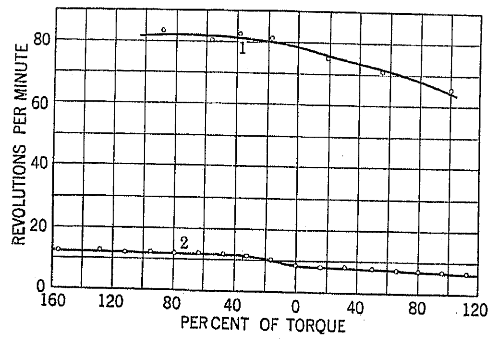

Fig. 7

Speed torque curves of gearless traction elevator motor at full speed and at low speed with variable voltage control.

and comfortable operation. The speed time curves are less uniform than those shown in Fig. 4 and show more variation in time for different loads.

Experience has proved that variable voltage control is smoother in operation than the older system and that passengers can be handled more comfortably and quickly.

An analysis of the test data shows the following reasons for these results:

1. The rate of acceleration increases uniformly as the car comes up to speed and is not subject to rapid changes such as are produced by increasing the armature current in steps.

2. The time required to reach full speed is reduced.

3. The accelerating time and retardation time is constant for all conditions of load.

2. *Regulation and Speed Control.* The speed at which elevator cars can be run depends very largely upon having a system of control that will give a positive low speed for making landings which does not fall off appreciably under load. Fig. 7 shows a test on an

equipment operating on reduced generator voltage. The speed is reduced to 1/10 of full speed at no-load and only falls slightly below this value when hoisting a load. With overhauling load the speed remains low. This flat regulation at speeds as low as 1/10 of full speed makes it possible for the operator to have complete control of the car under all loads.

In elevator work it is entirely practicable to operate the motor over this speed range, or greater, by control of the generator field. Fig. 3 shows the speed at which the generator fields can be changed. The generator field can be varied over such a wide range that very little field control on the motor is necessary. Motor field control,

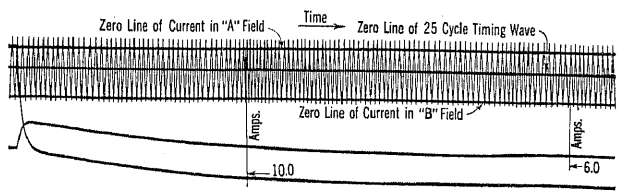

FIG. 8

Oscillograph records showing the rate of change of field currents of a low-speed elevator motor.

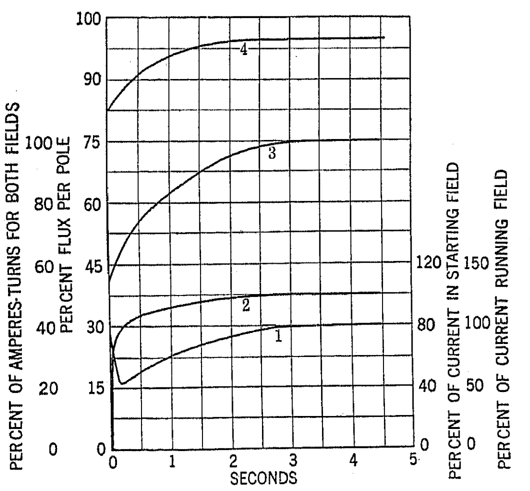

FIG. 9

Curves derived from the oscillograph tests shown in Fig. 8. The curves show the time required to change the motor speed by field control.

if used for any considerable speed range, requires a very large motor. With large low-speed machines it is not practicable to use a very great range of motor field control because of the slowness with which the field flux changes.

Fig. 8 shows oscillograph records of the field control of a gearless traction elevator motor. The motor has two field windings known as the running or B field and the starting or A field. With both fields energized the motor runs at 50 rev. per min. and with the starting field disconnected at 65 rev. per min. The curves in Fig. 8 shows the current in the running or B field with the motor at full speed and the current in the starting or A field when it is connected to the line to slow the motor down to 50 rev. per min. The current builds up quite rapidly in the A field but the current in the B field is reduced by the mutual inductance between the field coils.

Fig. 9 shows derived curves of the combined ampere turns of both field coils and the resultant field flux. Curve No. 4 shows that it requires approximately 3½ seconds for the field flux to reach its final value and

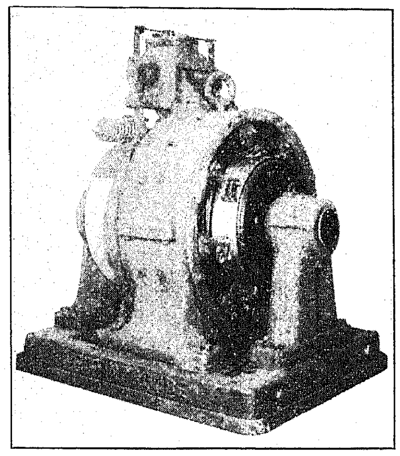

FIG. 10

Photograph of gearless traction elevator motor on which the tests shown in Fig. 8 were taken.

change the motor speed from 65 to 50 rev. per min. In practise an elevator must be retarded and stopped in from 1½ to 2 seconds so it is quite obvious that the full-speed range of this machine cannot be utilized. It is doubtful if a speed range greater than 10 or 15 per cent is practicable for this class of elevator motor. A machine of this type is illustrated in Fig. 10.

Armature series and shunt resistance gives inherently

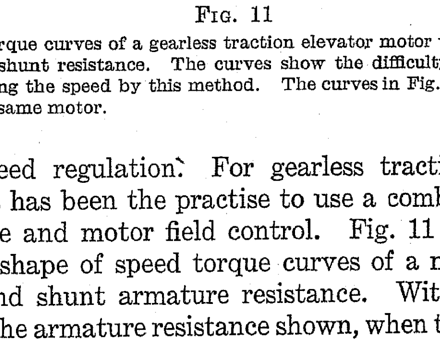

FIG. 11

Speed-torque curves of a gearless traction elevator motor with armature series and shunt resistance. The curves show the difficulty encountered in controlling the speed by this method. The curves in Fig. 7 and Fig. 11 are for the same motor.

poor speed regulation. For gearless traction equipments it has been the practise to use a combination of armature and motor field control. Fig. 11 shows the general shape of speed torque curves of a motor with series and shunt armature resistance. With a motor having the armature resistance shown, when the no-load

speed is reduced to 25 per cent of the full-speed value the motor torque is reduced to 70 per cent at stand still. This means that the motor will not have sufficient torque to hoist full load on this controller point, except by some automatic adjustment of the armature resistance. Considerable complication has been introduced in the control to make it possible to lift full load to the top floor. With overhauling loads it is difficult to make the speed low enough to obtain accurate stops. At best the speed range is quite limited and large currents are drawn from the line when operating on the low-speed points.

The method of speed control by varying the generator voltage shows considerably better speed regulation and a greater range than the other two methods. This is clearly shown by comparing the results shown in Fig. 7 and Fig. 11. In practise this better control results in the following advantages for the variable voltage system.

1. It is much easier for the operator to land accurately at the floors and the number of false stops are reduced.

2. The car may be "inched" to the floor level very accurately and quickly in case the operator does not stop accurately the first time.

3. The limit stops can be made in a minimum distance and without loss of time or over travel with all loads.

4. Elevators may be run at a higher speed than is possible with rheostatic control.

3. *Efficiency and Power Consumption.* The factors that affect the power consumption of an elevator are so many and varied that it is extremely difficult to predict what it will be for a new installation. The more important factors are as follows:

(a) Load and speed.

(b) Number of stops and starts per mile of travel.

(c) The number of miles per hour that the car makes while in service.

(d) The weight of the moving masses that must be accelerated at each start.

(e) Method of operation.

A large number of tests have been made in which the cars are operated on a fixed schedule with different loads and the power consumption measured. These tests are useful in making comparisons between different equipments but do not give accurate information for determining the power consumption in actual service where the cycle of operation may be quite different. Different operators handle the cars in different ways and this will have an effect on the power consumption. In actual operation considerable power and time may be wasted in the following ways:

(a) Acceleration and retardation for every start and stop.

(b) Inching the car to correct for inaccurate stops at the landings.

(c) Running at reduced speed when the cars are ahead of their schedule. (With rheostatic control).

(d) Making the limit stops.

(e) Long idle periods in which the standby loss in the motor field and motor generator sets uses up power. (With variable voltage control).

The power required to drive the elevator at full speed is usually considerably less than that used up in the items enumerated above. The distribution of the power losses will depend very greatly upon the system of control used.

Fig. 12 shows a typical cycle for a high-speed elevator with variable voltage control operating with the average

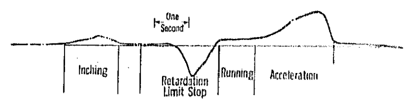

FIG. 12

Power cycle of high-speed elevator with variable voltage control tested with balanced load. The chart was made by a graphic wattmeter.

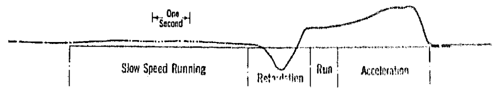

FIG. 13

Power cycle of high-speed elevator with variable voltage control tested with load. The chart was made by a graphic wattmeter.

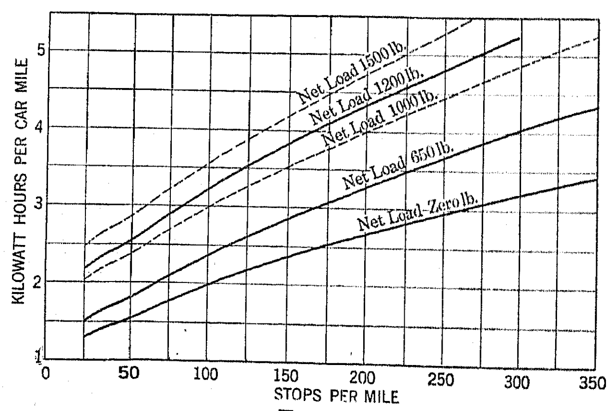

FIG. 14

Energy consumption tests of gearless traction elevator with variable voltage control. Duty 2000 pounds at 500 feet per minute.

or balanced load. The power input is greatest during the accelerating period, and falls off to a very low value as the car comes up to speed. During retardation the power becomes negative and is returned to the line. The effect of inching the car is shown directly following the retarding period. The maximum is only 25 per cent of that required during acceleration. This does not mean that the elevator motor does not develop sufficient torque to move the car promptly. On the contrary the current flowing in the generator and elevator motor circuit is high enough to develop full-load torque or greater but since the generator voltage is quite low the actual power input is also low. Fig. 13 shows a similar cycle but with a loaded car and shows a

period of low-speed running. In this case the power at low speed is ⅓ of that required to run at full speed.

A series of tests were made on a gearless traction elevator having a duty of 2000 pounds at 500 feet per minute and equipped with variable voltage control. Fig. 14 shows the energy consumption in kilowatt hours per car mile plotted against stops per car mile. With balanced car and 125 stops per mile the energy consumption is 2.2 kilowatt hours per mile. The energy consumption shown includes all the power taken from the line.

Fig. 15 shows a test made on an elevator having a capacity of 2500 pounds at 600 feet per minute with rheostatic control. Fig. 16 shows a similar test on the same motor with a smaller sheave and variable voltage control operating at 550 feet per minute. With balanced load and 50 stops per mile the energy consumption is 2.2 kilowatt hours for both equipments. At 150 stops per mile the energy consumption is 3.6 kilowatt hours per mile for the variable voltage equipment and 5.2 kilowatt hours for the rheostatic. While the two

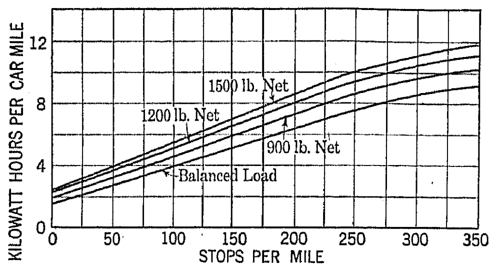

Fig. 15

Energy consumption tests of gearless traction elevator with rheostatic control. Duty 2500 pounds at 600 feet per minute.

motors are not working under exactly the same conditions the slope of the curves gives a fairly good comparison between the two systems of control.

From an analysis of the load curves and the test data we can draw the following conclusions:

1. The variable voltage system requires less power for acceleration and retardation because of the absence of rheostatic losses and because of the power returned to the line during retardation.

2. Very little power is taken from the line to make small movements of the car due to the low generator voltage.

3. Low-speed running does not increase the power consumption.

4. Power is returned to the line while making the limit stops.

5. The greatest gain in economy will be shown where the number of starts and stops is large.

6. Long rest periods will cause waste of power if the motor generator sets are left running. This waste can be eliminated by shutting down the motor generator set through a start and stop push button station which may be located at a point accessible to the starter or mounted in the car.

IV. Safety Features

Elevators have a number of devices which protect the passengers riding in the car. I shall discuss only those that are affected by the control system.

1. *Limit Stops.* An elevator control system should be so designed that the car will be slowed down and finally stopped as it approaches the terminal landings. In order to be sure that the car platform will come flush with the top and bottom landings under all conditions of load, the stop contact on the slow-down device must not open until the car has reached the floor level. It is preferable that the point of cut-off be a few inches beyond the floor level so that the operator will not form the habit of depending entirely upon the automatic device for making the stop. It is necessary then, when the car reaches the cut-off point, that it be slowed down to a low enough speed so as not to drift further than the distance provided for over travel. If the car runs by the over-travel limit switch it is not possible, with the usual connections, to back out and the assistance of an attendant is necessary to put the car into service again. To stop a fully loaded car within the usual over-travel distance has always been a considerable problem with rheostatic control because of the extremely poor regulation of the motor when operating at reduced speed with armature series and shunt resistance. The characteristics of the machine operating under these conditions have already been discussed. Refer to Fig. 11.

A switch is mounted on the car having contacts actuated by an arm and roller which engages a cam in the elevator shaft. As the car approaches the top and bottom landings these contacts operate to insert steps of resistance in the generator field, in the variable voltage system, which reduces the voltage. The car speed reduces with the reduction of voltage due to the regenerative braking that takes place until, as the landing is approached, the car is running at very low speed.

The inherent regulation of the variable voltage system makes it possible to slow down a fully loaded car in almost the same distance as an empty car. It is possible to stop the car at the terminal landings under all conditions of load within one inch of the same spot. The positive action of the automatic slowdown at the limits of travel greatly increases the safety of operation. The automatic slowdown and stop at the terminal landings is one of the elements in the system of safety devices provided for the elevator and it is important that it function properly.

2. *Emergency Stop.* When making normal stops with the regular controlling means such as the car master switch or the automatic limit stops, the generator field is reduced to zero which sets up regenerative braking in the elevator motor which slows it down. At the same time the friction brake sets which brings the car to rest. To provide against failure of the master switch contacts to function or a failure of the regular stopping cycle the car is equipped with the usual

emergency switch. This switch opens the armature circuit contactor which disconnects the elevator motor entirely from the generator and connects it to a low-resistance dynamic braking circuit. The coils to the brake contactors are opened and the brake circuit itself is also opened by auxiliary contacts on the armature contactor. This arrangement gives two entirely independent means of stopping the car and is an advantage over the older forms of control in which the emergency switch forms only an additional means of opening the same contactors that disconnect the motor in regular operation.

3. *Failure of Power*. The failure of the main power supply on a large system is a comparatively rare occurrence, but failure of power from some cause to elevator motors has been a rather frequent source of trouble. Failure of power to an elevator may be due to (1) failure of the main power supply to the building, (2) the opening of the main circuit breaker in the building, (3) opening of the circuit breaker or blowing a fuse in the line feeding the elevator. I shall analyze the result of a power failure under several conditions and discuss means for taking care of the condition.

When the motor is operating under positive load, that is when hoisting an unbalanced load, there is no particular danger from power failure as the car will stop of its own accord in a comparatively short distance. The condition of balanced or overhauling load presents a more serious problem. Let us consider first the case of overhauling load produced by a fully loaded car going down. Consider first the case of a d-c. motor controlled by armature series and shunt resistance and motor field control. With overhauling load the motor is operating as a generator and returning power to the line and is kept at constant speed by the supply voltage. The contactor magnets on the controller are energized from the supply voltage. If now the power source is cut off by an opening of the circuit breaker in the line to the motor, the reservoir into which the motor has been delivering its power will have been disconnected and the motor and car will overspeed. There will be no warning to the operator that the power has failed until the car has reached a considerable overspeed, probably high enough to trip the safety clamps under the car. The control magnets will be kept energized by the voltage generated in the armature of the elevator motor so that the dynamic braking circuits will not be set up or the friction brake disconnected until the overspeed governor driven by the car has opened its contacts. In other words, there is nothing to start the functioning of the control to stop the car until there has been an actual overspeeding of the car. After the control has functioned to stop the car the friction brake will be called upon to make most of the stop since the electrical braking will be rendered more or less ineffective due to the dying field of the elevator motor. Control schemes have been developed to connect the field of the motor to the armature so as to maintain the excitation. In some cases the motors have been equipped with special fields for this purpose. Such schemes are only partially successful and the principal difficulty is to initiate the functioning of the control before the car has reached considerable overspeed. In special cases the control circuits have been connected through auxiliary contacts on the circuit breaker.

Alternating-current squirrel-cage elevator motors that use a separate winding which must be excited from the supply line have no means of obtaining regenerative braking when power fails and the friction brake alone must stop the car.

Consider next the case of an elevator motor driven through an motor generator set with an a-c. driving motor and having either one or two generators. The motor generator set comprises a small direct-connected, self-excited generator to furnish d-c. excitation to the generator and motor fields, brake and control circuits. In case of overhauling load the elevator motor is acting as a generator, the generator end of the motor generator set is acting as a motor, the motor of the set acts as an induction generator and is running above synchronous speed. It should be kept in mind that the elevator motor is generating a voltage higher than its terminal voltage due to the drop in the windings. For the same reason the generator, acting now as a motor, is generating a counter voltage lower than its terminal voltage by the value of its internal drops.

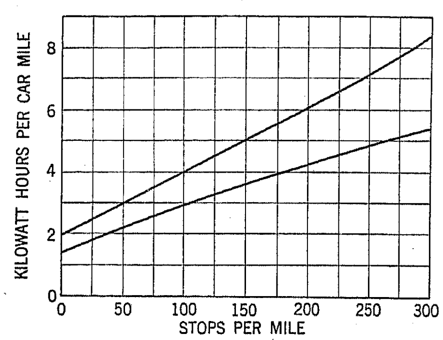

FIG. 16

Energy consumption tests of gearless traction elevator with variable voltage control. Duty 2500 pounds at 550 feet per minute.

When the circuit breaker opens the energy that is being developed by the descending car is expended in accelerating the motor generator set which speeds up until the generator voltage equals the voltage generated by the elevator motor, the internal drops reducing to a very low value. The result will be an overspeed on the set of 15 or 20 per cent above synchronous speed. The motor generator set is equipped with an overspeed device which opens a contact in the safety circuit of the elevator controller that sets the friction brake and sets up the emergency dynamic braking circuit. The motor generator set is now running free at overspeed and due to its inertia runs for several seconds before the direct-connected exciter

loses its voltage. The field of the elevator motor is connected directly to the exciter so that a strong field is maintained for dynamic braking long enough to bring the car completely to rest before the exciter loses its voltage. The same cycle is performed when the driving motor of the set is a d-c. machine. The only difference is in the connections of the field of the elevator motor which are such that the counter e. m. f. of the driving motor maintains the excitation on the elevator motor field. Tests have shown that the car is stopped promptly and without over travel when a power failure occurs while making the limit stops.

4. *Overspeed.* The cars are equipped with the usual overspeed governor which performs the usual functions of first slowing down the car by field control, opening the safety circuit and finally setting the wedge clamp safety under the car. The overspeed contact on the motor generator set acts as an additional factor of safety as it opens the safety circuit independently of the speed governor. It can be set to open its contacts before the governor trips and so stop the car entirely by means of the electrical and friction brakes, saving the inconvenience and loss of time in releasing the wedge clamp and resetting the governor before the car can be moved to the nearest landing.

IV. Maintenance

The upkeep of equipment is one of the factors that go to make up the cost of operating electric elevators. Large buildings usually employ someone who is competent to care for and maintain the elevator equipments. Such buildings usually have excellent elevator service and experience little trouble from shutdowns and delays. At the other extreme we find buildings in which no regular help is employed for this purpose and elevator maintenance consists of periodic inspection for which service contracts are often let.

Maintenance of the electrical equipment consists mainly of inspection, cleaning, making adjustments, oiling and installing renewal parts. The first three items involve labor costs only, while the last two items involve both labor and material. It should be the desire of every building owner to purchase equipment on which he can reduce the last three of these items to a minimum.

The art of designing rotating machinery has advanced to a point where maintenance is merely a matter of routine. Elevator machinery is usually installed in comparatively clean places so that insulation trouble is comparatively rare. The elevator cycle is such that machines which are designed to have the proper operating characteristics seldom reach, in actual service, the maximum temperature rise which they are guaranteed to stand. The use of commutating poles has made it possible to design high-speed d-c. machines that will commutate heavy-current peaks with practically no sparking. The present accepted standard of commutation is that the commutators shall improve their appearance, in actual operation. Bearings, oiling systems and general mechanical design have been developed to a high degree of perfection.

Elevator controllers have in recent years reached a high state of development but there is one inheren condition that has made the maintenance problem more difficult. I refer now to the rupturing of heavy currents in starting and stopping the motor and in performing other control functions such as changing speeds. A contactor in elevator service is rupturing heavy currents continuously and the arc produced when the circuit is opened is bound to burn away the contacts. Considerable improvement has been made in recent years in the method of rupturing arcs, such as the use of arc splitters, and improvements in the design of the magnetic blowout. The use of rolling contacts has considerably improved the life of the contacts themselves.

It is quite probable that these details are now pretty well standardized and that little improvement can be expected along this line. The next step is to eliminate the rupturing of major currents altogether and to control them indirectly. This is accomplished by switching only the field current of the generator, which, as its voltage changes, controls the elevator motor. The equipment can be so designed that the maximum current ruptured by the controller is not more than five amperes. From the standpoint of maintenance this results not only in an increased life of the contacts themselves but in reduced cost of renewal parts, since the contactors are much smaller in size than if they had to handle the motor current directly. The elimination of heavy arcs reduces the burning of other parts and the chances of damaging flashovers. The acceleration and retardation is governed by the characteristics of the generator field and does not depend to a great extent on adjustment of relays and contactors so that the controller requires very little attention to keep it in good operating condition.

Another item that has an effect upon the maintenance of elevators is the wear and tear on machinery incidental to severe service. The life of the cables and the wear on gears are both affected by the control equipment. High-speed geared elevators develop backlash in the gears and this is aggravated by the notching of the ordinary controller. Sharp peaks in the retardation torque have a tendency to cause slippage of the cables and reduce their life. Fig. 5 shows the smoothness of acceleration and retardation and the absence of abrupt changes in motor torque. This smoothness will result in longer life and less maintenance cost of the mechanical equipment.

V. Conclusion

In the foregoing part of this paper I have attempted to describe the variable voltage system of control as applied to electric elevators and to set forth the characteristics and operation obtained. In conclusion

I shall summarize its principal advantages for elevator work as compared with older systems.

1. Elevators running at the highest speeds may be driven from a-c. supply lines of any commercial voltage and frequency.

2. The acceleration and retardation are perfectly smooth and uniform.

3. A high rate of acceleration and retardation is obtained which permits the use of high car speeds and increased elevator capacities.

4. Positive speed control under all conditions of load makes it easy for operators to land the car accurately without loss of time.

5. High economy of power is obtained.

6. A number of inherent safety features make it particularly suitable for high car speeds.

7. Maintenance costs are reduced to a minimum and the reliability of service increased because of the simplicity and flexibility of the system and because no large currents are ruptured in operation.

Appendix

Symbols used in equation (1).

M_2 = Moment of motor armature.

V = Velocity of the car.

T_B = Torque developed by the friction brake.

T_L = Torque developed by the load.

K_1, K_2 = Constant.

Discussion

K. L. Hansen: Because of the fact that the inherent speed-torque characteristic of the induction motor makes it less suitable than the direct-current motor to applications where masses of considerable inertia have to be accelerated and retarded at frequent intervals, the application of alternating-current power to certain classes of elevators presented a formidable problem. It appears that the system of control described in Mr. Bouton's interesting paper was first thought of in connection with elevators as a solution to this problem.

However, it is evident from the paper that, even when considered purely from the standpoint of control, the system must have shown some very desirable characteristics in operation, as it has frequently been extended to cases where conversion from alternating to direct current is not the object, that is to elevators on d-c. power lines.

It has long been recognized, but has of late become much more forcibly impressed upon us, that in motor applications where the starts and stops are frequent, control of acceleration by means of resistors in the armature circuit is extremely wasteful of energy, and there is consequently a general tendency to devise more economical methods of control in such cases. Application of the system described in the paper to elevators where d-c. power is available is obviously in line with the general trend towards greater economy.

Another general trend in the evolution of control apparatus is to control transient conditions, such as acceleration and retardation of motors by continuous electromagnetic changes inherent in the machines, rather than by mechanical changes, such as switching operations in the main circuits. In this respect, the system described appears to be ideal, the switching operations of the main circuit having been reduced to a minimum. The advantages of having the acceleration controlled by a continuous change in the generator field flux are also clearly set forth in the paper as being smoothness of operation and reduced maintenance cost.

However, while the system is thus seen to possess some very marked desirable features, there are some drawbacks. The total machine capacity required is more than three times that required for the elevators themselves. This, of course, refers to capacity and not to physical dimensions, as the motor-generator set is undoubtedly relatively much smaller than the elevator motor, being operated at much higher speed. But even at best, the necessary additional machine capacity is undeniably a serious drawback. Furthermore, the losses in the additional machines, especially the standby losses, offset to a considerable extent the efficiency gained during acceleration and retardation.

It, therefore, becomes of interest to determine whether or not it is possible to devise a system which will materially mitigate these drawbacks and at the same time retain the most desirable features. I believe this is possible, and will briefly describe a proposed system and submit it for comments and criticism. The system is shown as applied to direct current only, the conversion being accomplished by other means when the supply is alternating current. It will first be described in combination with a three-wire supply line as the connections are then simplified somewhat.

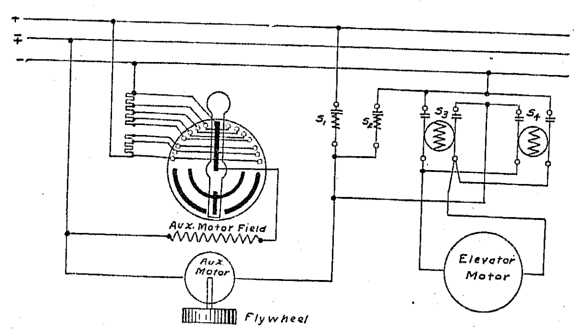

Fig. 1

For the sake of simplicity the diagrams show only the distinguishing features, omitting those common to other systems, such as the main disconnecting switches, the circuits energizing the magnet switches, the field circuit of the main motor, etc.

Referring to Fig. 1, it will be seen that the system employs an auxiliary motor, with a flywheel to increase the inertia of its revolving parts. In the standstill position switches S_1, S_3 and S_4 are open and switch S_2 is closed. The auxiliary motor is running at normal speed between neutral and negative line. The auxiliary motor starter, being of the usual type, has been omitted from the diagram.

To start the elevator S_2 is open and S_3 or S_4 (according to whether the motion is up or down) is closed, thus inserting the main motor in series with the auxiliary motor between neutral and negative line. Continued movement of the controller handle weakens the auxiliary motor field, and as the inertia prevents its armature from speeding up rapidly, sufficient current flows to accelerate the main motor armature.

When the auxiliary motor field has been reduced to zero the main motor is running between neutral and negative line at approximately half voltage and speed. Up to this point the auxiliary motor has absorbed energy, its e. m. f. being in opposition to the line voltage and its speed has therefore increased somewhat. Further movement of the controller handle reverses the auxiliary motor field and gradually strengthens it. The auxiliary motor now acts as generator, and by reducing its speed, gives up the energy which was previously stored. Its induced

e. m. f. is now in the same direction as the line voltage and therefore boosting this, so that the voltage impressed on the main motor continues to increase.

When the auxiliary motor field reaches full strength in the opposite direction its speed will have been reduced to approximately normal and its voltage added to the line voltage is approximately equal to the voltage between the outside main lines. The voltage of the main motor, being of approximate equality to the main line voltage, switch S_1 can be closed, making each machine run independently of the other, the main motor between the outside lines and the auxiliary motor between neutral and positive line. The switch S_1 is so connected and adjusted that it closes only when the controller handle is in running position and the main motor voltage bears a certain ratio to the line voltage.

To stop the elevator the operations are reversed by moving the controller to standstill position. During retardation the auxiliary motor voltage adjusts itself so that a regenerative current flows and a breaking torque is produced practically down to standstill.

It is obvious that the rate of acceleration and retardation follows a fixed law, precisely as in the system described by Mr. Bouton, if the controller is moved at once to the full running position in starting and to the off position in stopping. Equally, the rate of acceleration may be regulated by varying the resistance of a damper winding on the auxiliary motor field. Furthermore, the main current adjusts itself to retain approximately this rate under widely varying load conditions from large positive to negative or overhauling loads.

The acceleration and retardation curves and the speed-time curves when running at low speed can all be determined by mathematical analysis, but cannot be included in this brief discussion.

The current rating of the auxiliary motor depends on the relative amount of time consumed in acceleration and retardation and full speed running. At most it is equal to the current rating of the main motor, and as it is wound for one-half voltage its capacity is at most one-half that of the main motor. In case of d-c. power line the additional machine capacity is therefore less than one-fourth of that required with the control described in the paper. The losses, especially the standby losses, are, of course, correspondingly reduced.

Even when the supply is alternating current, the additional machine capacity and the losses can be materially reduced by using the auxiliary motor control and a synchronous converter for conversion from a-c. to d-c. current.

Fig. 2 shows the principal connections when the supply is a two-wire d-c. power line. In this case the main motor has two armature windings and two commutators connected in series during acceleration and retardation and in parallel when running at full speed. The switches S_1 and S_2 are double-pole. S_3' and S_4' always open and close simultaneously with switches S_3 and S_4 respectively. With these modifications the sequence of switching operations is the same as before and the operation is essentially the same as in the case of the three-wire system already discussed.

E. M. Claytor: Referring to Fig. 5A in Mr. Bouton's paper, it may appear that the maximum rate of acceleration would occur earlier than it actually does because the peak torque is reached in ¾ second after the start, while the maximum rate of acceleration does not come until one second after zero time. The rate of acceleration is proportional to the net torque available for accelerating the total equivalent mass having linear velocity. The curve in Fig. 5A is somewhat misleading in as much as it is labeled "Torque of rope sheave" which might be taken to mean net torque on the ropes for acceleration. As a matter of fact this curve is the total torque at 1 ft. radius (developed by the motor armature) divided by the radius of the driving sheave.

The net torque is what is left of the torque curve in Fig. 5A after the torques due to the brake, bearing friction, bending of cables, and sliding friction have been subtracted. This difference is represented by curve 2 in Fig. 3 shown herewith, and it is the true net torque used only for acceleration. The peak of this curve comes at the same time at which the maximum rate of acceleration occurs in Mr. Bouton's Fig. 4 for balanced load, *i. .,e* where the slope of that curve is steepest. Curve 1 shows the car speed as taken from balanced load curve in Fig. 4. Assuming that this acceleration curve is correct, we derive Curve 2, which is the net accelerating torque, in the following way.

Pick out some point, say at 1½ seconds, where we may assume that the brake and static friction have reduced to zero, and draw a tangent as accurately as possible to the acceleration Curve 1.

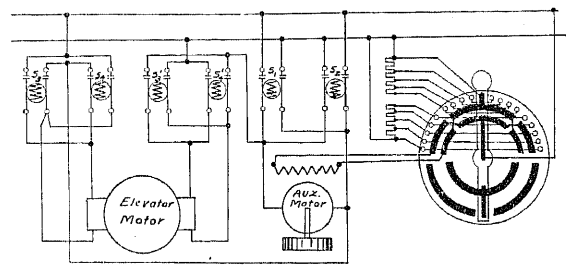

Fig. 2

Next take the total motor torque at 1½ seconds and from it subtract the running friction torque of 460 lb. as obtained from a total torque curve (not shown) at some point corresponding to 3 or 4 seconds. The difference will be 2200 lb. which is the net torque for the point on acceleration curve corresponding to 1½ seconds.

We now have the rate of acceleration, and the torque which produces that rate. The unknown quantity is the equivalent mass having linear velocity. This we obtain from the simple formula—

$$M = \frac{T \times 32.2}{a \times R}$$

Where, M = lb. mass having linear velocity.
T = torque in lb. at 1 ft. radius

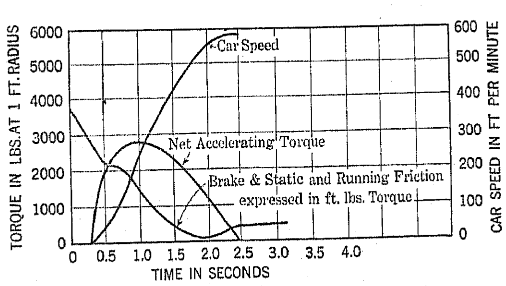

Fig. 3

R = radius of driving sheave in ft.
a = rate of acceleration in ft. per sec. per sec.
and 32.2 = gravity acceleration constant.

The equivalent mass in this case was 11,350 lb.

After determining the mass, we rearrange the same formula above as follows—

$$T = \frac{M \times a \times R}{32.2}$$

By substituting known values of M, by previous calculation, R, by measurement, and a, by drawn tangents to the graphic test curve, we can solve for T which is the net torque Curve 2 in the sketch.

Having determined that component of the total torque curve which is used only for accelerating the balanced car, we subtract that from the total torque curve and we have Curve 3 left. This latter curve represents all friction or anti-torque. We know from other oscillograph tests that the brake reduces its torque to zero in 0.6 second. This means that the static friction is about 2000 ft-lb. at the start and it does not reduce to zero until a point corresponding to $1\frac{1}{2}$ seconds. This indicates that the driving sheave and shaft have made more than a complete revolution before the static friction becomes zero.

The dip in the friction Curve 3 cannot be explained except by considering that oscillations or hunting occurs between accelerating torque and friction torque, or else the graphic meter had enough inertia in moving parts to overshoot the actual speed.

From the above analysis, we may draw the conclusion that

(a) An appreciable amount of power is wasted in friction during acceleration.

(b) A quick-acting brake on the pick-up is desirable.

(c) Anything done to reduce static friction will reduce the current and power peaks of the elevator motor.

W. F. Eames: In an effort to obtain what might be considered a perfect acceleration curve for an elevator, a number of curves have been analyzed, and although the results contain considerable speculation they are of interest in connection with the subject just discussed. It will be necessary first to define perfect acceleration and then to analyze the elements. Any remarks made in connection with acceleration apply in general equally well to retardation, as retardation may be considered as negative acceleration. Consequently we will consider only acceleration, and treat retardation as a special case.

Perfect acceleration as applied to elevators might be defined as that which will bring an elevator up to speed in a given time without discomfort to the passengers. Assuming that the speed of an elevator can be made to follow any curve in going from zero speed to full speed, some method must be used to select the best one. The problem of comfort to a passenger seems to be tied up psychologically in some measure with the idea of falling. That is, if the motion of the car is such as to suggest falling, a feeling of discomfort is produced. Falling is concerned with a high rate of acceleration especially a high rate suddenly applied, which corresponds to a high rate of change of acceleration. The continuous curve that represents values between zero and a maximum has necessarily an S shape and most of them can be represented by some combination of the powers of X in the general equation y = function of x.

Several curves have been plotted from equations of the form

Velocity $= K_1 t^2$ (Parabolic)

" $= K_1 t^2 - K_2 t^3$ (cubic)

" $= K_1 t^2 - K_2 t^4 + K_3 t^6$ (cosine)

and were all found to lie very close together, and to the eye showed no points where noticeable difference will be felt if an elevator were accelerated along any of them. Plotting the first and second derivaties the parabolic curve showed the highest accelerating rate and the lowest rate of change of acceleration. The cubic equation gave the opposite conditions and the cosine lay between.

Various observations indicate that the high rate of change of acceleration is more objectionable than a high rate of acceleration. If this is true the parabolic form is the most desirable of the three functions. It was also found that the variable-voltage elevator acceleration lies very close to the parabolic form at balanced car conditions and when lifting full load departs only slightly from it. Fig. 4A herewith shows the velocity curve for the variable voltage elevator rated at 2000 pounds at 550 feet per minute that has just been discussed by Mr. Bouton. The dotted curve shown in the same figure is a parabolic curve, that passes through the zero, mid-point, and full speed values of the velocity curve. Figs. 4B and 4C. shows the first and second derivatives, or the acceleration and rate of change of acceleration. The maximum acceleration is (7.5 ft./sec.)^2 and the maximum rate of change of acceleration is (6.4 feet/sec.)^3. As the operation of the car is very comfortable with the conditions shown, higher accelerations can be used than these shown and it is probable that with the variable-voltage system of control that a car can be accelerated to 650 to 700 ft./min. in $2\frac{1}{2}$ seconds without discomfort to the passengers. In this connection, however, it should be mentioned that as the rates of acceleration are increased other limiting factors appear in addition to the discomfort felt by the passengers. For example, slipping of the cables on the driving sheave occurs if the retardation rate is too great. This decreases the life of the cables. Also larger equipment is required when these high rates are used, than is required with the lower ones. This point becomes important especially when the elevator cab and other parts have a large inertia.

The above considerations apply equally well to retardation of the elevator. However, the rates used in retardation can be somewhat higher than those used in acceleration without causing discomfort. The reason for this is probably that a greater sense of security is felt because the car is slowing down. Although no extended experiments have been tried it has been found that, if a person shuts his eyes, much less discomfort is felt in an elevator using high rates of acceleration. If maximum rates are to be demanded in the future, it may become necessary to take steps

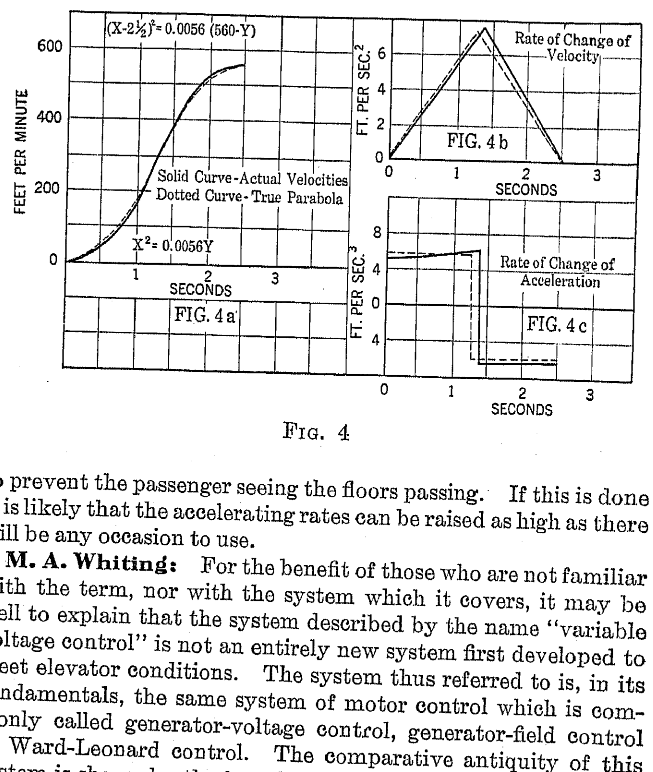

Fig. 4

to prevent the passenger seeing the floors passing. If this is done it is likely that the accelerating rates can be raised as high as there will be any occasion to use.

M. A. Whiting: For the benefit of those who are not familiar with the term, nor with the system which it covers, it may be well to explain that the system described by the name "variable voltage control" is not an entirely new system first developed to meet elevator conditions. The system thus referred to is, in its fundamentals, the same system of motor control which is commonly called generator-voltage control, generator-field control or Ward-Leonard control. The comparative antiquity of this system is shown by the fact that it helped sink the Spanish fleet off Santiago de Cuba in 1898. Merely as an indication of the extent to which this system is now used it may be mentioned that, over a period of 16 years, one manufacturer has built, or is now building, for steel-mill and mine-hoisting service alone, over 70 equipments totaling over 110,000 h. p. The corresponding totals for the other manufacturers covering these items and a complete list of other classes of service to which this system has been applied would also be impressive.

The new development presented in Mr. Bouton's paper is, therefore, not the fundamental system of "variable-voltage" or generator-voltage control itself but is rather the extensive application of this system to elevators. The problem, or the accomplishment, should not be belittled, however. Some of the previous practise in the application of generator voltage control

could be followed but some special problems were presented by the requirements of elevator service, and it has, therefore, been necessary to devise new practises.

One of the principal problems is that of speed regulation over the range of loads handled, which is discussed by the author under "Requirements of Elevator Service" and under "Characteristics and Operation." Attention is called particularly to the author's Fig. 7. The speed regulation shown on the low-speed controller point is much closer than is obtainable with any practicable rheostatic machine and provides a correspondingly

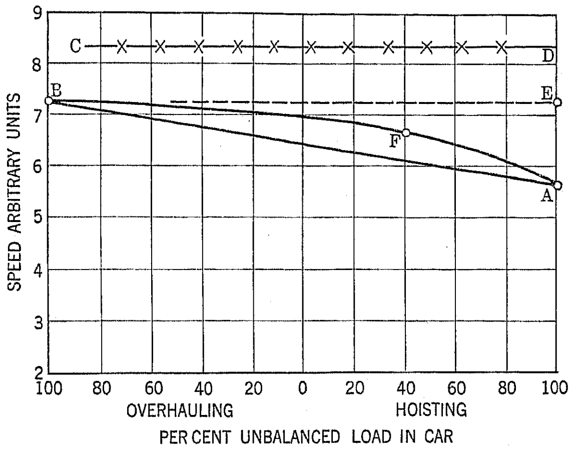

Fig. 5

greater ease of control in making landings. However, let us examine the author's Fig. 7 more closely. As the results are given in per cent of motor torque, an interpretation is required. It is reasonable to assume that 100 per cent positive torque corresponds to the hoisting of an elevator load not exceeding normal capacity; then when lowering the same elevator load, the motor torque will be not less than 60 per cent negative. The speed at 100 per cent load is about 6½ rev. per min. and at 60 per cent negative load is about 11½ rev. per min., or about a 75 per cent rise in speed from full load "up," to the corresponding load condition "down." If this speed regulation curve could be made flat at all loads, this would be found very useful in attaining a still greater ease of control for making landings.

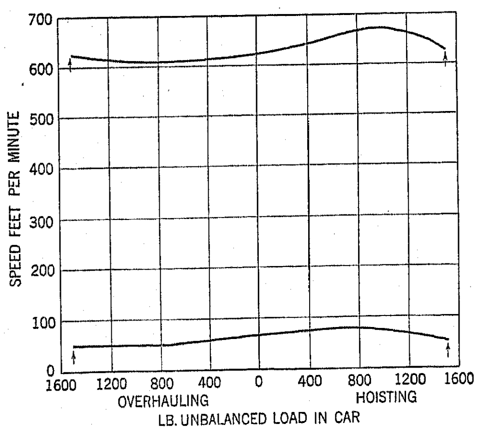

Fig. 6

On the full-speed point, the regulation shown by the author's Fig. 7 is from 64 rev. per min. at 100 per cent load to 82 rev. per min. at 60 per cent overhauling load, or a rise of 28 per cent. Let us consider further just what such a speed regulation at full speed means in the operation of an elevator.

Fig. 5 herewith shows a speed regulation curve for a hypothetical gearless elevator plotted to per cent unbalanced load in the car. The speed regulation (28 per cent rise from full load hoisting to full load overhauling) is assumed to be the same as that in the author's Fig. 7. The speed curve may be considered to be bow-shaped, as in the author's Fig. 7, but I believe that a nearly straight inclined line from *A* to *B* is equally typical, particularly if an extra contact on the speed governor is not used to operate within this speed range. Line *C-D* represents the speed at which the overspeed governor will set the safety clamps. It is commonly considered that the margin of speed, *B-C*, between maximum overhauling speed and the final emergency operation of the governor, should be not less than 15 per cent in terms of speed *B*. Let us assume also that the elevator rides comfortably and can be controlled without difficulty when overhauling at speed *B*. Now if a speed as high as *B* is suitable in all respects when thus lowering maximum load, a speed as high as *B* is also equally suitable when operating at balanced load or when hoisting full load; in other words, if speed *B* is right, a speed curve *B-E* is right.

The advantage of a flat speed-regulation curve, as *B-E*, will be greatest on express elevators during the rush hour going in. If the load goes up at speed *A*, and the empty car comes down (against the overbalance of the counterweight) at speed *F*, the average speed up and down will be only 85 per cent of the permissible speed *B*. Allowing about 30 per cent standing time and 70 per cent running time for rush-hour express operation, the loss of service per elevator due to the poorer regulation, compared with perfect regulation, is about 11 per cent.

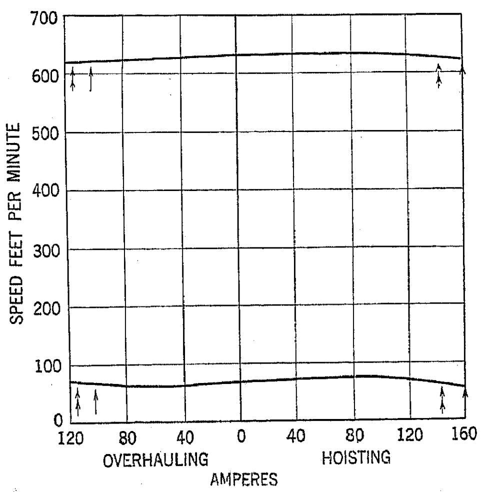

Fig. 7

In order to provide the maximum service possible from an equipment of a specified maximum overhauling speed, and also in order to obtain further improvements over previous equipments in ease of handling the elevator, an improvement in generator-voltage control has been developed by which regulations are obtained which approach closely the ideal which I have just described. I intend to prepare a technical paper in the near future covering this development, but some of the results are presented herewith.

Fig. 6 herewith shows results obtained on the first commercial installation embodying this development, the elevator being rated 600 ft. per min., 2500 lb. live load and counterbalanced for 40 per cent of the live load (maximum unbalance 1500 lb.). On the first or lowest speed point, the speeds at maximum load hoisting and maximum load overhauling are equal at 50 ft. per min., and the prevailing speed over the entire range of overhauling loads is actually *lower*, as an average, than over the range of hoisting loads.

On this same equipment, in Fig. 6, the full speeds at maximum load hoisting, at balance and at maximum load overhauling are

equal at 625 ft. per minute, and the overhauling speeds are lower, on the average, than the hoisting speeds.

Further developments of this system have been made and embodied in equipments of more recent manufacture. A shipment of three such equipments was made after only routine factory tests on the individual parts of the equipment; the machines were placed in successful commercial service promptly, without difficulty and without personal assistance from headquarters.

At the first opportunity, extensive factory tests were made on an equipment in accordance with these further developments. Numerous proportions and adjustments were studied, and a typical set of adjustments gave results as in Fig. 7 herewith. Since predictions may differ as to the mechanical losses in an elevator installation beyond the traction-motor armature, the results in Fig. 7 are given in amperes, as taken. If the mechanical efficiency is assumed as 80 per cent, the rated load of the elevator is represented by 160 amperes hoisting and 102 amperes overhauling. Or, on an assumed mechanical efficiency of 90 per cent, the corresponding loads will be 142 amperes hoisting and 115 amperes overhauling. On the former basis, when hoisting full load on the first speed point, the speed is 55 ft. per min. and when lowering full load, the speed is 67 ft. per min., an increase of only 12 ft. per min. at full load overhauling. On the basis of the higher mechanical efficiency, this regulation is even closer. If, on this regulation curve a horizontal straight line is drawn at 65 ft. per min., the speed at nearly all positive loads is slightly *above* and at nearly all negative loads is slightly *below* this average line. For all practical purposes, therefore, the speed regulation on the first speed point is flat over the entire range of loads.

The regulation on the full-speed point for the equipment in Fig. 7 (assuming 80 per cent mechanical efficiency, which is the less favorable case) is from 615 ft. per min. at full load hoisting to 620 ft. per min. at full load overhauling. The maximum speed, 630 ft. per min., occurs at balanced load and various heavier loads going up. The significant speed regulation is therefore 1 per cent, from full load up to full load down.

After this equipment (as in Fig. 7) is installed, results of its operation in actual service will be presented in the paper which I intend to prepare. In that connection, the system of control will be described and explained.

J. J. Matson: In Figs. 14 and 16 Mr. Bouton shows results of tests to determine elevator power consumption with various loads and stops per car mile. As the curves are obtained from tests the power consumption undoubtedly contains the motor-generator losses only during the period of test. Assuming this is true, the results greatly favor the variable-voltage control system. By this, I mean that if the power consumed, the stops made, the miles traveled and the average elevator load for one day were measured and the kilowatt hours per car mile calculated, the result obtained would be higher than is given in Mr. Bouton's curves. The reason is apparent if one stops to consider the actual cycle of operation for an elevator which consists of some time running, and some time standing (Includes time required for receiving and discharging passengers). During the standing time, which may be as high as 50 per cent of the total, the motor-generator set will surely be running and taking power. This power would, of course, be shown in the all-day run but when a test was run for power consumption, the running-idle losses of the motor-generator set would not be included as the elevator would be operated continuously until sufficient readings were taken to obtain the power-consumption values. The best way to compare power consumption for variable-voltage and rheostatic controlled elevators is on an all-day basis. Even under such conditions, the variable-voltage control shows the lowest power consumption, the saving increasing as the stops per mile increase.

A great deal of importance has been attached to elevator power consumption by all interested parties. In reality this is not borne out by a careful consideration of all factors. For example, assume a 20-story building having a hatch 7 ft x 6 ft. and the floor space renting for about $3.00 per sq. ft.; the elevator to cost $18,000; the actual charges then become on a yearly basis:

Rentable floor space occupied by elevator............	$2520
Interest depreciation, insurance, etc., (15%)...........	2700
Operator's salary..................................	750
Maintenance, etc..................................	300
Spare parts, re-roping, etc..........................	350
Power bill (20 miles per day, 2.5 kw-hr. per car mile, 300 days per year and 2c. power................	300
Total....................................	$6920

Thus, the power bill is the small part of the total yearly elevator bill, approximately 4.0 per cent.

Fig. 11 shows the regulation on a rheostatic-controlled elevator motor. The regulation between 100 per cent motor torque and 64 per cent generator torque (this assumes a mechanical efficiency of 80 per cent) is approximately 63 to 83 rev. per min. or 31.8 per cent. Tests on an elevator which has been installed about 18 months, show the speed regulation (without centrifugal speed governor) to be as follows: 100 per cent motor torque 64.5 r. p. m. Zero torque 62.0 r. p. m., and 64 per cent generator torque 68.5 r. p. m. This is regulation of 6.2 per cent. It is interesting to note that full-speed acceleration was obtained in about 3¼ seconds and with perfect comfort to passengers.

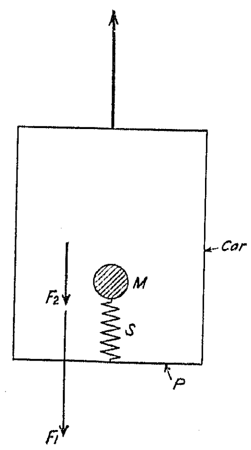

FIG. 8—THE GRAVITATION FIELD IN AN ACCELERATING ELEVATOR CAR

Bassett Jones: I want to add something to Mr. Eames' discussion of Mr. Bouton's paper. The fact that the most suitable time-velocity characteristic of a passenger elevator is a reversed parabola may be deduced directly from the mechanics of the passenger's body. This I have already discussed in "The Time-Velocity Characteristics of High Speed Passenger Elevators," *General Electric Review*, P. 111, February 1924.

In Fig. 8 shown herewith the mass, M, represents the mass of the passenger's body. The spring, S, represents the elastic elements of his bodily frame. If the car be standing still or traveling at any constant velocity, the force F_1 acting on M and causing a compression of S is the gravitational field of the earth. If the car accelerates on the up motion or retards on the down motion, a force, $F_2 = M\,a$, is added to F_1 and the spring is further compressed. If the car accelerates on the down motion or retards on the up motion, the force F_2 is deducted from F_1 and the spring expands.

Obviously if this force, F_2, is applied or removed suddenly as by constant acceleration, the resulting shock to the passenger's body will be uncomfortable. Therefore, it should change from zero to a maximum, and from a maximum to zero in some

gradual manner, and it seems reasonable to suppose that if this change be constant, the best conditions will result.

This requires that the *rate of change in acceleration* (or retardation) *be a constant*, that is,

$$\frac{d\,a}{d\,t} = p,$$

where p may be called the *physiological constant.* Therefore, if S be distance,

$$\frac{d^3\,S}{d\,t^3} = p \qquad (1)$$

From this, the velocity, V, in ft. per sec. at any time, t, is

$$V = 1/2\,p\,t^2 + C_1\,t,$$

and $C_1 = V_m/t_m - 1/4\,p\,t_m,$

or $V = 1/2\,p\,t^2 + (V_m/t_m - 1/4\,p\,t_m)\,t,$

where V_m is the maximum velocity in ft. per sec. attained in time, t_m, given in seconds.

Evidently the only possible case is when

$$V = 1/2\,p\,t^2, \qquad (2)$$

giving $(V_m/t_m - 1/4\,p\,t_m) = 0 \qquad (3)$

Therefore the time-velocity characteristic is a parabola. Also maximum acceleration reached is

$$a_m = p\,t_m/2.$$

Equation (2) holds between $V = 0$, $t = 0$ and $V = V_m/2$, $t = t_m/2$. From $V = V_m/2$, $t = t_m/2$ to $V = V_m$, $t = t_m$ the curve is reversed. A single equation for the entire curve may be developed, but is not a practical necessity.

From (3) it is obvious that

$$V_m = 1/4\,p\,t_m^2,\; p = 1/4\,V_m/t_m^2,\; t_m = 2\,(V_m/p)^{1/2} \quad (4)$$

Therefore if any two conditions, V_m, t_m or p, are given, the remaining condition is fixed. A few such ideal time-velocity characteristics are given in Fig. 9. The whole matter being more completely discussed in the article mentioned above.

From a practical standpoint it is not essential that the parabolic form be maintained except during the initial and final parts of the acceleration. Between these, the acceleration may be constant, or nearly so. Probably the time-velocity curve should approximate very closely to a parabola during the first and last 0.5 second of the acceleration period.

Obviously, for any given value of V_m the smaller is p the longer is t_m, and the round trip time for a given traffic will be increased.

Consequently, where comfort is a matter of moment, as in family hotels, hospitals and the like, a value of p smaller than can be properly employed, for instance, in office building equipment, must be used and the rapidity of service correspondingly sacrificed.

The next question is, what shall be the relative values of p in two such cases?

Having established as above, the manner in which the kinetic energy of motion must be communicated to the passenger's body, it is necessary to put a limit on the total amount that can be safely communicated in a given time without over stressing the elastic elements of the passenger's body. Given a certain time of acceleration, the impressed kinetic energy varies as the square of the velocity attained in this time, or as p^2. Mechanically speaking, the reverse of this case is precisely the same as determining the capacity of oil buffers for a given retardation time. If the oil buffer is to bring the car to rest in the same time, irrespective of the velocity, then, if the velocity of the loaded car be doubled, the capacity of the oil buffer must be quadrupled.

So, probably, if in two cases $p = 10$ and $p = 20$ for the same value of t_m, the discomfort of the passenger due to muscular stress, may be assumed to be as 100 is to 400 in the two cases. In the latter case he will experience four times the discomfort he experiences in the first case.

If, the ratio of comfort in the two cases is to be as 2:1, then, also the corresponding values of p are 20 and 14.

Assume that $V_m = 11.66$ ft. per sec. (700 ft. per min.) then from (4), and the values of p (20 and 14) given above, $t_m = 1.53$ and 1. 3. The latter of these is 19 6 per cent greater than the former.

Of course much of the above is theoretical in the sense that it is based on an assumed simplicity in the mechanics of the passenger's body that it does possess. Also, it requires a form of torque-time characteristic of the hoisting-engine motor that, so far as I know, can only be obtained by special adjustment and for one particular set of values of V_m and p for anyone motor and control, and for some one value of the load.

However, this discussion is intended merely to draw attention to the real problems faced in attempting to attain high velocities

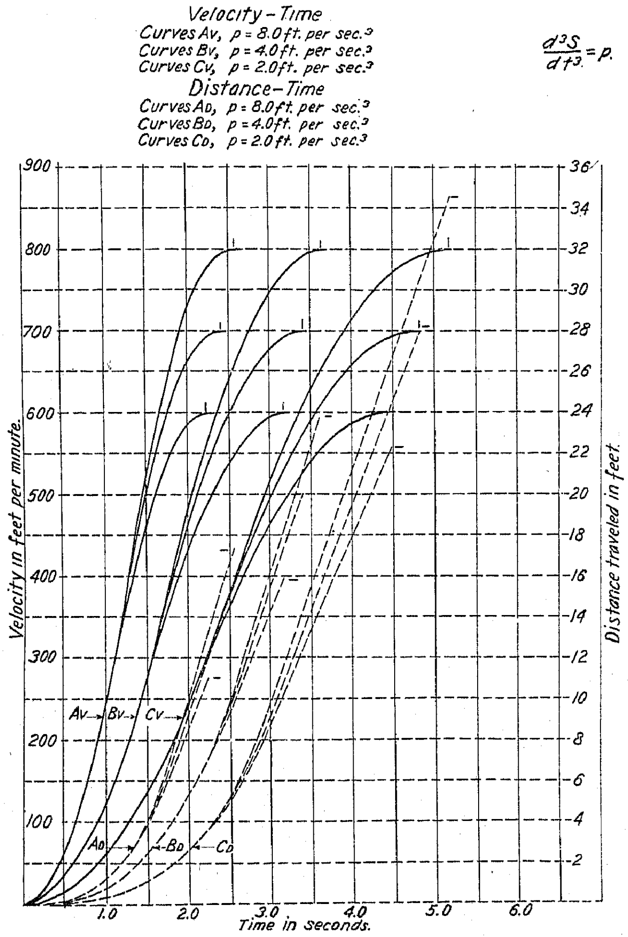

Fig. 9

and rapid acceleration in elevators. Definite solutions must wait on the necessary physiological tests required to set up the values of p.

A. A. Gazda: Looking back over the experience of the past three years in the installation and operation of upwards of 150 elevators controlled by the variable-voltage system, the one outstanding feature is its adaptibility to a broad range of applications. On one hand the advantage of smooth control for high-speed machines is quite apparent but on the other hand the feature of definite and positive speed points has been utilized not only in slower-speed passenger elevators but also in high-grade freight installations. For automatic or push-button controlled elevators particularly, we have found it of considerable advantage to have a system at hand whereby two or more definite speeds can be set at convenient values and thus insure accurate

stops even under changing load conditions. Hitherto, the nominal operating speed of automatic elevators has been limited by the design of induction motors with certain sub-synchronous speeds and in the case of direct-current machines by the lack of smooth transition from one speed to another. Introducing a motor-generator set (and the variable-voltage system) as outlined in Mr. Bouton's paper has solved both the problem of definite speed points and smooth transition. It is only necessary to locate the desired values on the generator-field rheostat and depend upon the time element of the magnetic circuit to make the swings smoothly. In accomplishing this, permanent damping windings must be provided. Also final adjustments may readily be made by placing discharge resistors across the shunt fields. If the time constants are too great the elevator operation will be sluggish. On the other hand short time constants throw severe peak loads on the commutators of both the generator and the elevator motor and if these peaks are frequent or of sufficient intensity the commutators will not stand up. This statement is made not to bring out disadvantages of the system but rather as a factor that must not be overlooked.

Another important field of application for this system lies in freight elevators which must be held level with the floor landing automatically. As shown in Fig. 7 of Mr. Bouton's paper a stable low speed can be maintained throughout the torque range and thus insure accurate stops. In such applications the problem really lies in changing the motor torque quickly on account of static friction. This has been accomplished by the proper choice of the generator series field and also by the use of momentary contact switches in the main control scheme. Our experience has demonstrated that this problem can be solved and there are now several installations of this type in successful operation.

In high-speed elevator work we find that the continued successful operation of the cars depends largely upon the care taken in maintaining the original adjustments particularly on the controller. Our experience with variable voltage installations has demonstrated that the original control adjustments are of a permanent character which do not change as contacts wear. Even as originally installed by average elevator constructors, the system is almost fool-proof and we have often been agreeably surprised by the smooth acceleration and deceleration obtained by inexperienced men. This ease of installation and operation is a factor of considerable importance from the standpoint of the elevator manufacturers particularly when it is so difficult to find competent mechanics.

W. L. Atkinson: Field experience with the system of control described by Mr. Bouton has indicated that we have here a means of obtaining operating characteristics in an elevator, not possessed by any other known means of control. While the comparative economic advantage for any given number of stops per car mile can be very readily analyzed and definitely stated, the important feature of smoothness of operation through the accelerating and decelerating periods, contributed by this method can only be demonstrated by actual experience with elevators in the field.

The company with which I am connected, has installed and in operation fifty-two elevators equipped with this system of control, operating at 400, 500, 600 and 700 ft. per minute, and in every installation a distinctive and characteristic smoothness is noticeable throughout the starting and slowing down periods. In the highest developed type of rheostatic control, making use of all the refinements which experience has shown to be of advantage we cannot attain a smoothness of operation with rheostatic control comparable with that quite ordinarily possible with the variable voltage scheme here described.

While we have been limited heretofore, to a maximum speed of about 600 ft. per minute, or in exceptional cases to 700 ft., we are now enabled by this means, we are quite sure, to go to speeds much beyond this limit without occasioning discomfort to passengers, and with the certainty of making definite stops under all conditions of loading.

Those of you who have worked on the traffic problem involved in moving the occupants of a densely populated tall modern office building in or out of the building, over the usual peake of say 20 to 40 minutes, will readily appreciate the value of any system of elevator control that offers a practical means of cutting down the time of a round trip or cycle of operation.

With modern elevator machinery there is no difficulty encountered in operating at any speed we may wish, once that uniform speed has been reached. The limitation has rather been imposed by the means available for bringing the car up to speed or slowing it down to a final stop, quickly and without discomfort to the passengers.

In a recent trial on an elevator in regular service equipped with the variable-voltage system of control, and having a nominal speed of 600 ft. per min., the car was operated at 850 ft. per min. without the occupants of the car noticing or being aware of the fact that it was not operating at the usual speed. From such data and experience in the field we are entirely confident in predicting successful operation of passenger elevators up to a speed of 1000 ft. per min.

Laurence D. Jones: Mr. Bouton's paper describes the application of the well known system of generator voltage control to the operation of electric elevators. When this system of control is used with any application where rapid rates of motor acceleration and retardation are required, these rates are in most cases dependent upon the rates of building up and dying down of the generator field.

As pointed out by the author, this fact offers one of the principal advantages of applying such a system of control to elevator service because it insures very smooth acceleration and retardation.

The inherent rates of change of generator voltage are dependent on the time constant of the field circuit which, in turn, depends upon the proportion of resistance and inductance in the circuit. It is possible to change the time constant of a field by changing the proportions of resistance and inductance. The usual method is to increase or decrease the resistance as the inductance is not so easily changed. The resistance may be increased by placing a resistor in the circuit and may be decreased by placing a short-circuited damping winding around the poles.

From the usual theory of building up of current in a circuit having resistance and inductance, the time required to reach a constant value depends upon the proportion of L to R. Bearing this fact in mind we find it rather difficult to understand how Mr. Bouton obtained the results shown in Fig. 3 of his paper which indicates that the use of a short-circuited damping winding has changed the rate of building up, but has not affected the time required for the voltage to reach a constant value. It is possible that the author has used some special means for producing the effect shown. If so, a description of how this was accomplished would prove of interest.

Similar tests which have been made under the same conditions as those described in Mr. Bouton's paper show a very material difference in the time required for voltage to reach constant value, with the field damped and undamped. In this case the time was 4.4 seconds with the damping winding in use and 2.0 seconds without this winding. Figs. 10 and 11 shown with this discussion are oscillograph records of the building up of field current and armature voltage of a generator having its field undamped and also damped. Fig. 12 is a comparison of the voltage curves for the two cases. The general conclusion from these tests is that the use of a damping winding is of value as a means of changing the time constant of the field so as to obtain the desired time for accelerating to full speed but has very little effect upon the shape of the curve.

From Part III of the paper one is likely to gain the impression that the traction motor will have acceleration and retardation

curves of the same shape as the building-up or dying-down curves of the generator voltage and that these curves are independent of the load. That this is not the fact is quite evident if we compare the shape of the acceleration curves in Fig. 4 with the curves in Fig. 3. The principal reason for the disagreement is that the shape of the speed curves is modified to some extent by voltage drop in the armature circuit. With further reference to Fig. 4, I would like to ask Mr. Bouton why a longer time is required for the motor to accelerate a loaded car going down to a

given speed than is required to accelerate a balanced load to the same speed.

E. B. Thurston (by letter): Mr. Bouton's paper leaves the impression that an elevator operated by a direct-current motor, supplied from a motor-generator set, should be called an alternating-current elevator, in case the motive power for the generator set be alternating current. It seems this impression should be corrected, because elevator motors for years have been supplied from a-c. to d-c. motor-generator sets, and have never been considered as alternating-current elevators. (Indeed were the variable-voltage generator driven by water or steam power the elevator would be called a hydraulic or steam elevator with the same line of reasoning.)

Fundamentally the only elevator that can be truly called an alternating-current elevator is one in which the elevator machine is driven directly by an alternating-current motor.

Comparing the two systems—variable voltage and the straight alternating-current, as defined in the preceding paragraph—it is seen that the variable voltage as given in the paper consists of six main elements, while the straight alternating current consists of but two, the elevator motor and its controller.

Although the paper under consideration refers to the alternating-current elevator equipment, it is noted that none of the test information contained therein gives any consideration to an alternating-current power supply, but deals only with equipment requiring direct current. If the paper leaves the impression that the curves apply to equipment having an alternating-current supply it is misleading, for the amount of energy returned to the line during slow-down will certainly be somewhat different from an a-c. to d-c. motor-generator set. Another very important consideration is the fact that the power factor will be very low during average elevator operating conditions, and idle and slow-down periods, which will be 90 to 95 per cent of the total time in service.

The paper compares only two types of control—variable-voltage and rheostatic, and these with direct current supplied, whereas it is a fact that the standard shunt-control direct-current elevator unit, consisting of the two main elements of motor and controller, shows in regular service an energy consumption still lower than either of these.

The tests given in the paper are interesting, but actually of little value even for comparison with other types of control.

Energy-consumption tests, to be of value, must show what the particular types of control under comparison are doing in actual service, where a corresponding number of hours per day, miles per day, stops per mile and kilowatt hours per car mile over a number of months are recorded. This recorded information will represent quite accurately average conditions, and will be of great value to engineers in general.

The different types of elevator control might more fittingly be compared by giving consideration to an increased number of items as follows:

Economy as to first cost.
Economy as to maintenance.
Economy as to energy consumption.
Economy as to space.
Safety.
Simplicity.
Number of main elements.
Total number of parts.
Continuity of service.
Speed regulation.
Accelerating and decelerating characteristics.

As engineers we instinctively aim towards ultimate simplicity of equipment with maximum safety and refinement of operation combined with a minimum kilowatt-hour consumption for regular operating conditions.

It is, therefore, self-evident that a straight alternating-current elevator with only two main elements, which will give any desired car speed with positive control, smooth, quiet, rapid acceleration and deceleration, and a low overall operating cost as well as all of the safety requirements, is a goal towards which we, as electrical engineers, should turn our interest and attention.

E. W. Seeger (by letter): Although the acceleration of an elevator equipped with variable-voltage control is exceedingly smooth, it is possible to get practically the same results with other types of control. In decelerating and stopping, however, the variable-voltage system has a decided advantage because of the

possibility of obtaining a sustained braking effect and a stable slow speed. The quick acceleration and retardation possible with this type of control will probably lead to the more general use of high-speed elevators for local service.

It is always difficult to compare data on the power consumption of elevators because so many factors, other than the electrical equipment, affect the result. The exact method of making the test plotted in Fig. 14 is not stated. If the load were placed on the car and the elevator then started and stopped the required number of times, the test would not show results which would be obtained in actual service, but would favor the variable-voltage equipment.

Another factor which will affect power consumption is provision for night service in office buildings. Although it is possible to start the set each time the elevator is required, it is doubtful if this practise will be followed and probably one set will be allowed to run.

After acceleration is completed and the motor is running at full speed, the variable-voltage system, due to the losses in the motor-generator set, is probably the least efficient of any of the accepted methods of control.

Even after taking the above factors into consideration, the variable-voltage system will undoubtedly show a saving on any installation where a gearless traction machine is justified. This is particularly true with "green" operators because the power required for inching is less.

With slower-speed elevators driven by geared machines, it is more difficult to justify the use of the variable-voltage system. The rheostatic losses are, in general, a much smaller percentage of the total power, landings are easier to make, and the service is less frequent. It follows that the maintenance expense is also smaller.

There is, therefore, a very definite field for the two speed a-c. motor on moderate-speed geared elevators. The acceleration and deceleration obtained with this type of equipment are as satisfactory as obtained on most d-c. installations. The average a-c. installation, however, is comparatively noisy, and for this reason the variable-voltage system has been installed in some cases where quiet operation is essential.

In the majority of variable-voltage equipments which have been installed, the car operating switch has been used, not only to control the contactors on the board, but also to vary the generator field resistance directly.

The generator field resistance is usually placed on the car, and inasmuch as a number of resistance steps are used, there is considerable wiring on the car which is comparatively inaccessible. The writer believes that a more satisfactory arrangement is to have the car-switch-control multi-point relays placed on the control panel. With this arrangement, only one set of resistance is required and it can be placed on the control panel rather than on the car, where space is at a premium.

B. M. Jones (by letter): It has been my good fortune to do some work on a variable-voltage elevator built by Mr. Bouton's company, and it was a pleasure to see the ease with which the elevator was controlled and the smoothness of its operation.

The writer has also done considerable work on some of the early two-speed a-c. elevators using squirrel-cage motors having two speeds, covering a range of approximately three to one. This means that the a-c. motor has two primary windings. For starting the motor it is thrown on the low-speed winding and as the car accelerates the motor is automatically transferred to the high-speed winding through resistance which smooths out the acceleration. The star point of the windings is brought out of the frame of the motor and the resistance connected in these leads before the starting connection is made. Magnetic contactors short circuit this resistance in steps to accelerate the car. When switching from high to low speed, the resistance is thrown in the high-speed winding before the latter is thrown on the line, thus smoothing out the change in speed from low speed to high.

In connection with these two-speed elevator motors, as well as with any elevator motor, the number of stops per minute and the duration of the stops have a great effect upon the heating of the motor, as does the class of building in which the elevator operates. For example there are some department stores five or seven stories in height in which during non-rush periods the car only pauses at each floor, and, seeing no passengers, the operator proceeds on to the next floor. This constitutes a full stop and start, but with very little rest period. This is very severe duty on the motor and is considerably different from that in a tall office building where the elevators runs three, four, five, or, in some cases, ten, floors without a stop, thus operating the motor a great portion of its operating time at a high speed and consequently deriving the benefit of its ventilating effect.

The question of first cost of an elevator installation is a quite important one and the method of drive influences this cost somewhat. These points were not touched upon in this paper. It is also very interesting to know the power consumption of elevators per car mile, and the comparative power consumptions of variable-voltage d-c. elevators and two-speed a-c. elevators, as well as the amounts of maintenance required on these two schemes.

The question of speed of elevators is very interesting, especially for a tall office building where the ability to handle the peak load in a space of half an hour two or three times a day is very important. However, the ability to operate an elevator at such a speed that the operator can make the landing at the floor accurately without a great amount of juggling up and down, to which passengers object strenuously, is very important and should be kept in mind by the elevator designers as well as the motor and control designers when laying out elevators for a tall office building.

E. M. Bouton: Mr. Whiting has shown some very interesting results obtained with variable voltage control, by paying particular attention to the details that affect the regulation of the motor. Unfortunately, he has not described the method by which he obtained the results.

In general, the regulation of the elevator motor can be improved by increasing the compounding of the generator or by using control contacts which manipulate the generator or motor fields in response to changes in motor load or speed. The generator compounding may be accomplished by putting series turns upon its own field poles or by putting these series turns upon an auxiliary generator which excites or affects the excitation of the main generator. If the generator is compounded so as to have a flat speed torque curve at high speed, it will probably have a rising curve at slow speed. This is because the generator fields are more nearly saturated at full speed and a given number of series turns is more effective at the lower saturation. It is entirely practicable to compound the machine in this way, except that if carried too far it has a tendency to make the equipment unstable.

I believe that a little further discussion of Fig. 7 and Fig. 11 would be helpful. Curve 1 in Fig. 11 shows the inherent regulation of a gearless machine at full speed without the corrective effect of any speed governor contacts when connected to a constant potential of 230 volts. The regulation at low speed with armature series and shunt resistance will be as shown by Curve 2.

The test illustrated in Fig. 7 consisted in taking the same machine and driving it with a variable voltage generator. The generator compounding was so adjusted as to give approximately the same regulation at high speed as was obtained on the constant voltage supply. The inherent regulation at low speed is then shown by Curve 2. A comparison of curves 2 in Fig. 7 and Fig. 11 shows the advantage that variable voltage control has over rheostatic control in making landings when adjusted for the same regulation at full speed.

It was not the purpose of my paper to show the maximum improvement over rheostatic control that could be obtained, but rather to show that the variable voltage system has certain inherent characteristics that make it superior to other systems. It is entirely possible, as is shown in Mr. Whiting's discussion, to make the regulation at full speed as good as is desired. I wish to state, however, that additional complications are involved if extremely close regulation is desired.

The tests shown in Figs. 14 and 16 include the motor-generator losses only during the period of test. For this reason, in actual service the all day power consumption would be somewhat higher. For example, if the elevator runs 20 mi. in a 10-hr. day, the no load losses will be, (at 1.25 kw. per elevator)—$1.25 \times 10 = 12.5$ kw-hr. total for the day. This loss must be distributed over the 20 mi. traveled and will be $12.5 \div 20 = 0.625$ (625/1000) kw-hr. per car mile for the idling losses. It would not be right, however, to add all of this to the test value shown in Fig. 14 since time was actually consumed in making the test. It would probably be fair to add ½ of this value or approximately 0.3 (3/10) kw-hr. per mile to the test value to obtain the actual power consumption of an elevator operating on the schedule outlined above. For night service the motor-generator sets can be shut down so that the losses do not occur except while the car is running.

I wish to point out also that the test results shown in Fig. 15 for rheostatic control do not show all the rheostatic losses that will be present in actual operation. The test does not include any periods of slow speed running prior to the stops nor does it include "inching" the car to make a landing while in actual service, these operations occur very frequently. If the motor is controlled over a wide range by armature series and shunt resistance as is the practise with gearless machines, the elevator will frequently consume more power while running at low speed than at high speed. For this reason the test values probably favor the rheostatic system more than the variable voltage system when compared with actual service conditions.

There seems to be quite a tendency among engineers when comparing variable voltage control with other systems to pay considerable attention to whether or not there will be a saving in power. As a matter of fact, in the majority of cases the other advantages of variable control that I have described, such as smoothness of operation, accuracy of control, saving in time, etc., are much more important considerations. I think Mr. Matson's analysis of the cost of operating elevators brings out quite clearly that the power consumed is a small item in the cost of operation.

L. D. Jones has questioned the results shown in Fig. 3 which show that the rate of building up of the generator fields is changed by the use of a damper winding, but the total time of building up is not materially affected. The inductance of the field circuit is made up of two factors, the self inductance of the main field winding and the mutual inductance of the short-circuited damper winding. If the inductance were actually constant, the field coil would have a true time constant and the field flux would build up according to the well-known logarithmic law. However, the inductance is not constant but depends upon the permeability of the magnetic circuit and upon the amount of magnet leakage between the main winding and the damper winding. Now keeping in mind that the field poles are being worked at a lower point on the saturation curve when the field starts to build up than when it has built up to higher values, and also that the increasing magneto force of the main winding will cause a redistribution of the leakage flux, it is not unreasonable to expect a change in the shape of the curve when the damper winding is added. For other proportions of magnetic circuit and proportions of windings I would readily believe that different results would be obtained, as Mr. Jones states that he obtained from his tests. The results I have shown in Fig. 3 were obtained on test with an oscillograph.

The speed time curves obtained in Fig. 4 were taken by driving a magneto by the elevator motor and recording with a graphic voltmeter the voltages of the magneto. The voltage of the magneto was calibrated in terms of car speed with an ordinary tachometer. The method is not absolutely accurate and these inaccuracies no doubt account for the discrepancies in the curves that Mr. Jones mentions. I think Mr. Claytor's analysis of the curves explains why the motor speed does not follow exactly the building up of the generator voltage during the early part of the accelerating period. During the rest of the accelerating period and during retardation up to the point where the brake sets, I believe the speed and the generator voltage follow each other very closely.

Mr. Hansen has described an interesting system whereby he uses a voltage of rotation in an auxiliary machine to first oppose the impressed line voltage and then add to it to accelerate the main motor to a higher speed. By this means the energy which in a rheostatic system is dissipated in resistance is here stored in a flywheel and then returned as energy used in acceleration. It would seem that this system would be quite useful for constant speed work where acceleration and stopping make up the principal part of the cycle. It has the one drawback for elevator work, that speeds lower than full speed are not available. If the controller handle were left on a slow speed point the main motor would not run at this low speed except momentarily, because the energy input to the auxiliary motor would accelerate the flywheel and the main motor would accelerate due to the reduction in counter e. m. f. of the auxiliary motor. A slow speed which is constant and independent of load is one of the important requirements of elevator service and this requirement is one of the reasons why the variable voltage system has proved so successful in this field since it provides not only for smooth acceleration but also for speed control.

The discussion by Mr. Eames and by Mr. Bassett Jones illustrate the extent to which elevator engineers have analyzed the passenger himself when providing a conveyance for transporting him, in a vertical direction. I have no doubt that in the future more complete physiological as well as psychological tests will be made to determine the effect of acceleration upon the passenger, but I believe that a more exact solution of the problem depends equally as much upon the development of more accurate methods of testing the elevator to determine how closely it fulfills the required conditions.

A Novel Alternating-Current Voltmeter

BY LEON T. WILSON

Formerly Connecticut Company Research, Fellow, Yale University

Review of the Subject.—*This paper describes an improved thermo-voltmeter, which may be used at all frequencies up to and including 1,000,000 cycles. This meter retains the usual high sensitivity of thermovoltmeters so that it requires a very small current—for full scale deflection about 2 milliamperes.*

At present it is made in ranges from 1 to 20 volts inclusive. Higher voltage ranges can be made but probably at the expense of lowering somewhat the upper limit of frequency at which the instrument is still accurate.

* * * * *

History of Development

THE voltmeter to be described was first devised in 1918 to meet the requirements of a particular problem[1]. As then used, the instrument was primarily a laboratory one but its usefulness in that problem was so well demonstrated that it was deemed advisable to put the instrument into a commercial portable form.

Accordingly two preliminary models were designed and built. One of these was successfully used by two seniors in Electrical Engineering at Mass. Institute of Technology, to measure the resistances of some condensers and inductance coils at high frequencies. This work was part of a thesis problem and to the writer's knowledge has never been published.

The other model was submitted to representatives of the Weston Electrical Instrument Co. for their consideration. Following some preliminary measurements, this company undertook to change certain details in the design of the preliminary model to meet their own standards and manufacturing methods.

Largely through the efforts of Mr. Caxton Brown, and Mr. W. N. Goodwin, Jr., the development of the present model has been accomplished.

Principle of Operation

In principle the voltmeter falls in a class of instruments commonly known as thermo-voltmeters. In their usual form these instruments have been on the market for years and therefore will not be described. As ordinarily made these voltmeters may be used at all frequencies up to about two or three thousand cycles.

In the new voltmeter this upper limit in frequency has been increased to approximately one million cycles. This material increase has been accomplished by means of special shields within the meter case and a special disposition of the component parts of the meter.

How the improvement was brought about will be discussed in some detail.

Theory of the New Features

Probably the theory of the new features may be presented best by first showing why the ordinary thermo-voltmeter fails at frequencies above three thousand cycles and then by taking the reader through the same steps that were taken by the writer in his development of the meter to the final form which overcame the various difficulties encountered.

The following analysis therefore will be confined to the specific circuit in which the voltmeter was first developed and used.

That circuit is shown in Fig. 1. An ordinary thermo-voltmeter is shown connected to measure the potential drop across the resistance $A\,B$. The thermocouple is shown external of the meter case but the analysis is essentially the same as if it were enclosed. In such a circuit at high frequencies it has been found that not only does the voltmeter fail to register the true drop across $A\,B$ but it will actually give a large reading with no e. m. f. across its terminals, that is, with the resistance $A\,B$ short-circuited and again with either one

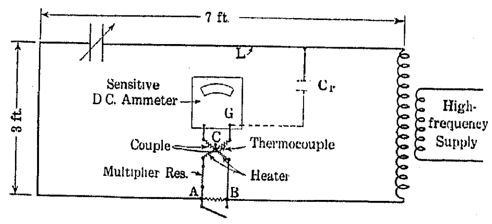

FIG. 1

of the voltmeter leads disconnected. In each case the reading was observed to increase as the meter was moved nearer the side of the circuit marked L.

Although this phenomenon appears mysterious at first sight, it is readily explained. It is due to extraneous or stray displacement currents. The principle one is that to the side of the circuit marked L because a greater difference of potential exists between that side of the circuit and the meter than between any other part of the circuit and the meter. For the present this is the only displacement current that will be considered.

Let us now trace out the path of this stray current. If $A\,B$ is short-circuited the current will divide between the paths $B\,C$ and $A\,C$. If only one lead is connected it will flow either from A to C or from B to C depending on which lead is disconnected. From C it goes to G which is that terminal to which are connected most of the metallic parts of the meter, such as the magnet, needle shield, and the like. From C it flows to L through the capacity existing between these metallic

1. *Proceedings* I. R. E., Vol. 9, page 56, 1921.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

parts and the line L. Although small this capacity is very real and cannot be neglected at high frequencies. It is represented by the fictitious condenser C_1 of equivalent capacity.

It will be seen that the stray current has, on its path, gone through the heater or at least through part of the heater. The current thus causes the meter to register and the observed phenomenon is explained. There still remains to be explained the fact that the observed reading increases as the meter is moved nearer the line L. This is due to the increase in the capacity C_1 accompanying the change in the position of the meter, which lowers the impedance of the path of the stray current and increases its value. The increased current produces a greater reading which is in accordance with the observations.

The phenomena we have just discussed begin to show at frequencies of about two or three thousand cycles and explain some of the reasons why an ordinary thermo-voltmeter begins to fail at such frequencies.

Now let us take the next step that was taken in the

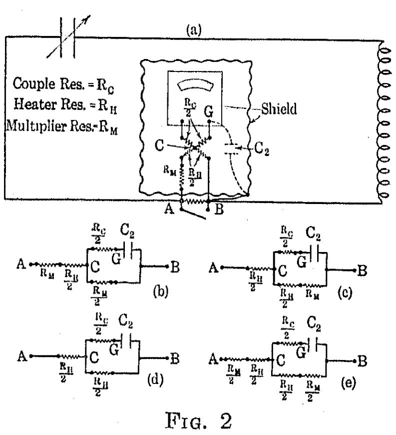

FIG. 2

development. We shall enclose the ordinary thermo-voltmeter in a metallic shield, as indicated schematically in Fig. 2a, and connect it to the point B and see what happens.

As before there will be a stray current from B to L but it does not now flow through the heater. Therefore when $A\ B$ is short circuited the meter is observed to read zero as it should. However a new difficulty is encountered. It is found that in measuring the drop across $A\ B$, if the leads to the voltmeter are reversed a different reading is obtained, not a common experience with an alternating-current instrument. The difference in the two readings is observed to be greater the larger the instrument series resistance.[2]

To explain this curious phenomenon we must first observe that there is a capacity existing between G and the shield, represented by the equivalent condenser C_2. This capacity must be taken into account in an analysis of the circuit through the voltmeter. When the leads of the voltmeter have the polarity shown in Fig. 2a the circuit through the instrument may be represented by Fig. 2b. When the leads are reversed the same circuit is represented by Fig. 2c. In both figures it is assumed that the heater and couple make contact at their respective electrical centers. Actual measurements of the resistances between terminals of the thermocouple showed this assumption to be justified.

Let us now compare Figs. 2b and 2c. It is at once obvious that although the same potential be applied between the terminals A and B in each circuit, the current through the heater in each case will not be the same. This explains why the meter gives a different reading when its leads are reversed.

It will be remembered that this difference in the two readings was found to be greater the larger the instrument resistance or stating it another way, the smaller this resistance the smaller the difference. To find an explanation for this observation, let us reduce the instrument series resistance to zero and see whether the difference in readings disappears. For this to be true both circuits must reduce to an identity. They do, for they both reduce to the circuit shown in Fig. 2d. Therefore with no series resistance the meter should have its reading unchanged when its leads are reversed. This conclusion was checked experimentally.

Why do the circuits 2*b* and 2*c* reduce to an identity without a resistor and not with one? Perhaps the answer to this question will show how to employ properly a resistor. A further study of the circuits shows that without a resistor there are equal resistances on each side of the contact between the heater and the couple, while with a resistor there is more resistance on the side in which the resistor is connected. This observation at once suggests splitting the multiplier and connecting half on each lead, so as to make the resistance on each side the same. Now let us determine whether or not the circuits 2*b* and 2*c* will reduce to an identity under these conditions. They do, for they both reduce to the circuit shown in Fig. 2e.

Two difficulties have now been overcome. The single shield makes the meter read zero when it should. The divided multiplier makes the meter read the same on the reversal of its leads.

However a closer study of Fig. 2*e*, shows one more difficulty to overcome. That difficulty is, that the reading of the meter is not independent of the frequency of the applied e.m.f., due to the fact that the current through the heater obviously depends on the impedance of the capacity C_2 which is not a constant but changes with the frequency.

In solving this problem we come to the final fundamental step in the development of the meter to its present form. That step consists in splitting the shield, as we did the multiplier, into two equal parts. One is connected to one terminal of the voltmeter; the other, to the other terminal, as is shown in Fig. 3a.

An analysis of the circuit through the instrument shows that it may be represented by Fig. 3b.

2. This series resistance corresponds to that marked "multiplier" in the drawings.

An inspection of this circuit shows its striking resemblance to an a-c. Wheatstone bridge. It is obviously balanced when C_3 equals C_4 and when the two resistances are equal to each other. That is, there is no alternating current flowing through $\frac{Rc}{2}$. When so bal-

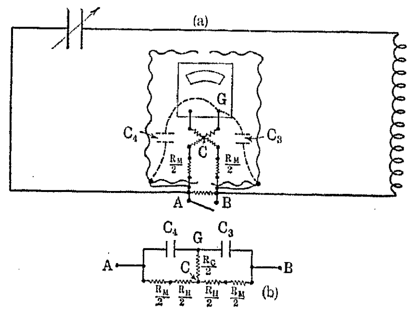

Fig. 3

anced, the current through the heater resistance depends only on the potential difference between A and B and not on the frequency, provided of course that the resistances have negligible inductance or distributed capacity.

In practice C_3 is made equal to C_4 by a symmetrical

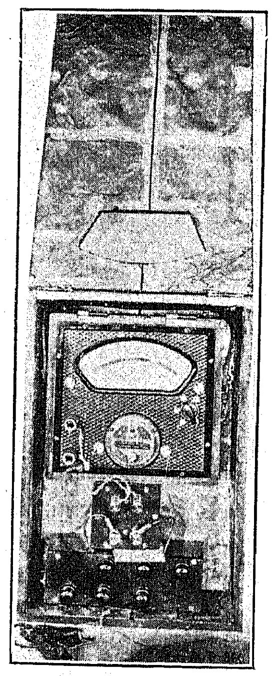

Fig. 4

placing of the meter with respect to the two halves of the shield, while the resistances are balanced by adjustment.

In this form the meter has met effectively the various requirements imposed on a high-frequency voltmeter.

The original laboratory form of the voltmeter is shown in Fig. 4.

Fig. 5 shows one of the two preliminary models in which the shielding, thermocouple, and multiplier resistance are all incorporated within the meter case.

Voltage Range

The Weston model is at present made in various voltage ranges from 1 to 20 inclusive. In these ranges the meter can be employed at all frequencies up to and including one million cycles with an error of less than 1 per cent of full scale value. Instruments of higher ranges can be built, of course, but it is doubtful whether they can be employed at so high a frequency with equal accuracy, on account of certain factors. For example, one of these factors is the distributed capacity of the multiplier resistance, which becomes more important the higher the voltage or the frequency.

Current Taken by the Voltmeter

On referring again to Fig. 3b it will be seen that the voltmeter draws two distinct currents; one through the resistances and in phase with the voltage; the other through the capacities C_3 and C_4 and 90 degrees out of phase with and leading the voltage. The first current is practically the same for all voltage ranges since the instrument resistance is proportionately greater the higher the range. The second current however is not

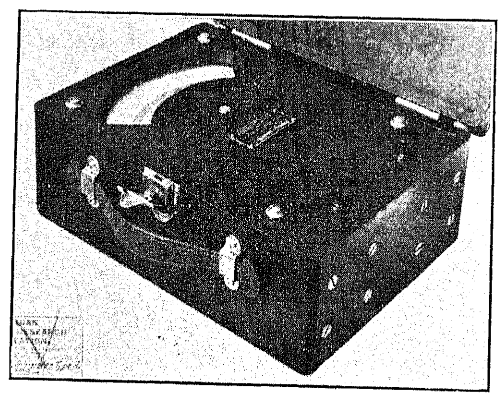

Fig. 5

the same for all voltage ranges. It increases with the applied voltage and also with the frequency of that voltage. This second current is small however and at the lower frequencies can be neglected entirely. At frequencies approaching the upper limit and particularly at the higher voltages this second current becomes appreciable and may equal or even exceed in magnitude the first current. That first current is only about two milliamperes so in any case the total current drawn by the voltmeter over its useful range is not excessive.

Precautions in the Use of the Meter

In addition to the usual well known precautions necessary in high frequency measurements, it is recommended that the voltmeter be kept well away from other parts of the circuit in which it is employed, in particular those parts which are at a widely different potential from the points to which the voltmeter is connected.

Also it is recommended that in general the meter be as symmetrically placed with respect to the various parts of the circuit in which it is employed as is feasible.

However, very good results have been obtained without taking any more than the usual care required in such measurements.

Discussion

R. S. Glasgow: The alternating-current voltmeter described by Mr. Wilson will be quite valuable in a large number of radio-frequency measurements. Particularly in the investigation of radio-frequency amplifier circuits is there a need of such an instrument. However, the type just described has too low a resistance to be employed in the majority of such circuits, as the radio-frequency current in the output circuit of the average vacuum tube amplifier is seldom more than a few milliamperes.

In order to overcome this objection to thermo-voltmeters I have employed a vacuum tube as an electrostatic voltmeter, using the circuit shown in Fig. 1, which is identical with a standard detector circuit. When a radio-frequency voltage, E, is applied to the terminals a b, the mean potential of the grid becomes more negative, causing a reduction in the average value of the plate current, I_p. The device may be calibrated by passing known radio-frequency currents through a known value of resistance, a typical calibration curve being shown in Fig. 2. Where considerable accuracy is desired a family of such curves should be obtained for various frequencies since the slope will vary slightly with the frequency of E. Since the resistance between the terminals a b is of the order of five to ten megohms, while the capacity can be reduced to less than 50 micromicrofarads, it is seen that the device can be bridged across almost any type of circuit without producing an appreciable change in the voltages and currents already present in the circuit. The terminal b should always be connected to that part of the circuit to be measured which is nearest ground potential.

By employing one of the several dry-cell types of tubes now available, the batteries, meters and tube may all be mounted in a shielded container and thus made portable. The accuracy of the device is of course lower than that of the volt-meter described by Mr. Wilson. Its calibration should be checked from time to time which is a common need with the majority of electrostatic voltmeters for low voltages. It will, however, enable the measurement of voltages across portions of a circuit wherein the amount of energy is too small to actuate the instrument described in Mr. Wilson's paper. The voltage range is limited only by the characteristics of the tube chosen and the plate voltage employed.

G. D. Robinson: It should be noticed that the indications of Mr. Wilson's meter depend upon the wave form as well as the effective voltage. A calibration made with one wave form may not hold for another.

Leon T. Wilson: The vacuum-tube voltmeter described by Mr. Glasgow in his discussion of my paper is not new. It has been in use in numerous laboratories for several years.

However Mr. Glasgow has rendered a service in bringing this useful device again to the attention of the electrical engineering profession.

The vacuum-tube voltmeter with its characteristic of a high input-impedance has a certain field of usefulness not covered by my voltmeter. On the other hand, as Mr. Glasgow mentions, it has the disadvantage of requiring frequent calibration. Also its calibration is dependent on the frequency, and therefore its calibration is materially affected by the wave shape of the voltage applied. In working with vacuum-tube voltmeters, it has been my experience that a great amount of care must be taken to insure reasonably accurate measurements. However, when such care is taken this type of voltmeter is a very useful instrument and well deserves the attention of engineers.

Mr. Robinson in his discussion states that "the indications of Mr. Wilson's meter depend upon the wave form as well as the effective voltage." The fact that the calibration of this voltmeter is practically independent of the frequency from low frequencies, say 25 cycles, to its upper limit, approximately 1,000,000 cycles, seems to me to be sufficient evidence to show that its indications, at least for all practical purposes, do *not* depend upon the wave form.

Since the presentation of my paper W. N. Goodwin, Jr. has kindly offered me the use of the results of his recent tests on the Weston model. The results follow:

The charging current, that is, that current taken by the voltmeter which leads the voltage by 90 degrees, was found to be one and one-half milliamperes for an applied e. m. f. of twenty volts and a frequency of one and one-half million cycles.

The error at full-scale deflection (20 volts) was found to be negligible at 600,000 cycles, 1/10 of one per cent at 1,000,000 cycles, and 4/10 of one per cent at 1,500,000 cycles.

Oscillographic Study of the Current and Voltage in a Permeameter Circuit.

BY W. B. KOUWENHOVEN and T. L. BERRY, JR.

Member, A. I. E. E.

Associate Professor, Electrical Engineering, Johns Hopkins University

Review of the Subject.—*The purpose of the investigation was to study the form of the voltage-time and current-time curves, existing in a permeameter circuit, and to reduce the time required for the reversal of the magnetizing current. The permeameters used in the investigation were of the U-shaped yoke type. Oscillograms were taken of the current and of the induced voltage during the opening and also during the reversal of the magnetizing current.*

The permeameter, with which the investigation was started, was fitted with brass end pieces to support the magnetizing coil. The oscillograms showed that the flux change lagged behind the magnetizing current. In fact, the secondary e. m. f. continued for about one second after the current change was completed. The cause of this lag was found to be due to eddy currents set up in the short-circuited paths provided by the brass end pieces. After these were removed oscillograms showed that the lag in flux behind the magnetizing current was negligible. This brought out clearly the fact that short-circuited paths in which eddy currents may be induced should be avoided in permeameter construction.

Two new permeameters were then constructed of the same type; one of these was made with a solid core of silicon steel and the other with a laminated core of the same material. Tests of these showed that use of the laminated core materially reduced the time required for the reversal of the current.

Several different types of switches were used for opening and reversing the magnetizing current. The oscillograms showed clearly that a quick-break snap switch operating under oil is superior to other types of switches.

* * * * *

THE purpose of the investigation was to study the form of the voltage-time and current-time curves in a permeameter, and to reduce the time occupied by the current reversal to a minimum.

One of the reasons for undertaking the investigation was the fact that a permeameter of the U-shaped yoke type, that had been constructed at the Johns Hopkins University, had never given satisfactory results. This instrument read too low in flux density, B, for a given magnetizing force, H. Another reason was that a search through the literature disclosed no publications showing the form of the secondary e. m. f. curve in a permeameter.

Permeameters

The permeameter, mentioned above, was of the *U*-shape type. The magnetizing coil consisted of 1935 turns of No. 16 B and S wire wound on a cast-iron core 5.08 cm. square. The ends of the spool supporting the coil were of 1/8 in. (about 0.3 cm.) sheet brass. The total length of the magnetic circuit including the specimen was approximately 65 cm.

During the investigation two other permeameters were constructed. The cores of these were of high-grade silicon tranformer steel. One was fitted with a solid core of silicon steel 6 cm. by 6 cm. square and the other with a core of 0.012 (0.0305 cm.) thick laminated silicon steel of the same dimensions. The cross-sectional area of the solid core was 36 cm. square and that of laminated core, allowing the customary 10 per cent stacking factor, was 32.4 cm. square. The ends of the spools supporting the windings in these two permeameters were of bakelite. These two permeameters were wound with the same number of turns, and were also of the yoke type.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

Circuit

The diagram of the connections used in the test are shown in Fig. 1. The current supply was taken from a storage battery, and the value of the magnetizing current measured by the ammeter A. A number of different types of switches were used for reversing the current and opening the circuit. In some cases automatic control was used for operating the switch and the oscillograph shutter simultaneously. In some of the tests condensers were placed in parallel with the primary winding of the permeameter, and in others, extra inductance was placed in the circuit. These conditions are described below.

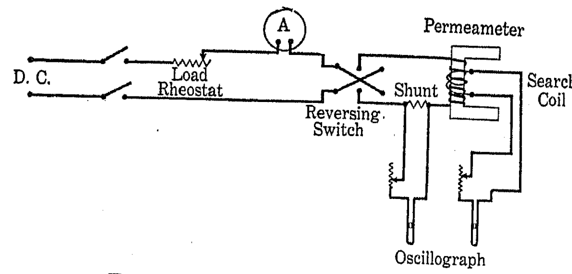

Fig. 1—Diagram of Connections

The shunt used in the magnetizing current circuit was non-inductive. The search coil consisted of 28 turns of No. 18 wire wound over the magnetizing coil of the permeameter. The e. m. f. induced in this search coil was measured by the oscillograph and the shape of this voltage curve shows the form of the e. m. f. that is induced in the secondary circuit of the permeameter.

Tests

Tests were made both of the opening and of the reversal of the magnetizing current.

Opening the Current

Two oscillograms were taken using a carbon break magnetic blow-out circuit breaker to open the magnetizing current of the permeameter with the cast-iron core. The circuit breaker was automatically tripped in this test. The results are shown in oscillograms 1 and 2, which are reproduced in Fig. 2. The magnetizing current was 7.5 amperes in both cases and in

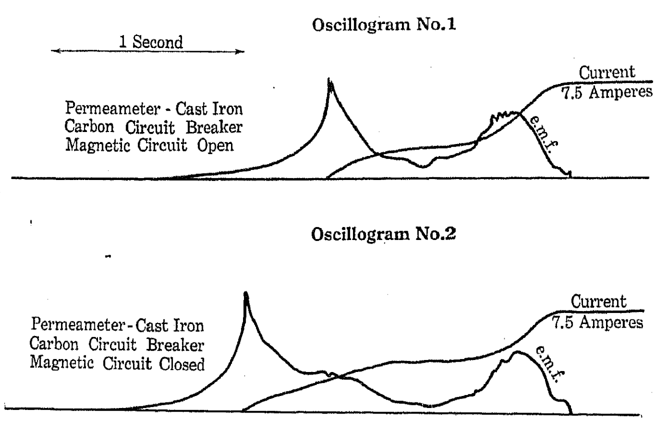

Fig. 2

oscillogram 1 the magnetic circuit was open, while in 2 it was closed with a soft iron specimen. As would be expected the time necessary to interrupt the current was greater in 2 than in 1. Oscillogram 1 shows that it required 1.25 seconds to reduce the current to zero and in 2 it took 1.68 seconds to accomplish the same thing. A study of the oscillograms show that the secondary e. m. f. has two pronounced peaks; one when

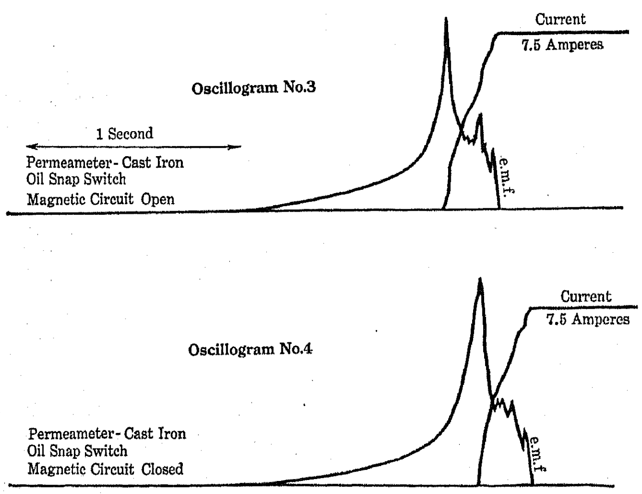

Fig. 3

the current starts to fall, and the other when it dies to zero; also that the e. m. f. in the secondary continues for some time after the magnetizing current has been reduced to zero. The explanation of this is given below.

Ballistic galvanometer readings were taken simultaneously with oscillograms 1 and 2, and were very erratic, as would be expected from the shape of the secondary voltage curve.

It was clearly evident that the circuit breaker did not give a quick clean break, and a 20-ampere snap switch immersed under oil was tried. The results with this switch are shown in Fig. 3, oscillograms 3 and 4. In 3 the magnetic circuit was open and in 4 it was closed. The time of interrupting the circuit was nearly the same in the two cases, 3 requiring 0.23 seconds and 4, 0.24 seconds. In oscillograms 3 and 4 there is only one pronounced peak of secondary e. m. f., but the secondary voltage rises to this peak in an irregular way. A study of these oscillograms shows also that the secondary e. m. f. continues to exist after the current has been interrupted. In fact, this continuation of

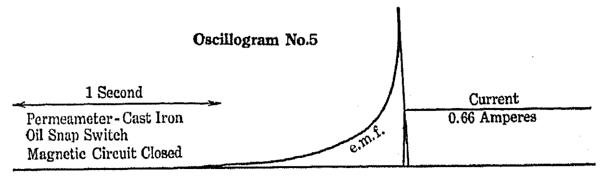

Fig. 4

e. m. f. after the cessation of the current lasts for about one second in all of the four oscillograms shown in Figs. 2 and 3.

In Fig. 4 oscillogram 5 is reproduced. This ocillogram was taken with a magnetizing current of 0.66 ampere through the solenoid of the cast-iron permeameter with a closed magnetic circuit and using the oil-break switch. It shows that the current is interrupted in about 0.02 seconds and also that the secondary e. m. f. continues for about one second after the magnetizing current ceases to flow. In other words, the secondary e. m. f. is maintained for about the same length of time irrespective of the current opened as found in oscillograms 1 to 4 inclusive.

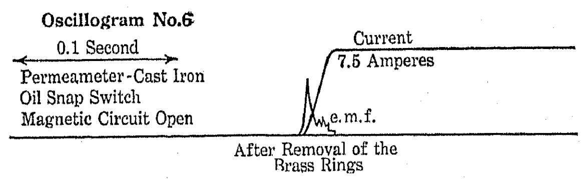

Fig. 5

These five oscillograms all show that the flux lags behind the magnetizing current that produces it. This lag was found to be due to the presence of eddy currents induced in the brass rings forming the ends of the spool supporting the magnetizing solenoid. This is conclusively proved by oscillogram 6, shown in Fig. 5. This oscillogram is taken with the cast-iron core permeameter with the brass rings removed. The oil-snap switch was used to break the magnetizing current and the magnetizing circuit was open. A study of the the oscillogram shows that the secondary voltage and current sink to zero practically simultaneously. The secondary e. m. f. builds up to a peak in an irregular

manner as before and then falls rapidly to zero. The total time that the secondary voltages continues is 0.02 seconds.

This series of six oscillograms brings out clearly the necessity of avoiding the presence of short-circuited paths in which eddy currents may be induced in permeameters. It also shows the superiority of the quick break switch operating under oil over the circuit breaker for opening the magnetizing current. The oil-break snap will open the circuit in less than 1/5 of the time required by the circuit breaker.

Two oscillograms were taken of opening the circuit under the same conditions except that in one the current was supplied by a 120-volt storage battery and in the other by a 10-volt battery. These oscillograms are very nearly identical. They show that it took a small fraction of a second longer, about one thousandth of a second as nearly as can be determined from comparing the oscillograms, to open 120-volt supply than the 10-volt supply.

Reversal of the Current

Before removing the brass ends from the cast-iron core permeameter, the problem of the reversal of the magnetizing current was investigated. In this work an ordinary double-pole, double-throw reversing switch, a special reversing switch that makes contact in the opposite direction before it opens the first circuit, and an oil-immersed snap reversing switch were tried. The special switch in its mid position short-circuits both the supply circuit and the permeameter winding. The oil-immersed reversing switch was a standard four-way snap switch such as is used in electric lighting circuits.

In the previous work the speed of a quick break under oil had been clearly demonstrated for opening the circuit in a very short space of time. It was, of course, realized that the problem involved in the reversal of the magnetizing current included the make as well as the break. It is, therefore, a question of the time constant of the circuit to a large degree. It was felt that this permeameter with the heavy damping, caused by the brass rings, was ideal to experiment with.

The results obtained with the three reversing switches are shown in Fig. 6. The current used was 0.66 amperes, and the magnetic circuit was closed. Oscillograms 7, 8 and 9 are for the double-pole, double-throw switch, the special switch, and the oil-reversing switch respectively. Oscillogram 7 shows that it takes considerable time to operate an ordinary double-pole, double-throw reversing switch of 180 deg. throw. The secondary e. m. f. sank to zero before contact was made in the opposite direction. Efforts to manually operate this switch at a high rate of speed were not successful. This type of switch is clearly unsuited for magnetic testing. Oscillograms 8 for the special switch, which has a throw of only about 15 degrees, shows clearly its superiority over the 180 deg. throw switch. The oil switch gave a much quicker break than the others, as expected. There is only one peak of secondary induced e. m. f. for both the special and the oil-reversing switches. All three oscillograms show the gradual building up of the current in the cast-iron core permeameter after its reversal. In all cases the secondary e. m. f. continues for several seconds before it sinks to a negligible value, for the special switch the time was 5 seconds and for the oil switch 3.9 seconds.

It is a well known fact that the theory of a ballistic galvanometer assumes that all of the charge passes through the galvanometer before it commences to deflect. Professor Laws has shown Laws-Electrical Measurements) that accurate results are possible with a ballistic galvanometer, provided the duration of the discharge is less than one twentieth of the galvanometer period.

It is apparent from oscillograms 7, 8, 9 and 10 that the largest factor influencing the time of reversal is the growth of the current. The use of a quick-break switch operating under oil will effectually solve the problem of opening the circuit in a very short interval of time.

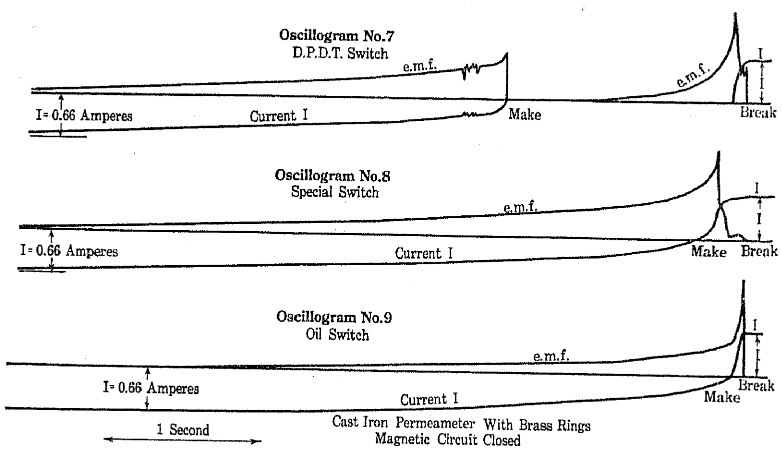

Fig. 6

Therefore, efforts were made to reduce the time constant of the circuit and to shorten the time required for the current to reestablish itself in the reverse direction. A number of schemes were tried.

Among these the effect of introducing a break in the iron of the magnetic circuit upon the time of reversal of the current was tried. Fig. 7, oscillogram 10, shows the effect produced by the introduction of two 1/16-in. gaps in the iron of the magnetic circuit. This oscillogram was taken with the special switch and 0.66 amperes of magnetizing current with the cast iron permeameter. In this case the secondary e. m. f. disappeared in 3.2 seconds as against 5 seconds without the gaps. With an open magnetic circuit the time fell to 1.8 seconds.

Another scheme of shortening the time of reversal of the current that was tried was to place condensers in parallel with the magnetizing solenoid of the permeameter, and neutralize the self induction of the winding.

Several arrangements were tried without success due to the production of current oscillotations in the circuit.

The method that met with the most success was to placing large inductances in series in the line between the source of supply and the special reversing switch, which does not open the initial circuit through the permeameter until it has closed the circuit in the opposite direction. As stated above, this special switch in its mid position short-circuits both the supply circuit and the permeameter winding. The low-voltage windings of a transformer were used for the inductance. Using this special reversing switch, the method reduced

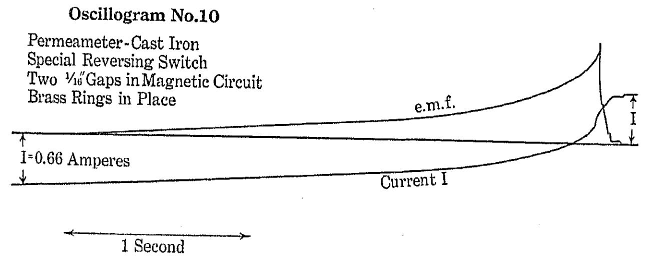

Fig. 7

the time of reversal about 40 per cent. The reason for this is that the inductance in the line tends to maintain the line current constant, and that the special reversing switch does not interrupt the line current, but simply reverses the current through the permeameter. The method of course failed to reduce the time of reversal when any type of switch was used that opened the first circuit; that is it opened the line current; before it closed the circuit in the opposite direction. This is due to the fact that in this case the extra inductance placed in the circuit is added to that of the permeameter windings and increases the time constant of the circuit.

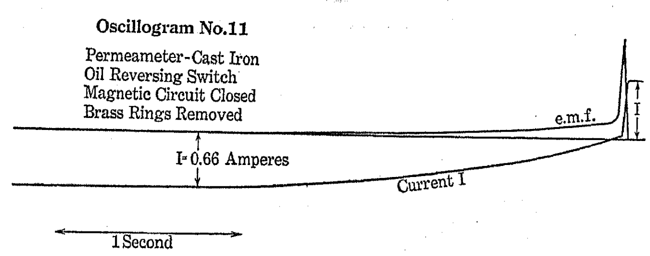

Fig. 8

In Fig. 8 oscillogram 11 shows the effect upon the time of reversal produced by removing the brass ends of the coils. Oscillogram 11 was taken with the magnetic circuit of the permeameter closed, and a magnetizing current of 0.66 amperes. The oil-reversing switch was used in taking this oscillogram. A study of this oscillogram shows that the secondary e. m. f. continues for 1.7 second, as against 3.9 seconds, shown in oscillogram 9, Fig. 6, taken under identical conditions, except as to the ends of the brass spool.

The investigation of the reversal of the current also brings out the importance of avoiding short-circuited paths in which eddy currents may be set up by the reversal of the magnetic flux.

Silicon Steel Permeameters

A number of tests were made with these two permeameters. Two of the oscillograms, 12 and 13, which were taken under the same conditions are reproduced in Fig. 9. Oscillogram 12 is for the solid silicon steel core permeameter and 13 for the laminated silicon steel core. A study of these shows that it required 0.23 seconds to reverse the current in the solid core permeameter compared to 0.08 seconds to reverse the same number of ampere turns in the laminated-core permeameter. The oil-reversing switch was used in both cases and the magnetic circuits were closed. In both cases the secondary e. m. f. dropped to a negligible value by the time the reversal of the current was completed. This test brings out the superiority of the laminated-core permeameter as far as the time of reversal of the magnetizing current is concerned.

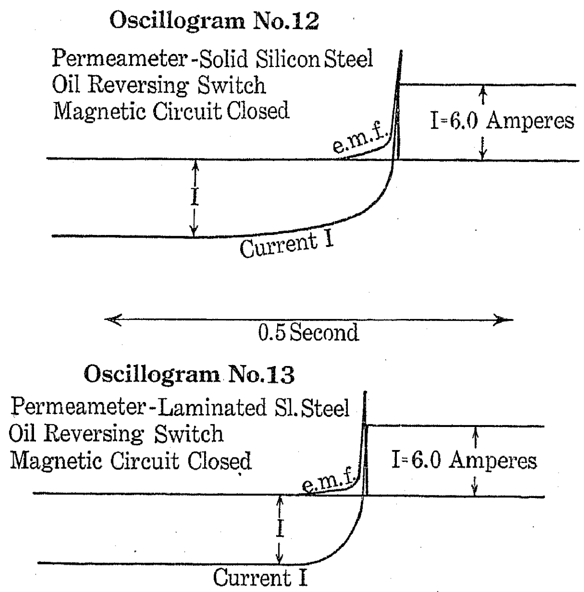

Fig. 9

Conclusions

The results of this investigation bring out clearly: *First,* the necessity of avoiding the presence of any unnecessary short-circuited path, which is cut by the flux of a permeameter. The frame upon which the coil for measuring the flux through the specimen is wound should be of such construction as to prevent the flow of eddy currents.

Second, that the use of a switch operating under oil will shorten the time of breaking the current.

Third, that the laminated-core type of permeameter will materially reduce the time required for the reversal of the current and thereby make the use of a short period ballistic galvanometer possible in magnetic testing. This will reduce the time required for a test.

The authors wish to thank Mr. H. C. Willis and Mr. W. C. Ball, postgraduate students in Electrical Engineering at The Johns Hopkins University, for their assistance in preparing this paper.

Discussion

S. L. Gokhale (by letter): In this discussion I intend to limit my remarks to two points, namely:

(1) The choice of the ballistic galvanometer for permeametry.

(2) The use of shunts to control the currents in the several magnetizing coils of a permeameter.

These remarks have reference to findings No. 1 and 3 in the 'conclusions' of the paper under discussion.

In the history of the ballistic galvanometer there was at one time the belief, that a ballistic galvanometer should have little or no damping if it is intended to function properly as a ballistic galvanometer. It is beginning to be recognized now, that the relation of ballistic function to freedom from damping is purely accidental, and that an overdamped galvanometer is not only as good, but in fact much better than the undamped galvanometer for purpose of ballistic measurement.

A ballistic galvanometer is a galvanometer for measuring an electric impulse by transforming it into a mechanical momentum in the first place, and subsequently into a deflection, in which form the impulse is ultimately measured. The impulse under measurement is either directly a current impulse $\int$ idt, or a votlage impulse $\int$ edt (although this also is converted into a current impulse before it affects the galvanometer). In the first case the total impulse is expressed as a charge or quantity of electricity: $\int \mathrm{idt} = Q$. In the second case the impulse which is generated by change of magnetic interlinkage is expressed in terms of equivalent flux change, $\int \mathrm{edt} = n \, \Delta \, \phi$. A ballistic galvanometer used for measuring $\int$ idt or Q may be called a quantometer; when used for measuring $\int$ edt or $\Delta \, \phi$ it may be called a flux meter. The relation of Q to θ or of $\Delta \, \phi$ to θ, (where θ represents the deflection), expressed generally as a graph, is the calibration of the galvanometer. (The term quantometer, used in the sense of fluxmeter as I have defined fluxmeter above, was first used by Mr. R. Bettie in the *Electrician* Dec. 25, 1902, p. 383).

The calibration of a ballistic galvanometer, may be obtained either empirically by a direct measurement of a known impulse, or indirectly by mathematical computation based on dynamic principles. In the latter case, the necessary data to be used as a basis of computation is obtained by measurements with a steady direct current, of known amount. The legitimate use of the dynamic formula involves in theory the fulfillment of two conditions, (1) long period, and (2) no damping. From this point of view a ballistic galvanometer may be defined as a galvanometer of long period and little or no damping. The first condition was easy to fulfill and was little thought of. The ballistic galvanometer thus came to be defined merely as a galvanometer of little or no damping. It is so defined even now in college textbooks, and dictionaries.

But times have changed; ballistic galvanometers for magnetic measurements are now generally calibrated directly by measurement of a known flux or interlinkage. The calibrating standard (which is frequently a mutual inductor) has its secondary coil in series with the test coil and galvanometer. Under these circumstances damping has no influence on the final results.

On the contrary, damping has some decided advantages, particularly when the damping is electromagnetic and follows the law.

$$r = - c. \, d\theta \, / \, dt$$

i. e., the resistance to motion due to damping is proportional to the angular velocity.

When an impulse is made up of two equal and opposite impulses with an interval of time between them, the total impulse being zero, the resultant deflection ought to be zero also. Such a case arises in the Bureau of Standards method of measurement by the compensated double-yoke permeameter. With an undamped galvanometer, it is impossible to say when the flux in the various test coils is balanced. Users of the compensated double-yoke permeameter are therefore compelled to use some type of over-damped galvanometer; the Grassot's fluxmeter seems to be the most popular (A. I. E. E. 1915 p. 2602, Fig. 2 B) although I prefer a regular ballistic galvanometer with a high internal resistance in the form of active copper.

The superiority of the overdamped galvanometer over the underdamped, may best be demonstrated by the following experiment:—

A ballistic galvanometer practically undamped when used with a high resistance *Rg.* in series with it, is connected as shown in Fig. 1. The reversing switch is operated with the key down. The impulsive emf. produces a ballistic deflection. The key is then released; under the influence of the critical damping shunt, the galvanometer returns to zero and comes to rest, without any

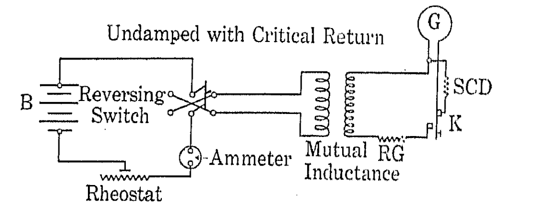

Fig. 1—Scheme of Wiring for Undamped and Overdamped Galvanometers

oscillations and with the least possible delay. The time taken up in the forward movement is ¼ of the complete free period. The time for return to zero is practically equal to the free period. During this time the reversing switch is generally brought back to the original normal position, so as to be ready for a second throw. The current is adjusted so as to produce a ballistic deflection of 100 mm.

The reversing switch is now operated forward and backward with the key down throughout the double operation. The final effect on the galvanometer ought to be zero; but the actual effect is positive or negative, large or small depending on the interval between the two reversals. It is never zero except by chance.

A low-resistance shunt *Sg* is now connected as shown in Fig. 2, reducing the resistance *Rg* until the deflection for the single reversal

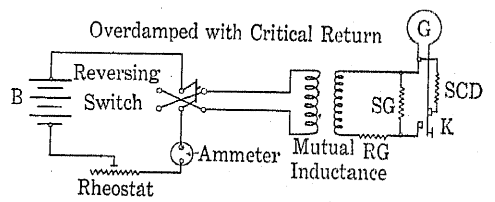

Fig. 2

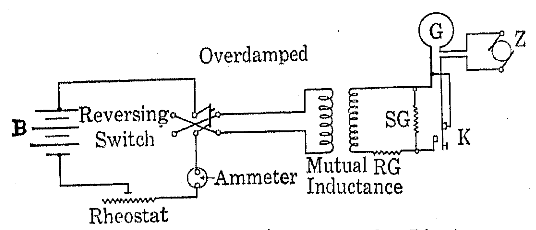
is 100 mm. as before. It will now be seen that the double reversal produces a double kick, the final result being a zero deflection as it ought to be. With a highly overdamped galvanometer the resultant deflection is zero even when the two reversals are separated by an interval of several seconds. Instead of the critical damping shunt, it is now the practice of our laboratory to use a zero-setting inductor Z (Fig. 3). Instead of waiting for the galvanometer to come to zero, the operator is then able to bring it to zero much more quickly and easily by turning the knob of the inductor.

As to the oscillographic study as a research by itself, Messrs. Kouwenhoven and Berry are entitled to credit for patience, and care with which the work seems to have been done; so to the practical value of the research, I expect the contribution to prove of value somewhere, but I fail to see its usefulness in perme-

ametry. For example, the authors have demonstrated the superiority of a laminated core over a solid core, in permitting the use of a short-period galvanometer (presumably undamped) in order to shorten the time spent in the test. This sort of solution ignores the nature of the problem.

The problem which confronts us in permeametry is not the choice of a test sample to suit our galvanometer, but the choice of a galvanometer to suit the sample. I had an occasion once, to measure the flux in the shaft of a turbo-generator. In such a case, a laminated sample for test is out of the question and one must choose his galvanometer to suit the material as it is. The research in question, was obviously undertaken with the behavior of undamped galvanometer in view. But as I said before, the times have changed. Twenty-two years ago Mr. R. Bettie demonstrated the possibilities of an overdamped galvanometer, and its immunity against errors due to slow or interrupted magnetic changes. (*Electrician*, Dec. 25, 1902, p. 383). In 1913 I had commenced an oscillographic study of the reversing switch, in connection with some difficulties I encountered in my experiments on the well known "Burrow's method," but the overdamped galvanometer seemed to be a complete solution of our difficulties and the oscillographic study was therefore discontinued.

It is true, that an overdamped galvanometer when deflected is very slow in coming back to its zero position; but one need not infer from this that such a galvanometer is slow for use, the fact being just the reverse. When a momentary impulse is applied, the overdamped galvanometer jumps almost instantly to the



Z = Zero Setting Inductor (Faraday Disc.)

FIG. 3

final position, where it stays long enough to take the reading conveniently; then it starts to creep back slowly, and would be several minutes in reaching zero if we had to depend entirely on its own free motion. It can however, be brought to zero very quickly by the zero setting inductor, or quicker still by reversing the first impulse when such reversal is possible and permissible, as it always is in permeametry. Consequently, the overdamped ballistic galvanometer is not only more accurate, but it is also easier to read and far more expeditious to use.

Messrs. Kouwenhoven and Berry have reached the conclusion that it is necessary to avoid a short-circuited path which is cut by the flux of a permeameter. This fact has long been known and has long been recognized as a serious obstacle in the way of simplification of modern permeametry. In Burrows' permeameter there are several magnetizing coils which call for independent adjustment of current. Dr. Burrows has recommended the separate-circuit system with separate reversing switches. At first we followed this plan, using a long-period ballistic galvanometer without damping; but the balancing of the circuit proved an impossible task. We therefore abandoned the separate circuits and substituted for it a system of divided circuits such as was partly used by Dr. Burrows. This was a considerable improvement, but not enough. About this time I discovered, (what was already well known to others), that an overdamped galvanometer was the best remedy for the trouble. At this time I learned also, that with such a galvanometer, I could use separate circuits just as easily as the multiple circuit. But both methods had their advantages as well as disadvantages. The separate circuits involves the use of a gang switch, which becomes a very complicated affair when the measurement is extended to hysteresis. The divided-circuit system does not need a complicated gang switch so far as permeability measurements are concerned, but it is not available for hysteresis

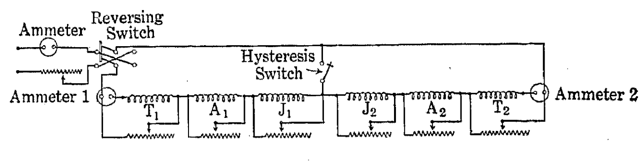


FIG. 4—SCHEME OF WIRING WITH FRACTIONIZING SHUNTS (UNCOMPENSATED)

measurements. A third conceivable system is the series system in which the several magnetizing coils are connected in series, the necessary independent control being obtained by the use of separate shunts for the several coils, see Fig. 4. Here we meet the condition referred to by Messrs. Kouwenhoven and Berry. Such a system, if it were permissible, would simplify the work considerably; but is it permissible? It is possible that the shunt would retard the change of flux in one coil much more than in

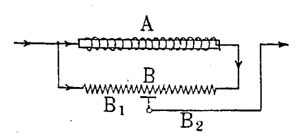

FIG. 5—FRACTIONIZING SHUNT (SELF-COMPENSATING)

A Magnetizing Coil
B Compensating Rheostat Shunt
B_1 Shunt Section
B_2 Compensating Section

the other. The difference of time might be so great as to make the balancing of the several circuits extremely difficult if not absolutely impossible. It is however possible to minimize the evil by the use of a self-compensating shunt, see Fig. 5. In this arrangement a part of the rheostat acts as a shunt and the other part as a self-compensating series resistance. The total resistance of the local circuit is therefore high and remains constant, being unaffected by the setting of the shunt. This scheme

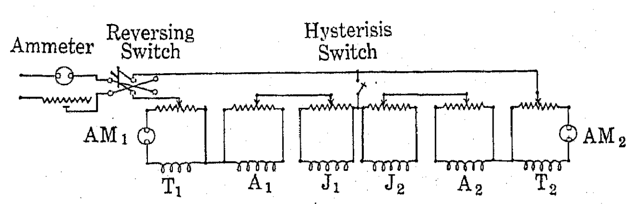

FIG. 6—SCHEME OF WIRING WITH FRACTIONIZING SHUNTS (SELF-COMPENSATING)

of wiring has been incorporated in the permeameter equipment of the General Engineering Laboratory of the General Electric Co. and has proved very simple and expeditious. (See Fig. 6.) This diagram represents schematically the complete magnetizing circuit, omitting the auxiliary apparatus. Section 1 is used for permeability tests up to H 25, the coils T_1, A_1 and J_1, being the three magnetizing coils characteristic of the Bureau of Standards method. Section 2 is an exact copy of Section 1, except that its polarity is reversed. Normally this section is cut out by means of the short circuiting switch "Hys.". When this switch is

opened, the coils T_2, A_2 and J_2 become operative and the resulting value of H is less than that produced by section (1) alone. This gives a point on the hysteresis loop. Section 3 (not shown in the diagram) contained more layers of coils T and A which raises the magnetizing force to 200 gilberts in steps of 25 gilberts or less as required. Tests for permeability are made by operation of the reversing switch alone, and for hysteresis, by the operation of the single switch "Hys". A complete discussion of the permeameter and the method of using it would be beyond the scope and purpose of this discussion. I have mentioned it here merely to show how by means of the self-compensated shunt, we avoided the difficulty referred to by Messrs. Kouwenhoven and Berry and at the same time eliminated the gang switch, which has always been since its invention, the dread of the operator who had the task of manipulating it.

W. B. Kouwenhoven: Mr. Gokhale's discussion of our paper and his description of the method he uses in operating the Burrow's Permeameter is of interest and value. Mr. Berry and I refer to an entirely different instrument, namely the Simplex Permeameter. This instrument is built with a U-shaped yoke usually of solid material. We found that better results could be more quickly obtained if the yoke were made of laminated material. Nothing was said regarding the use of laminated specimens. In our work an overdamped galvanometer was used when needed.

Mr. Gokhale states in his discussion that he fails to see the value of this paper, and in reply I will say, that, at the June Convention of the A. S. T. M., the engineers of two of our large electrical companies told me that they were now using laminated core simplex permeameters with excellent results.

Power Plant Auxiliaries and Their Relation to Heat Balance

BY A. L. PENNIMAN, Jr.
Associate, A. I. E. E.
Consolidated Gas, Electric Light & Power Co., Baltimore, Md.

Review of the Subject.*—In the larger central station steam plants, efforts to increase the over-all economy and ease of operation were responsible for the use of motor-driven auxiliaries receiving their power from auxiliary turbogenerators, called house turbines, the exhaust from which is used for heating feed water. This scheme is reliable and economical. It is handicapped by the fact that over a considerable range of load some of the auxiliary power must be taken from the main bus or some of the energy generated must be fed to the main bus. This resulted in transfer motor-generators, etc., which were additional complications.*

Still greater economy is possible by bleeding steam from the low-pressure stages of the main unit to heat the feed water. Considerable heat that would otherwise be rejected with the condensing water is reclaimed, thereby allowing of a smaller condenser than would otherwise be required, the performance of the main turbine also being improved due to somewhat relieving the congestion of steam in the low-pressure stages.

To utilize fully the advantages of stage bleeding, the auxiliary power must be obtained from the main turbine. In order to insure an uninterrupted supply of auxiliary power to the essential drives it is suggested that an auxiliary generator be connected to and driven by the main turbine, thereby supplying the necessary reliability as long as the main turbine is available for load.

Due to the advantages of variable speed drive for circulating pumps, boiler feed pumps, etc., and the necessity of having direct current for excitation, a direct-current generator may be used to advantage. The use of the direct-connected auxiliary generator with stage heating, gives a maximum of flexibility, is especially reliable in that it entirely eliminates all small turbine and gear troubles, and permits of the use of the unit scheme of grouping and supplying auxiliaries, with what appears to be a maximum of economy at no apparent increase in cost.

Furthermore, the use of closed heaters with the fresh water storage located within the condenser hot well seems to offer an economical and highly satisfactory solution for the de-aeration of the feed water and to eliminate the possibility of the water picking up further air after leaving the condenser.

THE steam power station designer is confronted by the following basic requirements:

1. Maximum reliability is essential for the existence of the enterprise.

2. Economy demands that the station heat cycle approach the Carnot cycle as nearly as possible. This results in getting the maximum percentage of heat units fed into the furnace delivered to the station bus in the form of merchantable power.

3. Simplicity and flexibility of operation so that the calculated results may be obtained with minimum effort under wide variations in load, temperature and in the quality of fuel obtainable.

4. The proper balance must be maintained between initial outlay and cost of fuel so as to produce power at the minimum net cost per unit, including fixed charges as well as operating expense.

The all-steam-drive type of auxiliaries has been developed to a high state of reliability. It is economical at that station load which will utilize all of the exhaust steam. The economy decreases with the load, becoming very uneconomical at low loads. Where turbine drive is used, the economy of the auxiliary turbine falls off with reduction in speed. This is an important consideration, as the demand on practically all auxiliaries decreases with the load on the station. The cost of auxiliary steam and exhaust piping is quite a factor inasmuch as the surface exposed to radiation is large. With the advent of higher steam temperatures, the reliability of the auxiliary turbines will be decreased, while the first cost and maintenance cost will be greater.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

The all-electric-drive with power obtained from the station bus is simple to operate, but is not reliable as any disturbance on the transmission system may affect the station auxiliaries. Electric motors and controls have been developed to a high state of perfection and of themselves are very reliable, take up a minimum of space and require but little attention, the maintenance cost being lower than is the case with steam-driven auxiliaries.

The feed water may be heated by bleeding the main unit to open heaters which except in the case of specially designed turbines is not very economical unless bleeding takes place at several points so as to always bleed the steam at slightly above atmospheric pressure with variations in load. Special bleeder valves must be used in order to insure the safety of the unit in case of total loss of load.

Efforts to obtain the reliability of steam drive without the attending disadvantages, together with the advantages of electric drive without the questionable reliability of securing the current for motors from the main bus, resulted in the house turbine which has the additional economical advantage of lower water rate than individual steam auxiliaries, due to their relative size, which is further augmented when the house turbine is operated at partial vacuum. The house turbine gives a clean layout due to the absence of numerous steam and exhaust lines, is reliable and simple to control. The water rate is not so good as that of the main unit and the dual transformation of power from mechanical to electrical and back to mechanical is seldom more than 80 per cent efficient. Due to the advantages of variable speed drive which is most economically obtained by the use of d-c. motors, the house turbine must either drive a d-c. generator through a reduction gear with its attendant disadvantages or a rotary convertor must be used which still further reduces the efficiency of conversion.

Inasmuch as all efforts for economy point towards the utilization of low-temperature heat and towards the most economical source of auxiliary power, attention in both cases is directed to the main unit.

The main unit is inherently more economical than any of the smaller auxiliary turbines or the house turbine. In it the steam expands to the lowest pressure compatible with the available condensing water. Obviously, therefore, if steam is bled from a number of successive stages of the turbine and used to heat the feed water which is passed successively through surface heat interchangers, the power obtainable from a given amount of steam will be greatest when that steam is bled at the lowest pressure, and the power obtainable per lb. of steam will decrease as the pressure at which the steam is bled increases. Inasmuch as the condensate is usually cooler than the exhaust steam entering the condenser it would be most economical, theoretically, to bleed steam from each of the lower stages of the unit. Practical considerations will probably limit the bleeding to three or possibly four stages, the highest temperature stage being able to deliver relatively hot feed water at light loads. It must be remembered that steam bled from the main unit decreases the congestion in the low-pressure stages of the turbine, thereby improving the total performance of the unit somewhat and also decreases the duty on the condenser.

It is quite probable that still greater amounts of low head heat can be bled from the turbine prior to rejection to the condenser and used to preheat combustion air for the boiler furnaces. While bleeding steam to preheat air is somewhat novel and requires some further development of heat interchangers for this purpose, it shows considerable thermal gain. Present types of stokers using forced draft can handle air up to a total temperature of several hundred degrees Fahr. without any great difficulty. Complications would undoubtedly result from the attempted use of 300 deg. air on pulverized-coal-fired furnaces where air-cooled furnace walls are used. In the writer's opinion, however, the air-cooled powdered coal furnace is destined to be short lived, due, first, to the fact that it is obviously uneconomical to allow high head heat, which should be utilized directly for generating steam, to be used for preheating furnace air when there is so much low head heat readily available; secondly, the air-cooled furnace has not been entirely successful, the furnace maintenance undoubtedly being very high and the time the boiler is out for furnace repairs must be a considerable percentage of the service hours. The solution of this question would seem to lie in the development of a boiler and furnace so designed that the water heating surfaces absorb a large percentage of the heat which is now taken up by the furnace walls. This will allow of still higher furnace temperatures with the attending increase in efficiency.

It would, therefore, seem that the greatest opportunity for economy lies in the use of power from the main unit for auxiliary drive, this power being applied as directly as possible, together with the use of the maximum economical amount of low-temperature steam bled at several points from the main unit. The question now arises as to whether this scheme provides the essential flexibility and ease of operation.

By the use of motors it is possible to obtain compact drives, reduction gear troubles are eliminated and the mass of auxiliary steam, exhaust and water-cooling pipes is eliminated. Where d-c. motors with field control for speed variation are used there is no appreciable decrease in economy of the drive with decrease in speed. When properly designed ball bearings are used, practically no attention is required and the units may be started, stopped or the speed varied from remote points. The steel industry has investigated the ball-bearing motor very thoroughly and have made out a very strong case in its favor. Due to their location it is desirable to be able to control the speed of forced and induced draft fans and the stoker and clinker

grinder motors from the boiler room firing floor, and they are usually so located as to make it impracticable to give them relatively continuous attention without having special attendants at the several elevations where they are located. Boiler-feed and house-service pumps should also be capable of operating under the control of automatic regulators with a minimum of attention. Variable-speed d-c. motors lend themselves to this form of control just as readily as do steam turbines without the attendant change in economy with change in speed and without the attention and troubles incident to turbine packings, bearings and the possibility of damage due to overspeed on account of loss of load.

When the extra storage of boiler water is located in the hot well of the condenser and the makeup admitted directly to this hot well it is feasible to keep the water in the hot well at the temperature of the exhaust steam by raising the temperature of the hot well by the condensate from the lowest temperature feed heater, plus some additional steam bled from the last stage of the main turbine when necessary. This eliminates the use of de-aerating apparatus and makes possible the location of the make-up float valve so that it is readily accessible to the condenser attendant who can also look after the boiler feed pumps. The division of duty between the hot-well pumps and boiler-feed pumps can be so arranged as to allow minimum water pressure on the closed heaters compatible with reliable operation. The hot-well pump can be run at constant speed, the total speed variation being taken care of by the boiler-feed pump. The duty on the circulating pump can be varied to compensate for changes in load and of circulating water temperatures. This eliminates the necessity for the use of two pumps of reduced size, one being used for cold water or light loads, two for warmer water and high load; it being possible to obtain somewhat better performance by using one pump and varying the speed. Where two pumps are used for added reliability it is more economical to run both at reduced speed than to shut one down and speed up the other. Practically the same reliability can be secured by interconnecting the discharge lines on adjacent condensers and providing somewhat larger driving motors, thereby enabling one pump to serve two condensers in emergency with only a slight reduction in vacuum. By the use of a properly-designed motor the large low-speed circulating pump becomes the most reliable piece of auxiliary equipment.

The static or steam jet type of vacuum pump has proved very reliable in marine service and is becoming increasingly popular in central station service. When equipped with inter and after condensers, using condensate, and located respectively before and after the low-temperature bleeder heater, they provide a compact and reliable unit whose performance compares very favorably with a hydraulic or reciprocating air pump at a somewhat smaller first cost, and should show a lower maintenance cost and require less attention than either of the other types. The air and non-condensible vapors from the bleeder heaters can be discharged directly to the inter-condenser thereby lowering the duty on the primary jets, which should use the minimum of steam possible as it is desirable from an economical point of view to do nothing which will limit the amount of steam bled from the main unit to the low-temperature heater. Most of the operating difficulties experienced with steam jet air pumps have been due to poor performance on the part of the reducing valve supplying steam to the jets. This may be entirely eliminated by the use of a properly-designed orifice installed in parallel with either a hand or solenoid operated valve which may be opened either manually or automatically in case of a drop in steam pressure.

Since stage bleeding together with electric drive offers opportunity for higher efficiency with a maximum of flexibility at a cost as low or lower than with any other form of auxiliary drive, it now remains to provide an arrangement for obtaining power from the main units in such a manner as to guarantee continuity of auxiliary power supply eliminating all chance of trouble on the main bus being transmitted in any manner to the auxiliary bus.

All power plant auxiliaries fall into three general classes with respect to the necessity of their having a continuous power supply.

First, equipment which does not require a continuous power supply, such as coal and ash handling equipment, circulating water screens, sump pumps, machine tools, etc. This class of equipment can be eliminated from the present discussion as continuity of service is not essential.

Second, the auxiliaries which are needed only when the station is carrying load and which have to be shut down in case of an interruption which greatly reduces the plant load. To this class belong forced and induced draft fans while coal feed and clinker grinder drives might well be included as they are normally supplied from the same circuits as supply the fans. As it is essential to check the fires as soon as a general interruption occurs it is an advantage to have fan motors trip out due to low voltage. Where automatic starting panels are used, the service is automatically restored as the main bus voltage comes back. In actual practise following a general interruption the station load does not come back immediately after the restoration of full voltage it usually being at least ten minutes after the restoration of service before the load is normal. This allows ample time for furnace conditions to become normal. Where the nature of the interruption is such as to result in low frequency and somewhat lowered voltage, trouble may be experienced in holding the motors on the line due to the operation of the low-voltage relays. This can be readily overcome by arranging to throw the affected motor controls on the station control battery. The individual controllers can then be brought up to full speed setting until the

trouble is cleared, should this be necessary. Where the total number of boilers is comparatively few the contactors can be provided with a mechanical latch which will hold them in the full-speed position.

It is of course essential that the proper safeguards be used to minimize interruptions due to failure of the transformers, circuits and switching equipment between the main bus and the several motors.

The writer has operated a fairly large generating station for about five years where the boiler auxiliary drives were fed from the main bus. There have been in that time the usual number of system interruptions and

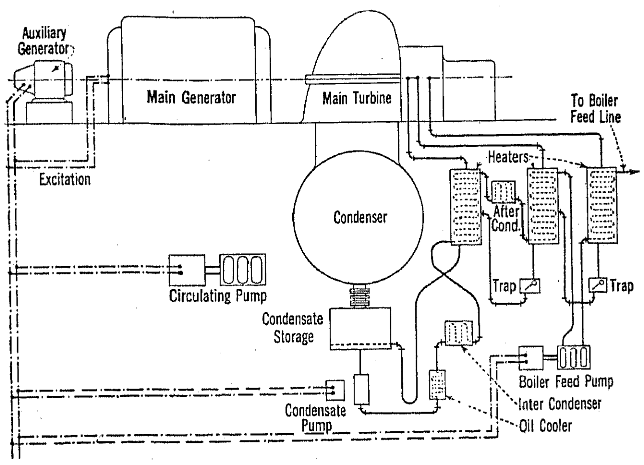

Fig. 1

disturbances without in a single instance causing any embarrassment due to inadequate power for the stoker fan and coal feed motors. It is the regular practise to have in service two banks of transformers either of which is of sufficient capacity to carry the essential service. The two transformer banks are supplied from either end of the main bus, each serving one-half of the auxiliary circuits and the other plant auxiliary load. The transformers are protected by necessary relays. The switches are so interlocked that if either high-tension transformer switch opens the corresponding secondary switch opens which in turn causes the switches supplying the non-essential auxiliary circuits to trip and parallels the two sections of the low-tension station service bus.

Third, the auxiliaries, which it is essential to keep in service in order to insure continuity of service and which it is essential to keep in service during times of interruption, are the exciters, boiler feed pumps and circulating pumps. Where the boiler-feed make-up storage is a part of the condenser hot well it is also essential that the hot-well pumps be kept in service.

The service for this third class of auxiliary drive can be most economically and advantageously supplied by a separate generator connected directly to and driven by each of the main turbine units.

Direct-connected exciters have been in quite general use for a number of years and have been so satisfactory that there seems to be no reason why the size of this piece of apparatus should not be increased sufficiently to take care of the additional load imposed by the so-called essential auxiliary drives. This auxiliary generator need be relatively small, in fact only about two and one-half per cent of the capacity of the main unit. This arrangement will require, as does the direct-connected exciter some auxiliary source of power for starting up. This can be taken care of by a motor generator, supplied from the house service transformers which if necessary can be equipped with a non-condensing turbine, exhausting to atmosphere, for starting up in case of a complete shutdown of considerable duration.

The attached sketch shows such an arrangement for a 25,000-kv-a. unit. The auxiliary generator is rated at 500 kw. 250 volts direct current. A 3000-gallon water storage will be provided in the condenser hot well. Three-stage bleeding will be used, the condensate from the high and intermediate temperature heaters will be trapped back to the next lower-temperature heater while the low-temperature heater condensate will be trapped back to the hot well where it will be used to heat the condensate and make up to the boiling point in order to drive off entrained air.

It will be noted that this scheme provides auxiliary power from the most efficient source, allows of the most economical scheme of feed heating without any complications. The auxiliary wiring is on the unit principle, the auxiliaries and generator being grouped together do not require long runs for low-voltage auxiliary feeders and there is no transformation loss in obtaining direct current for these drives. Careful analysis would seem to indicate that this scheme provides the necessary reliability without calling for any compromise that affects the economy of the general layout, at a first cost no greater, if not actually less than any of the arrangements in general use, with a maximum of flexibility of operation at varying loads, with a minimum of operating attendants.

Discussion

H. W. Brooks (by letter): Mr. Penniman's paper is of intense interest to many designers now working on *new* plant construction. There is, however, a vast field for application for heat-balancing devices in plants designed prior to the last three to five years as there are undoubtedly enormous losses taking place in many of these older plants owing to lack of proper heat balance. In private consulting practise last year the writer encountered a very interesting problem of this character in the plant of the Chicago, Aurora and Elgin Railroad Co. at Batavia, Ill., where a dual-drive exciter set of 300 kw. capacity was finally designed in cooperation with the manufacturer. The steam end consisted of a 200 lb. pressure, 150-deg. superheat, non-condensing, direct-connected turbine of the impulse type, while the electric drive end consisted of a three-phase, 25-cycle, 2300-volt, phase-wound, induction motor, both machines being direct-connected to the 300 kw. generator mounted between them and functioning at 750 rev. per min.

It will be noted from the following functions performed by this set that it covers all of the merits of the basic Clarke patents

on dual-drive heat-balancer sets and in addition covers automatically a number of new functions not heretofore performed automatically, and by so doing eliminates attention on the electrical end of the set previously required by either the operator on the engine-room floor or the switchboard operator. The complete functions of the set follow:

1. In case of failure of voltage on main a-c. generators motor cuts out and d-c. load is taken by the turbine.

2. In case of failure of frequency on main a-c. generators motor cuts out and d-c. load is carried by turbine.

3. In case motor is tripped out on account of under voltage it is restored to the line upon resumption of proper voltage.

4. In case motor is tripped out on account of low frequency it is restored to the line upon resumption of proper voltage.

5. In case of reversal of a-c. power caused by the induction motor, driven as an asynchronous generator, motor is tripped out and entire load carried by turbine and after turbine speed has been so reduced as to restore normal direction of flow on the alternating-current line motor is restored to the line.

6. In case of accident to the a-c. motor, motor trips and latches out and load is carried by turbine until such time as motor is repaired.

7. The various relays such as the frequency relay, selective watt relay, etc., are arranged with suitable interlockers in connection with the low-voltage relay equipment and the starting equipment so that each will operate independently.

8. Motor is capable of being thrown on the line either from zero speed or from full speed, which latter condition occurs when the set is started from the turbine end.

9. On reversal of d-c. power the d-c. breaker is open but need not necessarily be recloseable automatically upon restoration of normal direction of power flow. Should this occur, however, the steam and control must trip automatically to prevent running away of the machine in case low feed-water temperature should cause high-pressure valve at that time to be open.

10. Secondary motor control is entirely automatic, functioning at all times as the primary or breaker functions.

11. In general, in the event of any accident to the motor the turbine picks up the load and carries any part or all of it, and similarly in the event of an accident to the turbine the the motor must instantly pick up the load and carry any part or all of it. The combination is so arranged that the turbine will carry variable loads automatically normally, dependent upon the amount of steam necessary to pass through the turbine to keep the feed-water temperature up to 212 deg., the motor automatically pulling the balance. Load is automatically shifted from one method of drive to the other in such manner that the regulation of the direct current supplied will not be visibly affected.

12. Normally the turbine exhaust is automatically regulated in such manner as to pass only sufficient steam through the turbine to supply necessary exhaust steam heat to the incoming feed water so that no steam is lost by exhausting it to the atmosphere, the remaining load being carried by the motor.

13. Emergency features, however, are provided on the turbine as above mentioned so that if for any reason the electric supply to the motor should be cut off, the turbine would automatically open its valves and continue to drive the exciter without any interruption in the supply of excitation, even if by so doing considerably more exhaust steam would be supplied than would be necessary to raise the feed water to 212 deg., which means that in such abnormal circumstance exhaust steam would be wasted into the atmosphere.

Frank G. Boyce (by letter): I agree with the author that it is desirable to approach as near as possible all-electric drive for auxiliaries. However, I feel that it is good practise to have at least one boiler feed pump in the plant which is steam-driven, the thought in this being that continuous supply of water to the boilers is absolutely necessary in modern plants where the storage capacity in the boilers is reduced to a minimum and with the tendency towards higher ratings. It seems both economical and desirable to bleed the main turbines for stage heating of the feed water and preheating the combustion air for stokers.

I would suggest that instead of a direct-current generator being used mounted on the end of the main turbine shaft for source of auxiliary power, an alternating-current generator be used for this purpose and that the shaft be further extended to provide space for an exciter. The reasons why I would suggest this instead of the scheme suggested by the author are as follows:

1st, I am rather inclined to believe that the reliability of the unit would be somewhat reduced if the excitation were taken from the same generator which supplied power to the auxiliaries around the plant, so that troubles in the various motors and equipment would be transmitted to the field circuit and rotor, which might cause interruptions to service from the main unit.

2nd, I would suggest that the boiler feed pumps be driven by constant-speed alternating-current motors, except one emergency pump which should be steam-driven. This arrangement works very satisfactorily and instead of maintaining a constant differential pressure between the feed water and the boiler pressure, a constant feed-water pressure is held somewhat above the normal steam pressure. This will operate perfectly satisfactorily with modern types of boiler feed regulators. This, therefore, eliminates the necessity for variable-speed direct current motors on boiler feed pumps.

Of course, variable-speed drive for stokers is necessary and this could be obtained very nicely by the use of two rotary converters of sufficient capacity to furnish power for only the stoker motors. This makes a rather economical installation. However, it is also possible to obtain stokers driven by hydraulic pistons which eliminates the necessity for direct-current variable speed on the stoker drive.

The only drive now for which direct-current variable-speed motors seems necessary is condenser pumps. I suggest that a very economical arrangement is two pumps of different sizes installed on the condenser, one pump to be used at light load, a larger one at medium load, and both pumps to be used in case of very warm circulating water or heavy overloads.

I believe that the installation as mentioned, eliminating the direct-current variable-speed motor drives, will give as good satisfaction, will be more reliable, and the cost per kilowatt of investment will be less.

A. L. Penniman, Jr.: The discussion, by letter, of Frank G. Boyce admits the desirability of all-electric drive. The writer agrees that there should always be one boiler feed pump in a plant which is steam driven. This should be for purely emergency purposes and should take its suction from the service water supply. The turbine driving this pump may properly be allowed to exhaust to the atmosphere, as it will run only on very infrequent occasions.

Mr. Boyce's suggestion that an a-c. generator be direct connected to the main turbine shaft for auxiliary power is entirely feasible. It might be somewhat cheaper than a d-c. generator. A-c. motor drive for auxiliaries might also be slightly cheaper than d-c. motors. The combined efficiency of the generator and motors would, of course, be lower where alternating current is used with the motors running at reduced speed. In the writer's opinion the alternating current would be somewhat more reliable, due to the elimination of commutators and due to the fact that a short circuit could be much more readily cleared up than if direct current be used.

Variable speed motors driving the boiler feed pump are advisable though not necessary. On the closed system outlined in the paper the duty can be so divided between the hot-well pump and the boiler feed pump that the bulk of the work is done by the hot-well pump, leaving a relatively small amount for the boiler feed pump. The hot-well pump may then be driven at constant speed, the desired pressure being maintained by varying the speed of the boiler feed pump motor. It would seem that this

motor need be capable of carrying only 25 per cent of the power desired by the two pumps when both are operating at rated capacity.

The proof also includes a statement from the JOURNAL of Of February, 1924, having to do with the so-called Clarke Patents on dual-drive exciter sets in which, what are apparently the claims of the Clarke patent are stated as functions performed when the house generator is driven from the main turbine shaft. This, of course, is not a matter of fact, as the writer cannot conceive how, under normal conditions, the main generator can be driven by the main turbine and in turn supply the power for driving the auxiliary generator which is hooked on the same shaft. There can be no question that the auxiliary generator is driven by the main turbine. It is not called on to perform any of the functions performed by the dual-drive exciter.

The writer's scheme permits of taking the maximum advantage of stage bleeding from the main unit, and at the same time obtain a reliable source of power for auxiliaries by driving the auxiliary generator by the main turbine. Whether the generator supplies alternating current or direct current is largely a matter of personal preference of the designer and balancing the increase in first cost of direct current against its economy in operation.

Shaft Currents in Electric Machines

BY P. L. ALGER and H. W SAMSON

Member' A. I. E. E.

Both of the General Electric Company

Review of the Subject.—*This paper describes the causes of, and remedies for, the existence of "shaft currents" or "bearing currents" which sometimes flow across the rubbing surfaces of the bearings of electric machinery, thereby gradually damaging the shaft and bearings.*

Up to the present time the only cause of shaft currents that has attracted any particular attention has been the use of sectionalized stators, and the published discussions have been chiefly confined to synchronous alternators. Fleischman[1] and others have shown that sectionalizing causes shaft currents for the reason that the extra reluctance of the joints causes an unequal division of the flux between the clockwise and counter-clockwise paths in the yoke, thus giving a resultant flux linking the shaft.

Applying the same method of reasoning used in the case of sectionalizing to the general case of any machine with segmental punchings, the following facts are shown:

1. *A principal cause of shaft currents in revolving electric machines is the use of poles and segments in certain ratios.*

2. *The frequency of the shaft current due to joints in the stator yoke is an odd multiple of the frequency of the stator flux, the frequency of the shaft currents due to rotor joints is an odd multiple of the rotor frequency, and these frequency multiples are determined by the ratios of poles to segments.*

3. *Machines with 4, 8, 16, 24, 32, etc., poles are especially likely to have shaft currents, and machines with 6, 10, 14, 22, etc., poles are relatively immune.*

4. *By the proper choice of the number of segments for use with any machine, or by the use of segments with offset dovetails, or both, shaft currents can be effectively eliminated in most cases.*

The possibilities of shaft currents being caused by homopolar action as the result of magnetic flux flowing in the shaft, or by other means, are discussed, and it is concluded that such causes are seldom important. A possible useful application for the theory of shaft currents in the design of a high-current transformer is mentioned, and the possibility of obtaining multiple frequencies from a stationary transformer in this way is shown to be dependent upon the presence of magnetic saturation.

A table of combinations of poles and segments that will cause shaft currents is given, and a bibliography of the subject is appended.

1. Reference No. 8.

CONTENTS

INTRODUCTION

A common source of trouble in revolving electric machines is the presence of electric currents flowing across the rubbing surfaces of the bearings. These currents make their presence known by blackening the oil, pitting the bearing, and, in extreme cases, scoring the shaft.

Figs. 1 and 2 show photographs of damage done to a shaft and bearings by these currents. Other photographs are given by Adler[2], who states that currents greater than 1¼ amperes per square inch of bearing surface will damage the shaft, but that currents of lesser magnitude will harm the bearings only.

The usual type of shaft current flows in a circuit consisting of the shaft, the bearing pedestals or end shields, and the base. Interruption of this circuit by insulation under the pedestals, as shown in Fig. 3, is the most usual method of avoiding trouble from this source. In machines with end shield bearings, however, it is very inconvenient to insulate, and in no case does the use of insulated bearings afford any pleasure to either the manufacturer or the operator.

This paper has been written in order to present some supposedly novel ideas on the causes of shaft currents and methods of avoiding them. As the published information on this subject is rather scattered, and, being chiefly in German periodicals, is relatively inaccessible to American readers, the previously established principles of the subject are also explained.

First the three possible causes of shaft currents will be described, then the two causes of minor importance will be briefly discussed, next the major cause will be carefully examined under two headings, then means for

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

avoiding shaft currents will be explained, and finally a possible field of utility for shaft currents will be mentioned.

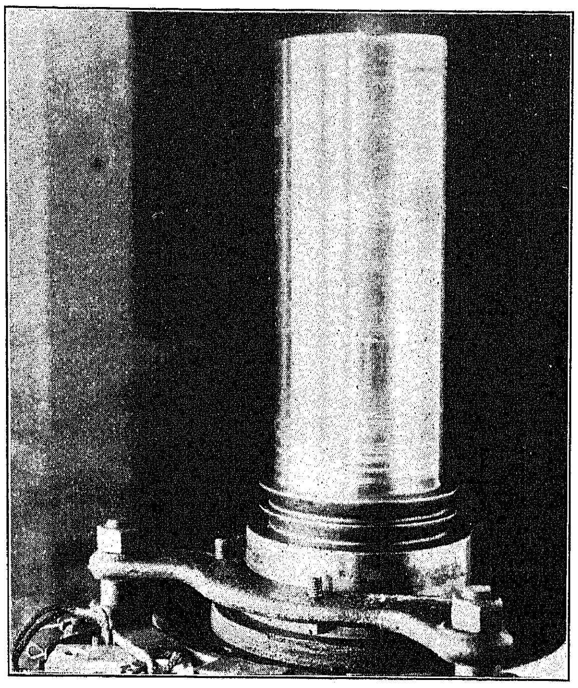

Fig. 1—Photograph Showing Effect of Shaft Currents on Shaft of 500-h. p. Induction Motor

Possible Causes of Shaft Currents

All shaft currents are due to the existence of an e. m. f. between shaft and bearing lining. There are three imaginable ways in which such an e. m. f. can be produced:

(a) By a direct or alternating flux flowing in the shaft.

(b) By a difference of potential between shaft and ground due to electrostatic effects, or to grounding of the rotor conductors to the core.

(c) By an alternating flux linking the shaft.

Of these, (c) is by far the most important, and the one which has occupied the greater share of the attention of previous writers. However, in order to leave a clear field for the study of (c) once it has been started, the minor causes (a) and (b) will be first considered.

Shaft Currents of Type (a), Due to Shaft Flux

If, for any reason, a magnetic flux flows in the magnetic circuit consisting of shaft, bearings, and base of a machine, a homopolar voltage will be induced in each bearing due to the revolving shaft cutting the radial lines of flux passing from shaft to bearing. The voltages so induced in the two bearings will exactly neutralize, if the flux passing through one bearing is equal to the flux returning from the other bearing to the shaft. Hence such shaft voltages will chiefly cause local currents within the bearings, and insulation of the bearing pedestal from the frame will be of little use, except in so far as it increases the magnetic reluctance of the flux path. The most convenient paths for such currents to flow in are from shaft to bearing through an oil ring placed at one end of the bearing and back from bearing to shaft through another oil ring placed at the other end of the bearing.

Whether the shaft flux is direct or alternating, a homopolar voltage will still be induced in the shaft, of the same frequency as the flux. Shaft fluxes will only appear as a result of a current linking the shaft. Only when an unsymmetrical construction of the windings is employed, such as sectionalized end rings for a squirrel cage, or a wave winding with only one bar per slot, will the multipolar machine be subject to this trouble. Homopolar machines, however, are likely to have a good deal of shaft flux.

An inspection of the developed two-circuit wave winding of Fig. 4 shows that the currents in the two circuits encircle the shaft in opposite directions, so that any inequality of these currents will give rise to a shaft flux.

A test was made on a large induction motor with such a winding on the rotor, to determine if appreciable shaft currents could be produced by shaft flux. One circuit of one phase of the two-circuit rotor wave winding was opened, and the motor was then operated under

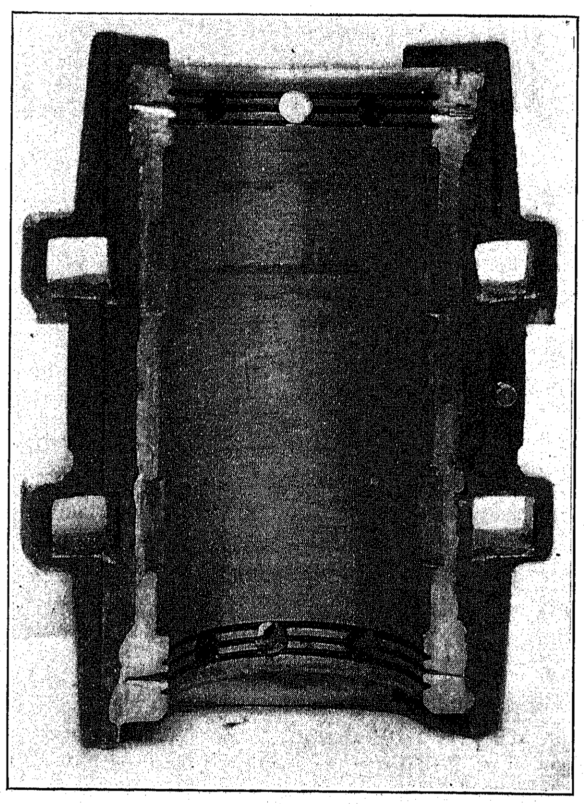

Fig 2—Photograph of Damaged Bearing of 500-h. p. Induction Motor

various starting and running conditions. Although under these conditions all the current of one phase of the rotor linked the shaft, it was found that only a few

millivolts were produced between shaft and bearings under the worst conditions. On disassembling the motor after these tests no signs of any shaft currents having been present could be detected.

There are other possible sources of shaft flux, such as uneven air gaps, and others listed by Buchanan[3]. No cases of shaft currents that could be proved due to these causes have come to the authors' attention, however, and it is their belief that the role of shaft fluxes in producing bearing trouble is a minor one. This belief is based on the experiment described above; and on the fact that insulation of the bearing pedestals is a generally accepted and succesful remedy for shaft currents, although such insulation would not materially reduce homopolar shaft currents due to shaft fluxes.

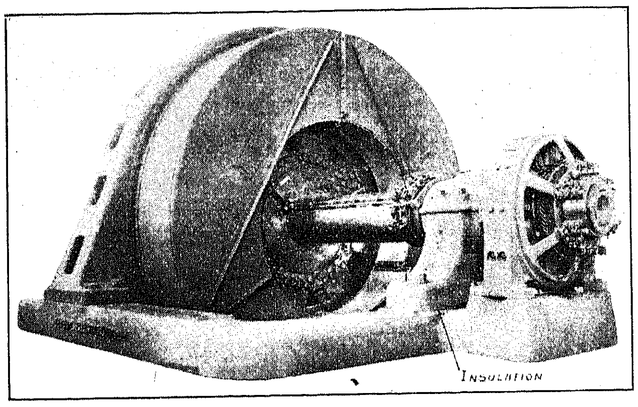

Fig. 3—Photograph of Insulated Pedestal Bearing

Two methods are available for avoiding trouble from shaft flux, if such trouble is feared. One is the use of non-magnetic bearing pedestals, or the equivalent. The other is the use of a coil linking the shaft through which current is passed in such a direction as to counterbalance the existing m. m. f. available for making shaft flux.

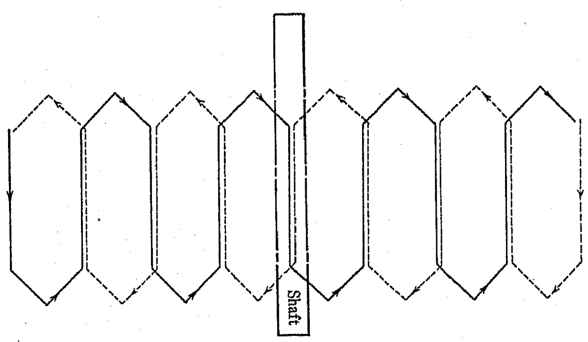

Fig. 4—Wave Winding Cause of Shaft Flux

Shaft Currents of Type (b), Due to a Potential Between Shaft and Ground

Electrostatic voltages between shaft and bearings may be set up by the friction of a belt or a pulley, or rubbing friction within the bearings themselves, or by reason of the potential of the rotor winding above ground. Electrical men are familiar with the sparks which may be drawn from a revolving leather belt on a dry day, and with the severe jolt that may be received from touching the frame of an electric motor placed on wooden blocks. Such shocks are evidence of the potential that may be built up by electrostatic effects. It is conceivable that for such reasons as these the rotor of an electric machine may be brought to a potential considerably above ground, and that when the potential reaches a certain value it may discharge through the oil film of the bearing. Constant repetition of such sparks might conceivably in time give the usual pitting effects of shaft currents.

If one part of the rotor winding is accidentally grounded to the rotor core, the whole rotor will be raised above ground potential to the potential of this point of the winding, and so an e. m. f. between shaft and ground will result. If, in addition, the rotor circuit is grounded elsewhere, a short circuit will occur through the bearings. An accident of this kind actually occurred in one instance, with the result that the shaft was badly scarred during the few moments that the power remained on.

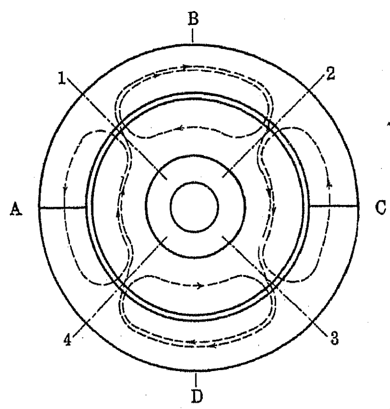

Fig. 5—Production of Shaft Voltages by Yoke Flux

No cases are known to the authors where shaft currents of this nature have given trouble except as the secondary results of accidents.

Shaft Currents of Type (c), Due to Alternating Voltages Induced in the Shaft

In every multipolar electric machine, the flux of each pole, after crossing the air gap, divides into two portions, one taking a clockwise and one a counterclockwise path through the yoke. If, for any reason, the clockwise flux, R, is not equal to the counterclockwise flux, L, the effect is the same as if their difference, $R-L$, flowed completely around the yoke. This circulating flux will link the shaft and, if it is alternating, will induce a voltage in the circuit composed of shaft, bearing pedestals, and base, causing a shaft current to flow. This type of shaft current is by far the most important,

3. Reference No 2.

and the one which has occupied the greater share of the attention of previous writers. It is characterized by the approximate equality between the shaft current at standstill, with the secondary open-circuited and full alternating voltage impressed on the primary, and the shaft current in normal operation. Also, this type of shaft current is approximately the same at no-load as at full-load. These characteristics serve to prove that it is not due to the load current, the end turn reactance, or the mechanical arrangement of the end shields, as has been variously suggested.

Consider for example, the classical case of a four-pole alternator with a stator built in two sections as shown in Fig. 5. At A and C the yoke flux passes through regions of much higher reluctance than at B and D. But pole 1 need not send its flux through A. On the contrary, it will send the major part of its flux through B to pole 2, allowing pole 3 to similarly send the larger part of its flux through D to pole 4. Thus the final distribution of flux gives a component linking the shaft, as shown by the sinuous curve of Fig. 5. As 1 will be a north pole at one instant and a south pole one half-cycle later, the flux linking the shaft will alternate at line frequency and will cause a shaft current of the same frequency.

This subject of shaft voltages caused by the use of sectionalized stators has been very fully discussed by previous writers, and reference to the articles listed in the bibliography will provide those interested with an over sufficiency of explanatory diagrams and discussions of the matter.

The general law which enables a prediction to be made as to whether or not any given sectionalizing of the stator will cause shaft currents with any given number of poles is:

(1) *Sectionalizing the stator will cause shaft currents if the ratio of twice the number of joints to the number of poles, expressed as a fraction reduced to its lowest terms, has an odd number for its numerator. The frequency of the shaft currents will be equal to this numerator times line frequency. If the numerator is an even number, no shaft currents will appear.*

For example, with 4 joints and 14 poles, the ratio reduces to 4/7, and as 4 is an even number, there are no shaft currents. With 2 joints and 8 poles, the ratio is 1/2, and line frequency shaft currents are set up. The foregoing rule applies only to machines with equally spaced and uniform joints. When the stator is divided into unequal sections special consideration must be given each particular case. In practically every case the joints between sections will vary enough to give some slight dissymmetry and, consequently, a small shaft current even though the numerator of the fraction twice joints over poles is an even number, but such accidental currents should not give serious trouble.

Sectionalizing the d-c. field of a synchronous or a direct-current machine will not cause shaft currents, since the flux linking the shaft will be unidirectional and constant.

Axial holes through the core for ventilation purposes, which are frequently used in high-speed machines, are another source of shaft currents, unless they are so located as to preserve perfect symmetry with respect to the poles. If the pattern of these holes is repeated every pole pitch, no shaft voltages will be produced; otherwise they will be. On the other hand, such axial holes may be so located as to partly neutralize the dissymmetries due to joints in the core, and so may be made to give beneficial effects.

The use of segmental punchings gives effects similar to sectionalizing. The joints in a segmental core are lap instead of butt joints, but they nevertheless have much higher reluctances than corresponding lengths of iron, and so they may cause marked variations between the reluctances of the parallel (clockwise and counterclockwise) paths in the yoke. Tests have indicated that at 8 kilolines per square cm., one lap joint has a reluctance equal to about 25 cm. of yoke, while at densities of 12 and 15 kilolines, respectively, the equivalent lengths of yoke path are roughly 20 and 10 cm.

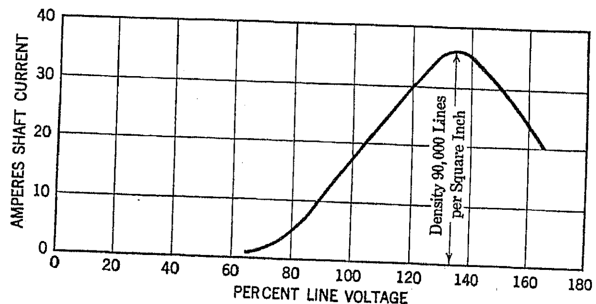

Fig. 6—Variation of Shaft Current with Voltage

It is the usual practise to provide each segmental punching with two symmetrically placed dovetails, and therefore to assemble a core with twice as many (lap) joints as there are segments. Thus the use of any given number of segments has the same qualitative effects as the use of twice as many sections. Therefore rule (1) previously stated also applies to the case of segmental construction. It may be restated as follows:

(2.) *The use of symmetrical segmental punchings will cause shaft currents if four times the segments over the poles, expressed as a fraction reduced to its lowest terms, has an odd number for its numerator; and the frequency of the shaft currents will be equal to this numerator times line frequency.*

For example, an eight-pole, six-segment, stator will have three times line-frequency shaft currents, and a 30-pole, 12-segment stator will have no shaft currents. The table of shaft current frequencies given in appendix, Fig. 15, will be found useful in determining what combinations of joints (two times segments) and poles are most favorable.

When the ratio of four times segments to poles is unity, all the poles share equally in the production of circulating flux and of shaft voltage. When this ratio is fractional, however, only a corresponding part of the poles contribute to the circulating flux, so that the greater the denominator of the fraction the lower will

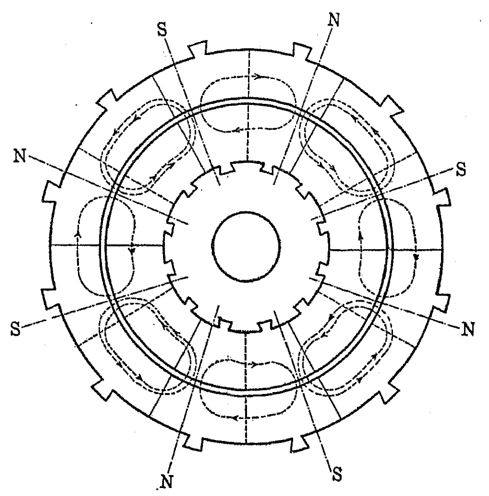

FIG. 7—PRODUCTION OF SHAFT CURRENTS IN AN 8-POLE 6-SEGMENT MOTOR

be the shaft voltage. Also, when the ratio is an odd integer greater than unity, the production of a shaft voltage is dependent on the presence of some degree of saturation in the yoke paths. For, referring to Fig. 7, which illustrates the flux paths in a motor having a ratio equal to 3 ($4 \times 6/8 = 3$), as adjacent joints in the

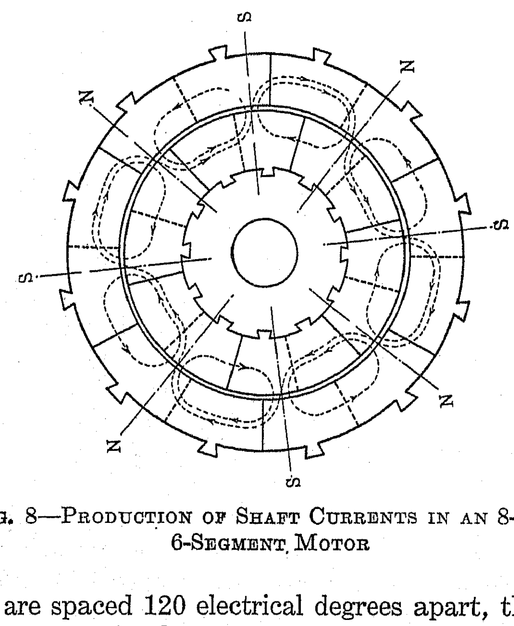

FIG. 8—PRODUCTION OF SHAFT CURRENTS IN AN 8-POLE 6-SEGMENT MOTOR

yoke are spaced 120 electrical degrees apart, the algebraic sum of the fluxes passing through 3 consecutive joints is zero, assuming a sinusoidal distribution. If, therefore, the ampere turns at each joint were proportional to the flux, the total ampere turns introduced by the joints into the clockwise flux path would be exactly equal to the ampere turns introduced into the counterclockwise flux path, and no tendency for a circulating flux to appear would exist. Actually, however, the ampere turns across each joint increase at a faster ratio than the flux, and so the two joints per pole in the clockwise flux path give less ampere turns than the single joint per pole in the counterclockwise path; a clockwise circulating flux being thus introduced.

In Fig. 6 a graph of a triple-frequency shaft current as a function of voltage is shown, which illustrates the effect of saturation. At very low densities the ampere turns across the joints are proportional to the flux, and at very high densities the entire yoke becomes so saturated that the reluctance of the entire flux path approaches that of air. In the first case the joint ampere turns in the clockwise and counterclockwise flux paths balance each other and in the second case the joint ampere turns become negligibly small in comparison with the ampere turns required for the

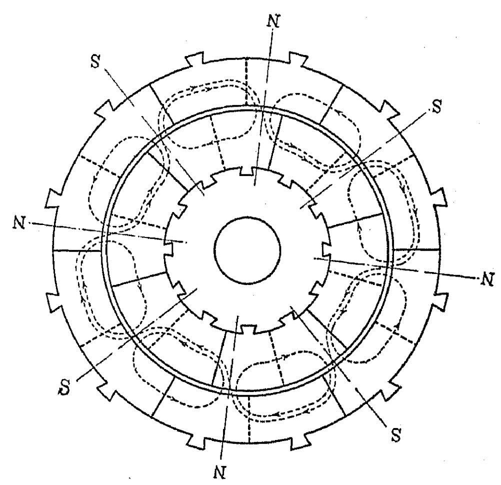

FIG. 9—PRODUCTION OF SHAFT CURRENTS IN AN 8-POLE 6-SEGMENT MOTOR

rest of the path; so that in both cases no circulating flux is produced. A very low value at reduced voltage is thus a characteristic of multiple-frequency shaft currents. Line-frequency shaft currents, on the other hand, are more nearly proportional to the voltage at low densities, and decrease less rapidly with saturation, as in these cases there are joints in only one of the flux paths.

When both rotor and stator of an induction motor are made with such a number of segments as to cause shaft currents, the resulting shaft voltage will be equal to the sum of the two shaft voltages that would be caused by the two sets of segments acting separately. The presence of rotor joints has very little influence on the effects of the stator joints, and vice versa. As the slip-frequency shaft voltages due to the rotor segments are small compared with the line-frequency voltages due to the stator segments, the rotor construction is of little importance in considering how to avoid shaft currents.

In order to obtain a clear idea of how a flux linking the shaft is set up in an induction motor with segmental rotor and stator, it is worth while to examine Figs. 7, 8 and 9. These show three positions of the rotor of an eight-pole motor with six segments in both rotor and stator. It is assumed that the slip is negligibly small, and so the center line of a north pole is in the same position on the rotor in every figure.

Consider first the stator alone. In Fig. 7 the flux is in such a position that there is an excess of flux in the clockwise yoke paths, as the reluctance of the eight

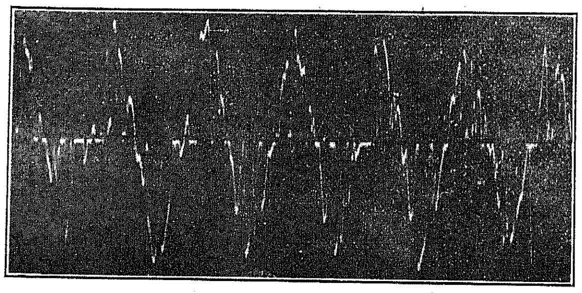

Fig. 10—Oscillogram of Shaft Voltage
Voltage across ends of shaft. Frequency 150 cycles; line frequency 50 cycles.

joints in series in the low-density regions of the core is less than the reluctance of the four joints in series in the regions of maximum core density. In Fig. 8 the flux has moved 1/24 of a revolution and now the counterclockwise flux predominates. In Fig. 9 1/12 of a revolution has been completed and the position is identical with Fig. 7. Thus the stator joints give a flux linking the shaft which completes 12 cycles per revolution, or gives three times line frequency.

Next consider the rotor alone. In all three figures the rotor joints give rise to a predominance of clockwise flux. If it is assumed that the air-gap distribution of

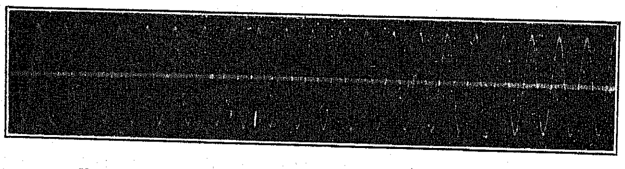

Fig. 11—Oscillogram of Shaft Current
Current across ends of shaft. Motor running light; frequency 180 cycles; line frequency 60 cycles.

flux is not affected by the unequal division of flux in the stator yoke, it is evident that the effects of the rotor joints are not dependent on the stator joints. At a later moment of the slip-frequency cycle the rotor joints will give a predominance of counterclockwise flux, and after one twelfth of a revolution of the flux with respect to the rotor the clockwise flux will again reach a maximum and a cycle of shaft-voltage variation due to the rotor segments will be completed.

Figs. 7, 8, and 9 give a net resultant clockwise flux in the first position, zero flux in the second, and a clockwise flux again in the third position. But one third of a slip cycle later the three positions will give counterclockwise, zero and counterclockwise fluxes. Therefore, the 180-cycle shaft voltage due to the stator segments is simply superposed on the 180 times per cent slip-cycle voltage due to the rotor segments and the magnitudes of each of the two voltages are the same as if they existed independently.

The shaft voltage shown in Fig. 10 was taken on a 16-pole motor with 12 segments in both rotor and stator. That shown in Fig. 11 was taken on an eight-pole motor with six stator segments and five rotor segments. In neither case is the shaft voltage due to the rotor segments (three times slip frequency in the first case and five times in the second case) large enough to be noticeable.

When an induction motor is at standstill, with open-circuit rotor, a shaft current due to the use of the same number of segments in both rotor and stator occurs at n times frequency instead of being composed of two different frequency voltages. But its magnitude then depends upon the rotor position, and it will vary through a complete cycle of values as the rotor is turned through an arc corresponding to one quarter of a segment. As the rotor accelerates the single-frequency shaft voltage breaks up into two components whose frequencies are at first near together and later separate more and more widely until, as full speed is reached, the shaft voltage consists of a large n times line-frequency component and a small n times slip-frequency component. Corresponding to these changes in the shaft voltage the shaft current will change its value in a seemingly erratic manner.

It is a well known fact that the slip of almost any induction motor may be counted by observing the beats of a millivoltmeter placed across the ends of the shaft. The discussion given above clearly shows that the beats of the millivoltmeter are due to a slip-frequency alternating flux encircling the shaft. And the widespread occurrence of this phenomenon shows that even very slight differences in the magnetic paths in the yoke will cause measurable shaft voltages. In many cases the ratio of rotor segments to poles is such as to give shaft voltages 3 or 5 times slip frequency instead of slip frequency itself. For this reason it is well to check the measured slip of an induction motor with a tachometer when the shaft voltage seems to give too high a frequency.

The two oscillograms of shaft currents shown on Figs. 10 and 11 pertain to induction motors with segmental stators having the ratio four times segments over poles equal to 3. In both these cases the oscillograms show the shaft voltages to be at three times line frequency thus verifying the rule (2). The pulsations in the voltage on Fig. 10 are ascribed to tooth-frequency variations in the core flux. It is interesting to note that any third harmonics in the core flux of these machines will give shaft voltages of the same triple frequency

that the fundamental flux does, as four times poles over segments for the 3rd harmonic is 1 instead of 3, as for the fundamentals.

In Figs. 12 and 13 are shown oscillograms of shaft voltage taken on two turbine generators with one-piece stator frames. Since in both cases the ratio of four times segments to poles is an even integer, the rules previously laid down do not explain these shaft currents, except on the assumption that they are due to inequalities in the core joints. Evidently the fundamentals of

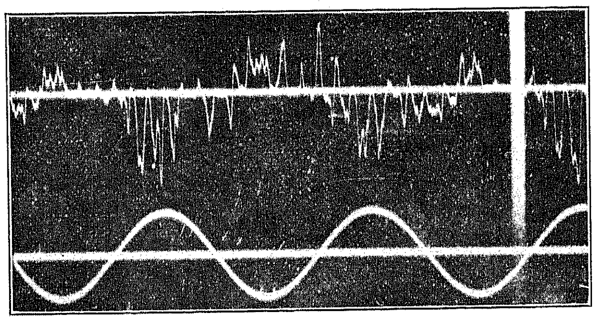

FIG. 12—OSCILLOGRAM OF SHAFT VOLTAGE
Upper curve, voltage shaft to frame. Lower curve, voltage wave no load.

these oscillograms are of line frequency, but the wave forms are extremely irregular. The reasons for these irregularities probably lie in the facts that the actual wave form of the alternator yoke flux is irregular, due to tooth pulsations, harmonics in the field flux, and saturation, and that the passage of this flux through so complicated a magnetic circuit as an annular steel core with irregular air gaps in it gives rise to a still more irregular m. m. f. wave form. If, however, all the

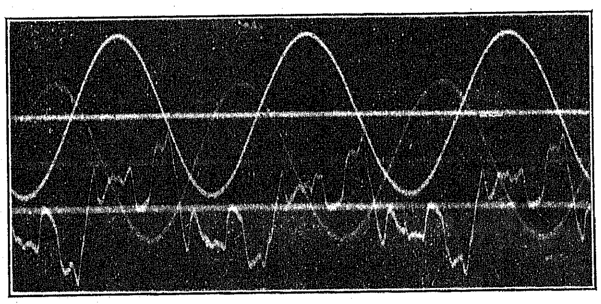

FIG. 13—OSCILLOGRAM OF SHAFT VOLTAGE
Upper curve, voltage, Phase 1-2. Middle curve, voltage, Phase 1-3. Lower curve, voltage, shaft to frame.

joints in the cores had been uniform, no shaft current should have appeared no matter how irregular the flux wave form.

It is the resultant m. m. f. acting around the periphery of the yoke that causes the circulating flux which links the shaft, and this resultant m. m. f., being the difference between two relatively large quantities, has a wave form that is more irregular the smaller its average value. The shaft voltages shown in Figs. 12 and 13 were actually quite small, so that their poor wave forms cannot be taken as an indication that the wave forms of the yoke fluxes were anything like as irregular as they are.

In well designed machines all the important fluxes and currents should have closely sinusoidal wave forms, and so the wave forms of any large shaft voltages should be reasonably sinusoidal. Thus the excellent wave form shown in Fig. 11 is not entirely a matter of chance, but an indication of good design. This motor has nearly closed rotor slots and a good ratio of rotor to stator teeth so that only very small tooth-frequency pulsations occur in the yoke fluxes. Also, the wave form of its exciting m. m. f. is very nearly sinusoidal, its gap permeance is very uniform, and none of the magnetic paths are too highly saturated. Consequently the wave form of its yoke m. m. f. should be very good, as the oscillogram actually indicates.

However, the irregularity of wave form of the three former shaft currents and the regularity of the latter are partly due to the differences in the voltage drops in the shaft circuit. In the turbine generator cases the voltage was taken from shaft to frame, so that the oscillograph current had to return through the other (inaccessible) bearing. In the induction motor cases the voltage was taken across the shaft through metallic brushes, so that the irregular voltage drop across the bearing was avoided. In taking Fig. 10 one brush was on the outside of the revolving shaft, making a rather irregular contact, while in taking Fig. 11 the contacts were made by axially-applied brushes on the two exposed ends of the shaft.

REMEDIES FOR SHAFT CURRENTS OF TYPE (C)

Of course the first essentials in avoiding shaft currents are to banish the combinations of poles and joints indicated to be objectionable by (1) and (2), or as tabulated in the appended table, and in every case to make the clearances between yoke joints as small and as uniform as possible.

Also, if the shaft and bearings are absolutely smooth and excessive speeds and bearing pressures are excluded, the oil films will act as effective insulators, and so damage to the bearings will be avoided. A large number of motors which are known to have triple-frequency voltages across the shaft of about one volt have been in successful operation for many years, so that small shaft currents are not necessarily dangerous. But any roughness on the shaft or excessive bearing pressure, will cause rubbing, which will allow the currents to flow, and these currents will soon pit the bearings and so aggravate conditions as to in time destroy the bearing surfaces.

The end play of the shaft will usually give intermittent metallic contact from one end of the shaft to the bearing lining, so that the fact that the oil films in the two bearings are electrically in series is of no importance in lessening the currents. The end play

explains the fact that frequently the voltage from shaft to ground will be zero on one end of the shaft and yet will be considerable on the other end. The presence of oil rings, which make metallic contact with the top of the shaft, affords a very convenient path for the shaft currents, and for this reason it will often be found that the first signs of bearing currents appear as scratches on the shaft under the oil rings. Thus permanent reliance can not always be placed on the oil film alone as an insulator.

The standard method of avoiding the effects of shaft currents is simply to insulate the bearing pedestals from the bed plate, or the bearing lining from the end shield. Such methods form the simplest way of getting around the difficulty, but they are difficult of adoption on machines with end shield bearings, and they are always a source of trouble and expense.

Several German patents have been taken out on other methods of avoiding these troubles. A common expedient is to place metallic brushes in contact with the ends of the shaft and connect them electrically to the frame, thus short-circuiting the bearings. But the contact drop of the brushes is so great that one-third to one-half the original current still flows through the bearings.[4] To improve this condition an A. E. G. patent[5] proposes to connect the primary of a transformer across the brushes, the secondary being wound around the core of the machine. By proper arrangements the voltage applied across the brushes may be made to approximately oppose and cancel the line frequency component of the shaft voltage.

Another patent[6] covers the case of a ring-wound coil encircling the stator yoke, this coil being fed with a line-frequency current of such a phase angle as to most nearly cancel the ampere turns set up by the joints. The current in this coil makes a circulating flux in the yoke which opposes the circulating flux set up by the dissymmetry of the magnetic circuit. This scheme affords a method of eliminating the line-frequency component of the shaft voltage but does not avoid the higher frequency currents shown in the oscillograms, Figs. 12 and 13.

A third patent[6] covers the use of an iron collar encircling the shaft inside the bearings, which collar is wound with a ring winding. Application of a suitable line-frequency voltage to this coil sets up an alternating flux whose phase relation to the circulating flux in the yoke is adjusted to give the best cancellation. This scheme also completely cures the fundamental frequency component of the shaft voltage but does not remove the higher frequency components. None of the patented schemes mentioned would benefit in any way the higher frequency shaft currents such as shown in Fig. 10 and Fig. 11 and in fact the application would exaggerate the shaft currents in these cases.

4. Reference No 6.
5. Reference No. 5.
6. Reference No. 5.

Liwschitz[6] has suggested the cutting of a notch or notches in the yoke in such a way as to add reluctance in the yoke paths that have lower than average reluctance and so bring all the reluctances up to the same level. The simple cutting of such notches in the finished yoke would be very objectionable on account of increased core losses. But a better result can be simply obtained by making butt joints in the punchings to balance the butt joints between sections in those cases where the desirable number of sections is such as to cause bearing currents with the given number of poles. For example, a two-section four-pole motor would now be built with butt joints between sections and lap joints elsewhere, and so would have shaft currents. By making two extra butt joints in the punchings halfway between the section joints, all poles would be made alike and so shaft currents would be eliminated. This assumes that all the four-butt joints could be made very closely alike.

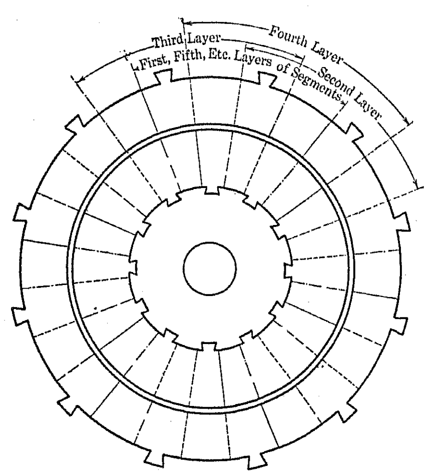

Fig. 14—Core Constructed with Offset Segments

Preferred Method of Avoiding Shaft Currents Due to Segments

The methods so far considered apply equally well to shaft currents due to sectional and segmental stators, but the methods involving the introduction of a bucking e. m. f. are of no use in the case of certain numbers of segments in both rotor and stator. If segments alone are the cause of trouble, as is most commonly the case, the best and altogether most desirable method of avoiding shaft currents is to use offset segments.

For, if the segments are laid out as in Fig. 14 instead of as in Figs. 7, 8 and 9 with the dovetail tags (or notches) placed at the ⅛ and ⅝ points instead of the ¼ and ¾ points as is usually the case, the core can be built up with four joints per segment instead of two, and ¾ of the full iron section at each joint instead of only ½. This will be accomplished by laying any single pair of layers of punchings with lap joints in the usual way and then laying the next pair of layers upside down, so that the new lap joints come midway between the first lap joints, as shown in Fig. 14. It is not impor-

tant that the dovetail tags come exactly at the ⅛ and ⅝ points, but it is essential that each tag come opposite a slot or a tooth, so that slots in the turned over punchings will coincide with those in the other punchings.

The usefulness of this scheme is somewhat limited by the fact that a blanking die with offset tags will seldom work with more than one number of slots per segment. If the tags are set at the ⅛ and ⅝ points, the number of slots per segment must be a multiple of 4, as 12, 16, 20 and 24. Thus one offset blanking die can be used

◇ Denotes combinations, seemingly the worst, where the above given ratio reduces to the odd integer 3. Shaft currents in each of these cases can be completely cured by offset segments.

○ Denotes all other cases given in this table that can be completely cured by offset segments.

COMBINATIONS OF POLES AND SEGMENTS PRODUCING SHAFT CURRENTS.

Fig. 15—Table of Shaft Current Frequencies

In any revolving electric machine, if the ratio of two times joints to poles expressed as a fraction reduced to its lowest terms has an odd number, N, for its numerator, shaft currents of N times line frequency will occur. By line frequency is meant the frequency of the magnetic flux in the jointed element of the machine. This table gives the values of N for various combinations of poles and joints. Combinations with which no shaft currents occur are indicated by dashes.

with 20 and 24 teeth per segment but not with 21 and 22. But the scheme can be used with any combination die. And, the use of this construction will probably reduce the yoke ampere turns and the core losses to a sufficient degree to make it worth considering for these reasons alone, regardless of the shaft current question. Transformer tests have shown that poorly made lap joints may increase the core loss by as much as 20 per cent, while at average densities each lap joint requires as many ampere turns as 6 or 8 inches of the full-section part of the yoke.

A crude alternative to the use of offset segments is to punch ventilating holes in the primary yoke in such a way as to create additional reluctances midway between the joints. These additional reluctances will offset the joint reluctances and so approximate the effect desired. This scheme of course increases the core loss and the yoke ampere turns, and so is not recommended.

Turning Shaft Currents to a Useful Purpose

By constructing both stator and rotor of symmetrical segmental punchings with butt joints and considerable clearances, it would be readily possible to make a large part of the total yoke flux link the shaft. In this way shaft voltages could be produced equal to a fair percentage of the volts per turn in the main winding, and relatively large currents could be drawn from the shaft at low voltages and with fairly good wave form. By making $2 \times \dfrac{\text{sections}}{\text{poles}} = 1$, 3 or 5, frequencies of 1, 3 or 5 times line frequency could readily be produced. Of course the multiple frequencies would only be due to saturation and so this arrangement would be very inefficient indeed if used as a power-frequency transformer.

Thus a nearly standard induction motor construction could be used to produce large low-voltage single-phase currents at any frequency $(2m - 1)$ times line frequency where m is any integer. Such a machine would have to deliver its current through brushes, and so would have some of the troubles of homopolar machines. Without proceeding to an extreme, an induction motor could be so constructed as to serve the dual purpose of rotating the shaft and also producing low-frequency currents. Of course, any such machine would have to have its bearings well insulated from the frame.

As previously noted, these shaft currents could be as well produced with the rotor stationary, and therefore the motor construction with bearings and air gap is entirely unnecessary, if the sole object is the production of these shaft currents. Such a machine would simply be a static transformer giving a secondary frequency 1, 3 or 5 times the primary frequency. If the frequency ratio is 1, the machine would be exactly equivalent to an ordinary transformer. If the secondary frequency is three or five times the primary frequency, due to proper choice of the segments, the machine is equivalent to a three or five-phase transformer of the usual type, with mesh-connected secondary.

These ideas on the utilization of shaft currents are rather fanciful, and it is not probable that they will be practically developed.

Conclusions

It is concluded that the most important cause of shaft currents is the presence of some dissymmetry in the magnetic circuits of the rotor or stator core, which causes more flux to flow in one of the two parallel (right and left hand) paths than in the other, and so gives a

resultant flux linking the shaft. The most prominent causes of such dissymmetries are sectionalized frames and segmental punchings. All cases where such divisions of the yoke will cause excessive bearing currents can be predicted by means of rules (1) and (2) given above. But the use of any sections or segments at all will give rise to some shaft voltages, due to the impossibility of making all joints exactly alike. These secondary shaft currents should not be harmful except in extremely high-speed machines like turbine alternators.

The most effective methods of remedying bearing currents, other than insulating, are to punch holes in the yoke in the regions of low reluctance, thus raising all parts of the yoke to the same level of reluctance, or to create a separate flux linking the shaft and opposed to the flux produced by dissymmetry or to make use of offset segmental punchings.

It is believed that the use of offset segmental punchings will effectively cure all ordinary cases of bearing currents in small induction motors, d-c. machines, converters and synchronous motors and, as offsetting the dovetails gives better core loss, lower yoke reluctance, and a more solid core construction, with very little expense or trouble (once the new dies are developed), it is recommended that this scheme be adopted whenever practicable.

Shows that a sectionalized stator causes bearing currents and gives data on the ampere turns required to force flux across lap and butt joints in the punchings.

Discussion

W. F. Dawson: I can endorse one point which Mr. Alger made, namely that shaft currents are often associated with high saturation in the stationary armature cores of synchronous generators.

Some oscillograph records give the interesting information that the e. m. f. of shaft currents is greatly reduced as the generator voltage, and consequently the saturation of the armature core, is reduced.

My recollection is that we had approximately 5 volts potential at normal voltage and only 0.05 volts shaft potential with 50 per cent armature voltage.

We have built more than 2500 two-pole machines, of which less than 1 per cent have developed observable shaft currents, but on the other hand practically all of those that have given trouble should have been immune according to Mr. Alger's formula and the tabulation given as Fig. 15.

G. E. Luke: This is an interesting paper in that it describes a parasitic current or a loss which is peculiar in its effects. We are not interested in its effects on the performance or efficiency; we are interested in it solely due to its mechanical effects on the bearings. The bearing is a very simple part of the machine, but it is also a delicate part. A highly polished bearing will give a very low coefficient of friction. It is very important to reduce that to a low figure in high-speed machines. Any increase in the roughness of shaft will increase this coefficient and may cause bearing failure.

There is one point not mentioned by the authors and that is in connection with ball bearings or roller bearings. Of course, these bearings are ordinarily not used in large machines, but I have heard it said that the question of stray currents is a very serious limitation to their use in large machines because the ball bearing is especially sensitive to any imperfection on the surface of the bearing or race.

There is another point I would like to bring out, and that is: how did they measure the stray currents in the bearing, except by the usual method of putting a shunt around the bearing and using an ammeter, insulating the pedestal and shunting the insulation? Do the authors have any other methods which they use for measuring the currents in the bearing when they have an unsymmetrical magnetic field? The method of insulation in a pedestal machine is easy, but when we come to a bracket machine, it is not so easy on account of mechanical difficulties. Do they have any suggestions there as regards the elimination of the stray currents?

W. J. Foster: Last evening a designing engineer who has had a great deal of experience told me of a little telltale device that had been installed on some large generators of recent manufacture. It consisted in placing a low-voltage incandescent lamp across the insulation underneath the pedestal. The lamp stays lighted in varying degrees of intensity all the while, unless the insulation breaks down, and then it goes out. It is quite important that some such telltale device be installed, otherwise something may happen, such as I have seen on visiting plants, where after four or five years when a change in the management or a change in the operators has taken place, the insulation under the pedestal may be forgotten. In one case, iron steps had been placed on the base resting against the pedestal thus short-circuiting the insulation.

F. D. Newbury: As the authors of the paper bring out, the major cause of shaft currents has been known for a long time. I remember very distinctly a memorandum that Mr. Lamme circulated, I think it was in 1908, emphasizing the fact that the dissymmetry of the magnetic circuit was one of the principal causes of shaft current and cautioning against the use of certain combinations of poles and segments.

There is a possible inference from the paper that I hope will be avoided, that is the thought that insulation is, from this time on, to be frowned upon as an evidence of improper design. As Mr. Dawson brought out, there are cases in which results are difficult to predict, where, even with proper relations between poles and number of segments or between numbers of segments in the rotors and stators of induction motors, we do find shaft currents in spite of the proper relationship, and I think that all designers will continue to use bearing insulation as a precaution, even in those cases where shaft currents would not ordinarily be predicted.

A. M. Perry: On a trip through the Southeast about a year ago, I had the opportunity to observe a vertical-shaft water-wheel generator unit on which they had had considerable trouble with the bearings melting. They didn't look into the cause of the trouble, but they did put slip-rings on the lower end and the upper end of the shaft and connected them to a ground so that there was a very low-resistance connection between the shaft and what would correspond to the pedestal of the bearings. They told me that this method eliminated the trouble entirely.

W. J. Foster: In line with Mr. Newbury's remarks and Mr. Dawson's, that there may be cases of shaft currents where they would not be expected in accordance with the theory on which this paper is based, I would like to have the authors, in closing, make a statement as to whether they rule out all other causes.

Personally, from my own experience, I consider mechanical dissymmetry at the two ends of the shaft in certain cases as responsible,—for example, in a 12-pole vertical machine with a 6-arm bracket at the top and no corresponding bracket underneath; where shaft currents were much in evidence, it seemed to be perfectly natural to ascribe the reason to the stray flux cutting the arms synchron-

As I understand the paper, it does not necessarily shut out other sources of trouble besides the particular relations of the segments in the core.

E. A. Smith (by letter): Referring to the paper of Messrs. Alger and Sampson, I have noticed that a considerable number of the tests mentioned, have been treated in detail in some of the foreign societies' publications in which a special study is being undertaken to eliminate stray shaft currents. Particularly in Germany the electrical manufacturing concerns are trying a method of insulating the bearing pedestals from the base of the machines. They have so far not been able to insulate the end shield bearings but they are employing a non-magnetic babbit lining and non-magnetic pedestal.

No doubt in due time, by installing these non-magnetic babbit linings and by splitting the yokes as set forth in Messrs. Alger and Sampson's paper these stray shaft currents will be very much eliminated.

Most of this trouble has been found in synchronous and induction machines, where, uneven air gaps were found to exist, but in a few cases where new machines were installed, the trouble was due entirely to the flux traveling along the shaft to the bearings.

Tests were made in these cases and as far as could be observed, the only remedy would be for manufacturing concerns to investigate these conditions thoroughly and eliminate them as much as possible.

P. L. Alger: We believe that certain irregularities in the construction of the core are inevitable and therefore that any machine will have some shaft current, even though it is very well constructed, if you measure it with a delicate enough instrument. Therefore, it is not desirable to remove the insulation from very large and important machines, even though it may be believed that they will have no shaft currents. But we do believe that a great many machines do not need any insulation, although they are now provided with it as a matter of standard practice; and also we believe that certain machines which now, because of their classification, have no insulation, would be better provided with it.

I agree with Mr. Foster and Mr. Newbury, that it would be very undesirable to provoke a series of troubles with shaft currents by removing it, but I do think that operating men may profitably measure the shaft voltage in machines they have operating, and in those cases where it is not a vitally important, large, machine and where they find no shaft current by tests, they may with impunity take less care of the insulation. If enough experience is accumulated we may be able to make some progress in avoiding the troubles we now have.

The question was asked how we measured the shaft current. We do that ordinarily by merely placing an ammeter between the two ends of the shaft. In that way we measure a current in parallel with the path through the bearings. But we believe that when the oil film is still intact and not damaged by any cause, that the current flowing through the bearings themselves is negligible in comparison with that which will flow through a short-circuit path around the ends of the shaft. In those cases where we have had to insulate end-shield machines, we have done it by placing a band of insulation around the bearing itself, inside the bearing housing. In that way it is possible to make a satisfactory insulation, but it is very inconvenient to do, and if the bearing is removed it must be very carefully handled, so we do not wish to do that when it is possible to avoid it.

This question of shaft currents is particularly important in machines built for ship propulsion, where space is valuable and where the presence of salt water and of various other pieces of apparatus makes it very difficult to insulate, and also where end shields are almost always used to save space. We therefore believe it particularly desirable to apply this theory to machines intended for ship propulsion.

I will call your attention to the fact that in this paper as printed, the figures have been misarranged. Fig. 7 should be Fig. 8; Fig. 9 should be Fig. 7 and Fig. 8 should be Fig. 9. Furthermore, the true Fig. 9; that is, the one that is called Fig. 8 in the paper, has been turned through 90 degrees to the left, so that the top is now at the lefthand side. These figures are so much alike that it is hard to follow through the discussion without having the right titles.

Eddy Current Losses in Armature Conductors

BY R. E. GILMAN*

Member, A. I. E. E.

Power Engineering Dept., Westinghouse Electric and Mfg. Co., East Pittsburgh, Pa.

Review of the Subject.—*This paper is an extension to the author's paper in Vo. XXXIX Pages 997 to 1047 on Eddy Current Losses in Armature Conductors. In this present paper additional formulas are given for the cases where transposed coils are used and also methods given for quickly estimating the increased loss due to eddy currents.*

THIS paper is a supplement to the one presented by the author in the A. I. E. E. JOURNAL, Vol. XXXIX, Part I, for 1920. It is realized that the value of the formulas presented in this type of a paper depends upon their completeness and upon the simplicity of their application. Consequently, additional formulas have been added, covering types of windings neglected in the original paper, and an effort has been made to simplify the application of the formulas. An example has been worked through completely as an illustration.

In the original paper, presented in Vol. XXXIX of the A. I. E. E. TRANSACTIONS, a summary of the results were given between pages 1038 and 1045. This summary covered seven formulas for the calculations of the additional losses in the slot portion of a conductor for different groupings, and an additional formula for the loss outside of the slot portion. These seven formulas were designated A to G, inclusive, and occur on pages 1042 and 1043. They cover the usual winding combinations with coils wound "straight up" and "turned over," as illustrated on page 1012. The short circuits between strands were limited, however, in location. For short circuit occurring at the end of one-half turn, formula B applied. For a short circuit at the end of each full turn, formula D and F applied, and when the short circuit occurred only at the start and finish of the coil, then formulas C, E and G applied. With the above limitations, it is not possible to accurately determine the eddy current losses in a transposed multiple turn coil of the type using two coil sides per slot.

The data in this paper give the formulas necessary to cover this latter case. The nomenclature followed in the original paper will be used in this one, but additional terms will be employed where necessary. These additional terms will be explained at the time they are first used in the text. The formulas only will be given without going into their development which follows the outline previously laid down in detail.

The six formulas necessary to cover all the usual winding combinations with strands short-circuited at one-half turn or each full turn, or at the end of any integral number of full turns, are given below.

When conductors consist of solid bars and there are two coil sides per slot, formula A in Volume XXXIX applies.

When conductors are stranded and the strands are short-circuited at the end of each half turn, and there are two coil sides per slot, formula B in Volume XXXIX applies.

When the coil is wound continuously straight up and there is one coil per slot with a short circuit between strands at the end of ϕ turns, the formula is

$$\text{Ratio} = n^2 \left[\frac{m^2 - 1}{3} + m^2/4 \cos\beta - (m^2/4 + \theta^2/12 - 1/3) \right] M_s + [m^2/4 + \theta^2/12 - 1/3]\, M_c + O_c \quad \textbf{(III)}$$

When the coil is turned over, and there are two coil sides per slot, with a short circuit between strands at the end of turns, the formula is

$$R_t = n^2 \left[\frac{m^2 - 1}{3} + m^2/4 \cos\beta - (m^2/16 + \theta^2/12 - 1/3) \right] M_s + [m^2/16 + \theta^2/12 - 1/3]\, M_c + O_c \quad \textbf{(IV)}$$

$$R_b = n^2 \left[\frac{m^2 - 4}{12} - (m^2/16 + \theta^2/12 - 1/3) \right] M_s + [m^2/16 + \theta^2/12 - 1/3]\, M_c + O_c$$

When the coil is turned over, and there is one coil per slot, with a short circuit between strands at the end of turns, the formula is

$$R = n^2\, [m^2/4]\, M_s + \left[\frac{\theta^2 - 4}{12} \right] M_c + O_c \quad \textbf{(V)}$$

The formula for the loss ratio in the end turns for any of the winding combinations above is given by

$$R = O_c + \frac{n^2 - 1}{n^2}\, M/r^2\, (K) \quad \textbf{(VI)}$$

The new symbols employed have the following meanings: ϕ is used to designate the number of turns in the coil without a short circuit. In general, this would be the number of turns in the coil as formed in manufacture.

---

*Deceased

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

θ is used to designate the number of groups in a transposition. θ can be any integral factor of the slots per pole per phase. m is previously used as the equivalent number of conductors in a slot carrying equal currents. From the definitions above, $m = \phi\,\theta$ for one coil per slot windings, and $m = 2\,\phi\,\theta$ for two coil per slot windings. For example, a two-turn coil for a two-coil per slot winding, if transposed in five groups, would have a value of $m = 20$. A summary of the values given to the other symbols is shown on pages 1040 and 1041 of volume XXXIX.

In formula **VI**, r is used to indicate the ratio of a full turn to the embedded portion. K is used for the coefficient of M_c in that formula which covers the particular winding combination under investigation.

The six formulas give the loss ratios for any usual winding combination for the embedded and end portions of the coils. The most common winding in this country is completely covered by formulas **IV** and **VI.**

In investigating additional losses in armature coils caused by eddy currents, there are two things which it is desirable to know. The more important of the two is the amount of the excess where it has its greatest value. The average value for the entire coil is of secondary importance. The principal purpose of eddy current investigation is to determine the probable temperature rise of the coil. The insulation to ground, or the coil insulation for a 13,200-volt coil is 0.2 of an inch or more in thickness, where mica is used for insulating. The expected temperature drop through such a wall for an average heat dissipation of 0.6 of a watt per square inch would be in the neighborhood of 40 deg. cent. It is obvious, therefore, that any temperature gradient within the wrapper is of secondary importance, and that an average temperature within the wrapper can be assumed without appreciable error. As a consequence, the formulas have been shown indicating the loss ratio for all strands within a ground wrapper.

Formulas **IV** and **VI** cover the great majority of the windings in common use in this country. The application of these formulas appears complicated; in fact, however, it is a relatively simple matter to apply them, provided a preliminary approximation is employed. To illustrate, we will work out an example.

Let it be assumed that it is desired to limit the eddy loss factor in the top coil of a slot to 1.35. Let us assume further that the following conditions obtain. Our winding is to be of the two-coil per slot turned over type. The machine is assumed to be three-phase, four poles, sixty cycles, and to have seventy-two slots. The copper depth total in a slot can be 4.5 inches. The width of copper is 0.5 of an inch and the width of the slot is 1 inch. Assume that the ratio of the coil length to the embedded portion is 2.3. The coils are to be three turns per coil, and are to lie in slots 1 and 15.

The problem is to determine what winding combination will conform to our condition, and limit the loss factor in the top coil to 1.35 when the top coil carries currents in phase with those in the bottom coil. Also, to determine the loss factors for other parts of the coil, as follows: The factor for the top coil, when currents in the bottom coil are 60 degrees out of phase. The factor for the bottom coil and for the ends. And, finally, the factor for the whole winding as a unit.

The preliminary approximation referred to consists in first simplifying formula **IV** and then tabulating the results for different values of m and n. It was shown in the original paper that for small values of $\alpha\,h$ say less than 0.3, that $M_s = \frac{(\alpha\,h)^4}{3}$ and also $M_c = \left[1/n^2 + \frac{n^2-1}{n^2}\,1/r^2\right]\frac{(\alpha\,h)^4}{3}\,n^4$. See TRANSACTIONS, Vol. XXXIX, page 1038. Introducing these values and omitting O_s for the present, we find that formula 4 could be written with $(m\,n\,\alpha\,h)^4$ as a factor. Three new formulas will be written, and their values will give, when added to O_s the loss factor for the top coil side, for the bottom coil side, and for the end portion, respectively. One other change has been introduced in the formulas; that is, since $m\,n\,\alpha\,h$ is a factor, it can be given a definite value, say six and for any change, the incremental loss in excess of O_s will vary as the fourth power of the changed value to six. The simplified equations are

The incremental loss in excess of O_s for a top coil

$$\frac{36}{m^2\,n^2}\left[4 + 3\cos\beta + 1/4\,(3 + 1/\phi^2)\left(\frac{n^2-1}{r^2}\right) - 4/m^2\left(1 + \frac{n^2-1}{r^2}\right)\right] \quad (1)$$

The loss factor in excess of O_s for a bottom coil

$$\frac{36}{m^2\,n^2}\left[1 + 1/4\,(3 + 1/\phi^2)\left(\frac{n^2-1}{r^2}\right) - 4/m^2\left(1 + \frac{n^2-1}{r^2}\right)\right] \quad (2)$$

The loss factor in excess of O_s for the end portion

$$\frac{36}{m^2\,n^2}\left[1/4\,(3 + 1/\phi^2)\left(\frac{n^2-1}{r^2}\right) - 4/m^2\left(1 + \frac{n^2-1}{r^2}\right)\right] \quad (3)$$

In simplifying the equations (1), (2) and (3), above, for our first approximation, it will be noticed that for a value of ϕ equal to 1, the loss increment is a maximum. Also, it will be noticed that if we neglect that term in our equations, which contains m as a factor, that with these two changes the equations are very simply written. It can also be shown that for small values of $n\,\alpha\,h$ that O_s is essentially equal to unity.

With these changes, a table can be given, covering the incremental loss in the top coil under its maximum condition for loss. In this table, the assumption has been made that $r = 2$, and that $\cos \beta = 1$. The table is plotted for various values of m, and for n equal to 1, 2 and 3, respectively.

m	10	12	16	18	20	24	30	36	40	
factor	..	..	0.985	0.776	0.628	0.432	0.280	0.194	0.158	$n=1$
factor	0.690	0.481	0.270	0.222	0.174	0.121	0.078	0.054	0.043	$n=2$
factor	0.355	0.247	0.140	0.110	0.090	0.063	0.040	0.028	0.023	$n=3$

If we consider our problem, and assume that the copper temperature is known, say 100 deg. cent. total, then the calculation of α will be derived as in the previous paper, and would give a value of 1.83. The total copper depth was given as 4.5 inches, and this is equal to $m\,n\,h$. $4.5 \times 1.83 = 8.25$, and the values of the increment of the loss from the tables will be in the ratio of 3.58 for a coil 4.5 inches deep. Consequently, since the limit of the loss in the top coil was to be 1.35, the increment from the table will be 0.098, in order to keep the loss ratio to 1.35. In this connection, it is necessary to remember that there is a manufacturing limitation on the thickness of strands that can be handled; particularly, if mica tape is to be used to insulate the individual strands. A strand of 0.07 inches is about the smallest that can be successfully handled. From our table, therefore, it is evident that m must be 18, and n must be 3, in order to keep the increment approximately 0 098. This gives us a strand of a thickness of 0.0835 inches.

Having derived m and n from the approximation table, their values and the other factors given in our assumptions can be substituted in formulas (1), (2) and (3), for an accurate determination of the various loss factors. There are five factors to be determined: First, the loss in the top coil for $\cos \beta = 1$; Second, the loss in the top coil for $\cos \beta = 0.5$; Third, the loss in the bottom coil; Fourth, the loss in the end portion; and Fifth, the mean factor for the whole winding. These factors can all be determined by substitution in formulas (1), (2) and (3), except the last one, which is a factor of the ratio of the end windings to the embedded portion. The figures are given in the table below:

	Col. 1	Col. 2
Top coil $\cos \beta = 1$ Formula (1)........	0.1005	0.3600 a
" " $\cos \beta = .5$ " (1)........	0.0783	0.2810 b
Bot. coil " (2)........	0.0264	0.0946 c
End portion " (3)........	0.0141	0.0505 d
Factor for entire winding..............		0.1185

Column 2 is obtained from column 1 by multiplying by the factor 3.58. The loss increment for the whole winding can readily be obtained, as it is equal to $3\,a + 3\,b + 6\,c + 15.6\,d$ divided by 27.6. 15.6 is obtained from $(r - 1) \times 2 \times$ coils per pole and phase.

To the above figures in column 2 we have to add the value O_s. It is shown in the original paper how to obtain this value, but an approximation, when $m\,n\,\alpha\,h$ is equal to 6, is given by

$$O_c = 1 + \frac{130}{m^4\,n^2}\left[1 + \frac{N^2 - 1}{r^2}\right]$$

and for any other value of $m\,n\,\alpha\,h$ the increment of loss above unity is to be increased as the fourth power of the ratio of this value to 6. In our case, $O_s = 1.0025$.

It has been shown how relatively simple it is to predetermine the loss ratios in the different parts of a turned over two-coil per slot winding with transposition. It is recommended that any one who has occasion to use the approximation frequently will find it most convenient to plot his values on log-log paper. That is, on paper with logarithmic ruling for both ordinates and abscissas. If this method is followed, the table becomes a series of straight lines for different values of n.

One of the purposes in presenting a paper of this kind is to show that designing engineers are fully alive to the importance of theoretical investigations and the necessity of taking into consideration details in design which tend to improve the performance of their apparatus. This paper further illustrates how relatively simple it is to estimate accurately the effect of as complicated a phenomeon as the loss due to eddy currents in a stranded conductor.

Discussion

James Burke: With reference to Fig. 14 of the paper showing the offset segments, our company has used offset segments uniformly and continuously for 18 years in segmental punching machines and has not experienced any trouble from shaft currents.

P. L. Alger and R. F. Franklin: In view of the addition of Mr. Gilman's comprehensive papers to the already extensive literature on the eddy current losses in the conductors of large a-c. machines, it seems appropriate at this time to review the subject and describe the points of interest in the various articles from the point of view of a designing engineer. From this aspect, it is very desirable to be able to find in the shortest time and with the greatest accuracy and clearness what the eddy-current losses will be under any given conditions. Each of the articles that has appeared has features of particular value for the solution of certain problems, but most of them may be relatively inconvenient for use in the solution of any particular problem.

The first article to treat the subject in a comprehensive way was that by A. B. Field in the 1905 A. I. E. E. PROCEEDINGS. In this article, the physical phenomena of eddy currents are very neatly presented, accurate formulas starting with the classical differential equation are developed for most of the standard cases, and some interesting side-lights on the use of approximate formulas for the losses and on the calculation of reactance are given. This article may still be regarded as the best comprehensive review of the whole subject, considering synchronous machines, induction motors, and d-c. apparatus.

Mr. Gilman's article in the 1920 A. I. E. E. PROCEEDINGS treats the subject of large synchronous machines in much greater detail than Field's article. In it are derived accurate formulas starting with the classical differential equation for the eddy

losses in special cases not considered by Field, such as the carrying of a single strand through the whole phase belt before clipping it to the other strands of the same conductor. The alternator designer will find in this article formulas for all windings in use at the present time except those in which twisted conductors are employed. However, Mr. Gilman does not preserve the physical view of the phenomena while carrying out the solution of the equations, which is so necessary to a clear understanding of the effects of changes in conditions from those directly considered.

Mr. W. H. Taylor has published an extremely interesting article on the subject in the JOURNAL of the I. E. E. for April, 1920. He goes to the other extreme from Mr. Gilman by beginning with the physical viewpoint and building up the losses as a result of the summation of the effects of component eddy currents due to each conductor separately. In this way he derives formulas in the form of infinite series, in which only the first term is ordinarily used. However, the accuracy of these formulas is entirely sufficient in all cases of alternator windings in which the losses are not so excessive as to be unreasonable. Taylor treats all the standard cases of alternator windings and several curious cases in addition. For example, he shows that a coil that is turned over at the connection end but is wound straight up at the other end would have a very small loss, if such a coil were mechanically feasible to make. On the whole, I believe that Taylor's article is the best from the point of view of the designer of synchronous machines, as his formulas are the simplest (they require no curves or tables) and his presentation renders it easy to see the effects of whatever changes in the winding the designer may be able to imagine. Taylor also does not consider the twisted conductor of the Roebol type although he does treat the conductor that is turned over in the middle of the slot.

The twisted conductor has been considered at some length by German and French writers. For example, Fleishmann has shown that the circulating-current loss in a conductor will be completely eliminated if every strand in it has the same r. m. s. height in the slot. However, the use of such twisted conductors requires that they be clipped at each end, and so precludes the use of a machine-wound coil. For this reason, as well as because the labor in making them is greatly in excess of that for a normal conductor and the space factor of the slots is reduced by their use, they have not been adopted in this country. Therefore, most of the continental literature on the question is of relatively little interest to American designers.

The induction-motor designer is also interested in the question of eddy-current losses, since it is possible by exaggerating the eddy currents in the squirrel cage to obtain a greater starting torque per kv-a. than in the ordinary motor. Here, however, the losses are purposely made as large as possible, and so they fall outside the range of accuracy of Taylor's formulas. Also the feasible types of conductor are widely different from those used in alternators which are discussed by Taylor and Gilman. Finally, it is necessary in this case to consider the reactance as well as the resistance, and none of the articles so far mentioned gives any adequate method for calculating the reactance. For these reasons I believe the induction-motor designer had best put all his energy into the study of the article by Prof. W. V. Lyon in the 1922 A. I. E. E. PROCEEDINGS.

This article treats the whole subject of eddy currents by the vector method used by Kennelly and others in the solution of transmission-line problems. By this method the vector impedance of a conductor carrying alternating current is carried through the whole series of equations and found numerically, as a ratio to the d-c. resistance. This contrasts with the method followed by all the other writers in which the losses are separated from the reactive power at as early a stage as possible and thereafter they only are considered. While Lyon's article does not give numerical results directly usable by the designer, he does give methods and formulas which with a little further work can be put in a form to give accurate and complete values for the effective impedances of all kinds of squirrel-cage conductors. Thus this article is the most basic and comprehensive for use as the foundation of future work on the subject.

M. S. Vallarta: In a discussion on a paper by W. V. Lyon,[1] I presented certain results of an experimental investigation undertaken in the Research Division of the Electrical Engineering Department, Massachusetts Institute of Technology, the purpose of which was to test the correctness of the premises on which Field's[2] one-dimensional theory of skin-effect in armature conductors is built up. As all resistance-ratio formulas given in the paper under discussion are based on this theory, a reexamination of its underlying assumptions in the light of recent developments does not appear superfluous.

Perhaps the most fundamental and least evident of these assumptions is that the component of magnetic field strength parallel to the slot side vanishes everywhere within the cross-section of the conductor. In view of its importance, especial efforts were made in the course of the investigation already referred to in order to bring to light conclusive experimental evidence on this point, but in spite of them, the conclusion, stated in 1922, was: "No satisfactory proof of Field's assumption of no component of field strength parallel to the slot side has been found."[3] Unexplained discrepancies, ranging from 2 to

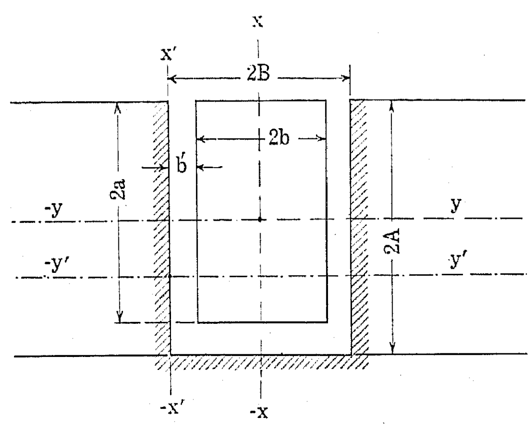

FIG. 1

5 per cent, were observed between calculated and measured resistance-ratios. Such discrepancies were believed to be due to the fact that the current density is not actually constant along planes parallel to the slot bottom, *i. e.*, that skin effect is not one-dimensional. The purpose of these lines is to show how far this two-dimensional skin effect may be expected to come into play and how it affects resistance-ratio formulas.

In a recent paper, Steidinger[4] has examined the problem for the case of a *single massive* conductor which does not completely fill the slot and given formulas for the Joule loss. We consider a single massive rectangular conductor of width $2\,b$ and height $2a$ embedded in a rectangular slot of width $2\,B$ and height $2\,A$ (Fig. 1). On its cross-section the current distribution is a function of x and y, that is, Field's assumption of one-dimensional skin effect, in which the current density is a function of x only (x = distance of current element from bottom of slot), is given up. The time variation of all electromagnetic quantities is assumed to be monoperiodic, as is done in Field's theory and elsewhere in the literature. We therefore write:

$$c = u\,(x, y) e^{j\omega t}$$

1. W. V. Lyon, "Heat Losses in Stranded Armature Conductors," TRANS. A. I. E. E., Vol. 41, p. 199, 1922.
2. TRANS. A. I. E. E., Vol. 24, p. 761, 1905.
3. TRANS. A. I. E. E., Vol. 41, p. 212, 1922.
4. *Archiv. fur Elektrotechnik*, Vol. 12, p. 149, 1923.

where c is the current density at a point $(x\ y)$ and ω is the circular frequency of this current. $u\ (x\ y)$ is determined by Maxwell's circuital equations:

$$\Delta \times H = \frac{4\pi}{c}\left(\sigma E + \frac{\epsilon}{4\pi}\frac{\partial E}{\partial t}\right),$$

$$\Delta \times E = -\frac{\mu}{c}\frac{\partial H}{\partial t}$$

with $\Delta . H = 0$ $\quad \epsilon \Delta . E = 4\pi\rho$

where H and E are the magnetic and electric field strengths, σ, ϵ, μ, the conductivity, permittivity and permeability, c is the velocity of light in free space, ρ the space electrical density, all expressed in absolute (Gaussian) units; and Δx, $\Delta .$ denote the operator's curl and divergence, in Gibbs' notation. Since skin effect is assumed to be two-dimensional, $\frac{\partial}{\partial 2}$ is an annihilator and the electric and magnetic field-strength components satisfy the equation—derived by curling from the two circuital equations:

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = j\,\frac{4\pi\sigma\mu\omega}{c}\,u - \omega^2\frac{\epsilon\mu}{c^2}\,u$$

but, since in a metal the displacement current $\frac{\epsilon}{4\pi}\frac{\partial E}{\partial t}$ is negligible compared with the conduction current, this reduces to:

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = j\,\alpha^2 u \text{ with } \alpha^2 = \frac{4\pi\sigma\mu\omega}{c}$$

Field's[5] equation is obtained from this, provided the conductor completely fills the slot, by simply noticing that for one-dimensional skin effect $\frac{\partial}{\partial y} = 0$ and that in electromagnetic units $c = 1$.

A particular solution of this last equation is:

$$u\ (x, y) = C \cosh\left[x\ \sqrt{n^2 + j\ \alpha^2} + \beta\right] \cos\ (n\ y + \gamma)$$

where C, n, β, γ are arbitrary constants, which may be complex numbers. By symmetry $u\,(+\,y) = u\,(-\,y)$, so $\gamma = 0$. n is determined by the condition equation obtained from the boundary conditions—continuity of the magnetic field—upon the plans $y = -\,b$ $y' = b'$

$$n \tan\ (n\ b) + \sqrt{n^2 + j\ (\alpha^2 + \beta^2)}\ \tan\left[b'\ \sqrt{n^2 + j\ (\alpha^2 + \beta^2)}\right] = 0$$

where b' is the distance from slot side to conductor, (see Fig. 1). This equation has an infinite number of complex roots n_k.

Likewise, the constant β is determined by the boundary conditions at the top and bottom. There is a difficulty here because the boundary conditions at the top of the conductor are not definitely known. In an alternator, they would depend on the relative position of the slot with respect to the pole face. If we write the solution in the form:

$$C = A\ e^{j\omega t} \sum_{k=1}^{\infty} C_k \cosh\left[x\ \sqrt{n_k^2 + j\ \alpha^2}\right] \cos\ (n_k\ y)$$

there is another difficulty because the normal solutions are not orthogonal and hence the coefficients C_k cannot be determined by Fourier's method. We shall not go into this here, but refer to Steidinger's paper (l. c. p. 152) for details. In what follows, the argument is limited to the fundamental harmonic ($k = 1$).

Assume that the conductor carries a total current $\sqrt{2}\ I\ e^{j\omega t}$. The average over a cycle of the total heat loss in the conductor is

$$\bar{Q} = \tfrac{1}{2} \int \rho / c /^2\ d\ v$$

ρ being the resistivity ($\rho = 1/\sigma$) and the integral being taken through the volume of the conductor. Integrating, and again referring to Steidinger's paper for details, we get:

$$Q = R\ I^2 \left[m_1\ a\ \frac{\sinh 2\ m_1\ a + \sin 2\ m_1\ a}{\cosh 2\ m_1\ a - \cos 2\ m_1\ a} \right]$$

$$\left[m_2\ b\ \frac{\sinh 2\ m_2\ b + \sin 2\ m_2\ b}{\cosh 2\ m_2\ b - \cos 2\ m_2\ b} \right] \qquad (1)$$

where R is the ohmic resistance, $m_1 = \alpha\ \sqrt{b/B}$ and $m_2 = \alpha\ \sqrt{b'/B}$. The resistance ratio K is $Q/R\ I^2$ by definition.

The function in parentheses is always greater than unity except for argument zero, when it becomes unity; it has been tabulated and plotted.[6] It is *only when the conductor completely fills the slot* ($b' = 0$) that the above equation reduces to Field's corresponding formula, which is derived also by Gilman, Lyon and others. It is only in this case that the resistance ratio, calculated by using one-dimensional skin-effect formulas, such as those given by Rogowski, Gilman, Lyon and others[7] can be expected to agree with facts. This conclusion is wholly in accordance with experimental evidence available to date.

In all practical cases, where the conductors do not completely fill the slot, the resistance ratio is *greater* than that calculated from one-dimensional formulas, such as given by Mr. Gilman in the paper under discussion. That the two-dimensional correction is usually negligible, but may easily become important is perhaps best shown by two illustrative examples.

As a first instance, take the test coil used in our M. I. T. investigation. Its dimensions, assuming a massive conductor, are, $2\ b = 1.418$ cm., $2\ a = 3.58$ cm. The slot dimensions are, $2\ B = 1.905$ cm., $2\ A = 7.62$ cm. The conductor is assumed to be laid flat on the slot bottom, symmetrically with respect to its sides. Then $b' = 0.24$ cm., and from the above formulas, $\alpha = 1.671$ cm.$^{-1}$ at 60 cycles for commercial copper and $m_2 = 0.861$ cm.$^{-1}$. The correction due to two-dimensional skin effect [2nd parenthesis in formula (1)] is 1.03 approximately, whereas the measured value was 1.02. Too much worth cannot be attached to this check, first, on account of the special construction of the coil which largely eliminated two-dimensional skin effect, second, in view of the uncertainty in the elimination of the iron loss, and third in view of the smallness of the correction.

As a second example, take the generator quoted in Gilman's paper under discussion. Here $2\ B = 1$ inch, $2\ b = 0.5$ inch. So $b' = 0.634$ cm. and $m_2 = 1.182$ cm.$^{-1}$. The two-dimensional correction is here about 1.12.

It should be carefully emphasized that the resistance-ratio formula (1) takes into account the fundamental harmonic only and that the two-dimensional skin-effect theory of n conductors per slot has not yet been worked out. In this sense, the above examples are only illustrative. Judging from available experimental evidence, two-dimensional skin effect seems to be more effective for conductors near the top than for those near the bottom. It follows that care and judgment should be exercised by the designing engineer in the use of Gilman's formula, particularly in the case of wide slots and highly insulated conductors.

R. B. Williamson: About 17 years ago the subject of eddy-current losses in armature conductors was brought before the Institute in a paper by A. B. Field. Previous to this it was known in a general way that generators sometimes developed high temperatures in the windings for no well explained reason. Such temperatures were not due to lack of sufficient copper, because the apparent current density in the copper was in many of these cases quite low. Mr. Field's paper showed that the excess heating was due to eddy currents and gave means for

5. This equation is also the starting point of Lyon's and Gilman's papers.

6. For instance by W. Rogowski in *Archiv fur Elektrotechnik*, Vol. 2, p. 97, 1913, also by W. V. Lyon, TRANS. A. I. E. E., Vol. 40, p. 1361, 1921 (Fig. 3). Notice that our m_1 is Gilman's "α" or $1/\sqrt{2}\ j$ Lyon s "α."

7. For instance Emde, *Elektrotechnik und Maschinenbau*, Vol. 40, p. 301, 1922. Also, Mayer, *Archiv. fur Elektrotechnik*, Vol. 12, p. 349, 1923.

estimating the amount of such excess loss. This paper, however, gave the methods of estimating the loss for solid conductors only, or for those infinitely laminated. In windings as actually made, the lamination can only be partial, and Mr. Gilman's previous paper presented before the Institute carried Mr. Field's work further and showed how to estimate the eddy current loss for different arrangements of winding and various degrees of stranding of the conductor. The present paper takes up some additional cases not covered by the previous one, and the two papers taken together form a very complete treatment of the whole subject. It is not possible to build successful large generators without taking this eddy-current effect carefully into account and arranging the winding accordingly. Contributions such as these by Mr. Gilman, while on the face appearing highly theoretical, are of the greatest practical importance to the designer and will doubtless form a valuable reference on this subject for many years to come.

S. L. Henderson: I think it has been pretty well brought out today that Mr. Field's article on eddy currents covered only two cases of conductors, namely, that of the solid conductor and that of the infinitely stranded conductor; obviously, only one practical case—the solid conductor.

I happened to be associated with Mr. Gilman at the time he developed an eddy-current formula and assisted him with the tests for checking the results of this formula, and while I am not entirely familiar with Mr. Taylor's article or with the discussion of Mr. Vallarta on whether the case comes under the one-dimensional or the two-dimensional theory, this much I do know: That the tests we made checked within one per cent of our calculation, and it is obvious, therefore, that in view of the other features of design which are not accurately determinable, any formula that will give results within one per cent is acceptable.

The comment was also made that Mr. Gilman's formula appeared involved and required considerable effort to apply. Of course, my point of view may be warped inasmuch as I have been using this formula probably for four or five years, but with the formula and the curves I think it is possible to check the eddy-current loss in any armature conductor within ten minutes; probably five minutes in the average case.

I think there was also a statement made that Field's article would cover most of the cases. This might be true on small machines, but where the size gets beyond, say, 1000 or 2000 kv-a., the conductors are stranded either twice or more times, and consequently it is necessary to be able to calculate the amount of eddy-current loss in the conductor, and it is only possible to do this with the aid of the formula as worked out by Mr. Gilman or possibly as stated by Mr. Taylor or Professor Lyon.

Tooth Pulsation in Rotating Machines

BY T. SPOONER

Member, A. I. E. E.

Research Engineer, Westinghouse Electric & Mfg. Co.

Review of the Subject.—1. *An experimental method is presented of checking the magnitude of flux pulsations in the teeth of rotating machines where both members are slotted. The method consists in using metallic electrodes shaped like the teeth of a machine and an electrolyte or mercury to represent the air. Voltage is applied between the two members and the current through the tooth under consideration is measured. The magnitude of this current under different conditions is proportional to the magnitude of the flux which would flow under the analogous magnetic conditions.*

2. *The test results are compared with the pulsation amplitudes as calculated by two methods. The test results are in general slightly lower than the calculated but the agreement is fairly good.*

3. *It is believed that either of the above-mentioned methods can be used to calculate tooth pulsations without serious errors where saturation effects are not appreciable. These methods should be specially useful in determining which of two or more designs would be subject to the lesser pulsation losses.*

4. *The effect of saturation in the iron is determined experimentally by making the ratio of the mercury to the electrode resistance small. This ratio corresponds to the magnetic permeability. The effect of the tooth resistance on the amplitude of the pulsation is calculated by assuming three resistances in series, namely, the stator and rotor tooth resistances and the air gap resistance. The calculated and test values check reasonably well.*

5. *It is shown that the effect of saturation on pulsation amplitude for actual machines can not be calculated by adding directly the air gap and tooth reluctances due to the fact that the permeability of iron is not constant. In order to actually calculate the effect of saturation, it is necessary either to plot portions of the magnetization curve or to make use as we do of the incremental permeability values.*

6. *The method described of allowing for saturation is too complicated for ordinary design calculations but is useful in giving a clearer picture of just what these effects are and could be successfully used for special cases where the extra labor involved was warranted.*

7. *These methods do not apply when short-circuited windings are present in the slots. It is hoped at a later date to consider this aspect of the problem.*

8. *We believe it is possible by the use of the outlined methods below to calculate simple, reasonably reliable correction curves for saturation effects which may be used both for the case of uniform mean flux and for a sine distribution of the mean flux.*

INTRODUCTION

WHEN the rotor and stator of a rotating machine are both slotted, high frequency flux pulsations are produced in the teeth which give rise to hysteresis and eddy-current losses. These losses may amount to a considerable percentage of the total core losses of the machine. In order to predetermine the magnitude of the losses and to reduce them to a minimum by proper design it is first necessary to be able to calculate the magnitude of the tooth pulsations. These pulsations are the result of local changes in the air-gap reluctance and are reduced by saturation effects in the iron of the teeth; namely, when the reluctance of the teeth is appreciable with respect to the reluctance of the air gap the tooth pulsations are less. Also the presence of short-circuited windings in the slots such as in the case of rotors of squirrel-cage induction motors or the damper windings of salient-pole machines tend to reduce these pulsations. These latter effects, namely, of short-circuited windings, will not be considered in this paper but it is hoped that at a later date we may deal with them also.

There are various methods of estimating the magnitude of tooth pulsations but a discussion of these will be reserved until we have first described an experimental method which we have applied to this problem. It is a simple matter to measure the magnitude of tooth pulsations in an existing machine and it has been done in several ways. For instance, we may place an exploring coil around the tooth in question, excite the core with direct current, reverse the direct current and note the deflection of a flux-meter or ballistic galvanometer connected to the exploring coil. Or we may slowly revolve the rotor and note the amplitude of the deflection of the fluxmeter. Again we may connect the exploring coil to an oscillograph and from the record with the rotor revolving determine the amplitude of pulsation by the following method due to Hoseason.[2] If the ratio of the amplitude of the tooth-frequency voltage ripple to the fundamental-frequency voltage amplitude be divided by the ratio of the tooth frequency to the fundamental frequency we shall have the amplitude of tooth flux pulsation with reference to the fundamental flux.

Hoseason has used another method, namely, to connect his tooth exploring coil to an electrostatic voltmeter, apply normal alternating voltage to the stator and obtain the maximum and minimum voltage readings when the rotor is revolved very slowly. Another method is one which we have used with a fair degree of accuracy, namely, simply to connect the tooth exploring coil to an a-c. voltmeter of the dynamometer type, excite the stator with direct current (full current in one phase and one-half reversed in the other two for a three-phase machine), and calculate the tooth pulsations from the readings, thus:

$$E_T = E_F \sqrt{1 + (1/8 + 1/8\,n^2)\,P^2} \qquad (1)$$

E_T = total tooth voltage,

1. This is one of a number of articles being published by members of the Core Loss Committee of the National Research Council.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

2. Tooth Frequency Iron Losses in Slip Ring Induction Motors, D. B. Hoseason; *Electrician*, Sept. 7, 1923.

E_F = voltage as calculated from the fundamental frequency flux (no tooth pulsations)
n = the number of teeth per pair of poles,
P = flux pulsations based on the fundamental frequency flux.

If the frequency is sufficiently high it is necessary to correct the dynamometer readings for the inductance error of the instrument. The above formula was developed by Dr. J. Slepian and is based on the assumption of a sine wave fundamental-frequency and tooth-frequency flux distribution. Any of these methods are satisfactory for completed machines but do not give us a means of predetermining the tooth pulsations for new apparatus.

Experimental Method

For a number of important investigations involving the determination of magnetic or electrical flux distribution, an electrolytic method has been used in which the electrodes were shaped like the magnetic or conducting portions, and an electrolyte took the place of the air. The current is caused to flow from one electrode to another and will follow the same path in the electrolyte as a magnetic flux, for instance, would follow in the air when passing from one ferro-magnetic member to another. As previously used the electric field was explored in the electrolyte by means of a potentiometer or millivoltmeter arrangement and the equipotential lines plotted. The current or flux lines were of course obtained by plotting perpendicular to the equipotential lines. A similar method making use of templates cut from high-resistance sheet to simulate teeth and slots has been used very successfully by Douglas[3] and by Roeternik[4]. We believe this method was first suggested by Carter. As used by most investigators this method was capable of giving results corresponding to the condition of infinite permeability only. Roeternik simulated the condition of moderate permeabilities by using a comparatively low-resistance template for the iron portion and joined to this a high-resistance template for the air portion. These methods, while yielding quite accurate results, are very slow and tedious.

It would have been possible to attack the problem by using the method of Hele-Shaw[5], in which a viscous liquid is caused to flow through certain definite channels and the flow lines indicated by dyes introduced in the liquid in suitable manner. This is also a tedious process.

For our work we have made use of a modification of the electrolytic method but have greatly simplified the experimental process by automatically integrating the current for maximum and minimum reluctance conditions. The method is made clear by referring to Fig. 1.

In order to determine experimentally the magnitude of the tooth pulsations, use was made of the analogy between the flow of electric currents and the distribution of magnetic flux. A set each of copper and brass blocks were machined from solid material having the dimension shown in Fig. 2. The thickness was ½

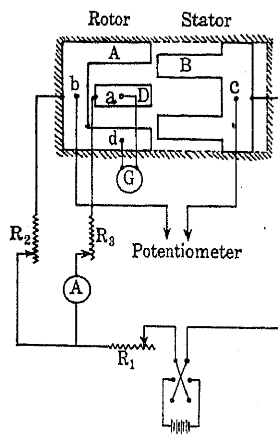

FIG. 1—DIAGRAM OF CONNECTIONS FOR TOOTH PULSATION TESTS

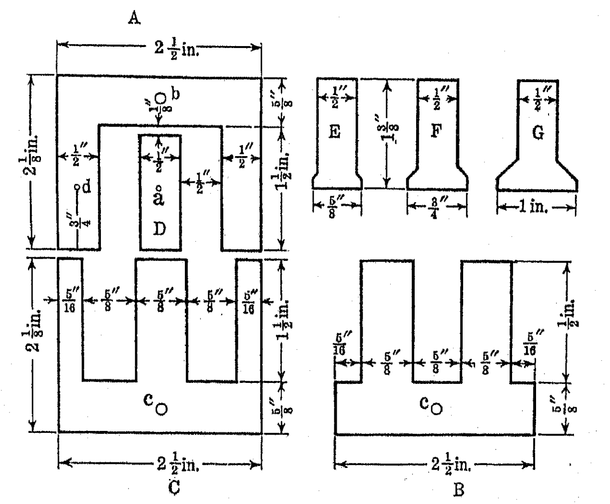

FIG. 2—COPPER AND BRASS BLOCKS FOR TOOTH PULSATION TESTS

inch (1.27 c m.). A tray was filled with paraffin wax with an opening left large enough to take a set of blocks arranged as shown in Fig. 1. The sides of the opening are shown by the dotted lines. Electrical connections were made to the blocks as indicated.

The principle of operation is as follows, tooth D being the one under test. It will be noted that block D is electrically separated from A in order that the current flowing into it may be measured. The openings between the blocks are filled with an electrolyte or mercury so that its level is just flush with the top of

the blocks. The blocks represent the iron teeth of a machine and the liquid represents the air. The ratio of the resistivity of the liquid to the resistivity of the block material gives the effective permeability. All we have to do then is to measure the current flowing into the block D for various conditions and this will be equivalent to the flux which will flow under the corresponding magnetic conditions, since the current corresponds to the flux and the voltage to the magnetomotive force. It will be seen that with the arrangement shown in Fig. 1, we have a maximum reluctance or resistance between tooth D and the teeth of the block B. Now if we remove block B and substitute block C (Fig. 2) we shall have the condition of minimum resistance. This change of blocks corresponds to a movement of the stator with respect to the rotor of one-half a slot pitch. The tests are made on the assumption of constant difference of magnetic potential between the stator and the rotor yokes and this corresponds to a constant electromotive force between points b and c.

The method of test was as follows. The block B was adjusted to the right or left (Fig. 1) to give a definite air gap between the stator and rotor blocks. The resistances R_2 and R_3 were adjusted until the galvanometer G showed no deflection. This means that tooth D and the teeth of A were at the same potential. Contact points a and d should really be at the left end of the teeth but it was thought better to put them as shown in order to allow the current in the tooth D to become uniform over the cross section. R_1 was next adjusted until the potentiometer connected to b and c gave the desired voltage which was kept constant for one set of readings. The ammeter A was then read. The battery was then reversed, the resistances adjusted and the ammeter again read. This reversal was for the purpose of eliminating thermoelectric effects. The air gap was then changed and another set of readings of the ammeter obtained. After the required range of air gaps was covered, block B was removed, block C substituted and the tests repeated. The percentage pulsation was then obtained by dividing the difference between the two ammeter readings for a given air gap by the maximum ammeter reading. The maximum instead of the average was used since in general hysteresis losses can more easily be calculated on a basis of maximum flux. After completing a set of tests with tooth D, it was removed and E, F and G substituted and the tests repeated. These latter teeth gave results for partly closed rotor slots. This gives a construction which of course is not met in commercial machines but for the purpose of checking our calculated results this does not matter.

If we use an electrolyte it will be seen that for all practical purposes its resistance is infinite with reference to the resistance of the copper or brass blocks. This will correspond then to the condition of moderate and low inductions in the teeth in which the permeability of the iron is many times that of air.

If, instead of an electrolyte, we use mercury with the copper blocks, for instance, we obtain a ratio of resistance of the copper to the mercury of approximately 55.5, which will be equivalent to a permeability of this value. By using brass blocks and mercury we obtain an effective permeability of 13.6.

With an electrolyte of course it was out of the question to use direct current so we went to a 500-cycle supply. In place of the galvanometer G, we used a telephone receiver and for the ammeter a thermo-electric instrument. Voltage was maintained constant by means of a Paul voltmeter placed outside of the ammeter A. Suitable corrections were made for the change in voltage due to the $I R$ drop in the ammeter. The resistance R_3 was eliminated.

TEST RESULTS

Preliminary Tests. Instead of using metallic electrodes a much greater range of permeability could be obtained by using a higher resistance material and various electrolytes. This would have the advantage also that only one set of electrodes would be required. Accordingly we first made a set of electrodes of cast tellurium (silicon was also considered but was abandoned due to the difficulty of machining and due to the difficulty of casting without blow holes). Tellurium has a resistivity of about 0.2 ohm-cm. which is the same order as that of high conductivity electrolytes. This would enable us to obtain effective permeabilities from the lowest values desired to the highest by simply varying the concentration of the electrolyte. Two difficulties were encountered. The first was the difficulty of making good electrical contacts with tellurium. This was overcome by coating the material where desired with copper by means of the Schoop spray. It was then possible to solder different parts together. The second and more serious difficulty was the fact that, no matter how carefully it was cleaned, the surface of the tellurium developed a much higher resistance than the average for the material. This means that the effective permeability could not be accurately determined.

After abandoning the tellurium, electrodes were made of a special graphite material supplied by Mr. G. M. Little and having a specific resistance of about one ohm. This was open to the same surface-resistance objection as the tellurium although to a much less degree. Both materials give good results with higher resistance electrolytes but were not suitable for a study of the effect of permeability changes.

Final Tests. With the copper and brass electrodes no serious difficulties were encountered. The tests under infinite permeability conditions were made with the copper electrodes and a strong copper sulfate solution. For the tests with the mercury bath the working surfaces of the electrodes were carefully

amalgamated. The top and bottom surfaces and the sides, except the working surfaces, were insulated with paraffin. Some precautions had to be taken against thermoelectric effects since the maximum currents in tooth D were of the order of 15 amperes and the maximum voltage drop between b and c only a fraction of a millivolt. Four air gaps were used for each set of blocks, namely, 0.04 in. (1.01 mm.), 0.081 in. (2.03 mm), 0.105 in. (3.8 mm.) and 0.180 in. (4.57 mm.).

Typical test results are given in Figs. 3-6 plotted between per cent pulsation based on the maximum

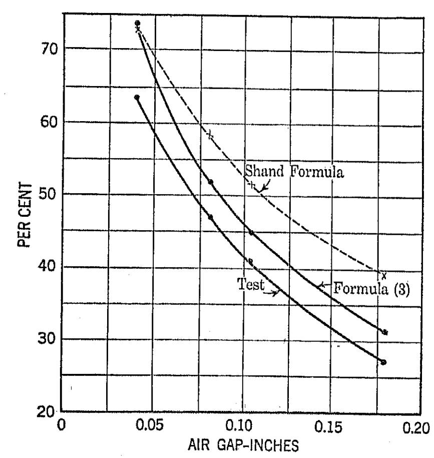

FIG. 3—TEST AND CALCULATED TOOTH PULSATIONS FOR TOOTH D AND INFINITE PERMEABILITY

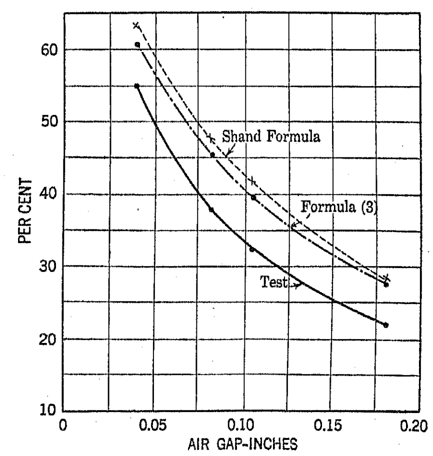

FIG. 4—TEST AND CALCULATED TOOTH PULSATIONS FOR TOOTH E AND INFINITE PERMEABILITY

current or flux and the air gap in inches. These curves are for infinite permeability. Fig. 7 shows the curve for tooth D and a permeability of 55.5, and Fig. 8 the corresponding curve for a permeability of 13.6. Fig. 9 gives a comparison between the test and calculated values for an air gap of .04 in., (1.01 mm.) and various permeabilities. Fig. 10 gives similar results for an air gap of .180 in. (4.57 mm.). Fig. 11 shows the relation between air gap and per cent pulsation of tooth D and the three permeability conditions.

METHOD OF CALCULATING PULSATIONS

The tooth pulsations could doubtless be predicted quite accurately by the well-known graphical method of plotting the flux flow lines. A good recent example of the use of this method is given by Lehmann,[6] for checking the accuracy of his air gap reluctance formulas for the case of slotted rotors and stators. This method, however, is quite laborious.

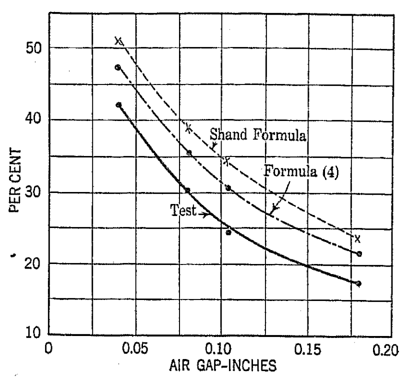

FIG. 5—TEST AND CALCULATED TOOTH PULSATIONS FOR TOOTH F AND INFINITE PERMEABILITY

A comparatively simple mathematical method which has frequently been used for air-gap reluctance calculations is to assume that the air-flux paths follow straight lines and arcs of circles. This method gives results when applied to the case of one smooth and one slotted member which check Carter's more exact calculations very well. Still[7] has recently used this method quite successfully in considering air gap

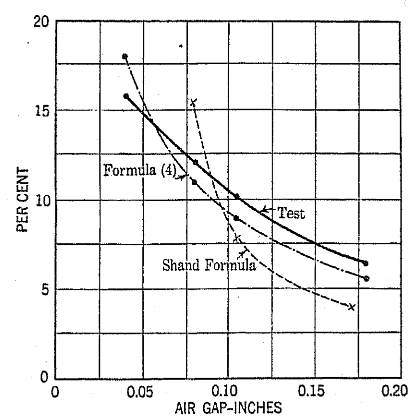

FIG. 6—TEST AND CALCULATED TOOTH PULSATIONS FOR TOOTH G AND INFINITE PERMEABILITY

reluctances when saturation effects are present. Mr. E. B. Shand has used this method for deriving curves according to certain definite assumptions by means of which he is able very quickly to estimate the mag-

7. Flux Distribution in Air Gap and Teeth of Dynamos. Alfred Still; *Electrician*, Feb. 10-17, 1922.

nitude of the tooth pulsations for the case of infinite permeability. His data are not yet published.

Some time ago we devised formulas for calculating tooth pulsations making use of Carter's fringing constants which apparently work very well. Hoseason[8] has recently suggested the use of such a method but did not go into details as to how to apply it. Our method is as follows. Referring to Fig. 12, suppose we calculate the effective width (t_e) of the stator and rotor teeth by using Carter's fringing constants[9] and assume that all the flux crossing the air gap is confined to those widths and that it is of uniform density. Suppose that we also assume that the flux flows only over those portions of the effective tooth widths which happen to be opposite each other. Now by calculating the change in

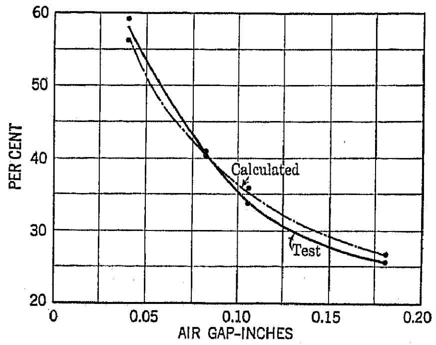

FIG. 7—TEST AND CALCULATED TOOTH PULSATIONS FOR TOOTH *D* AND A PERMEABILITY OF 55.5

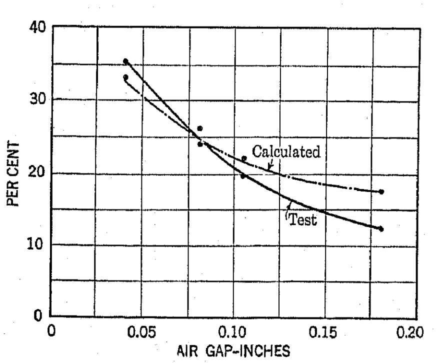

FIG. 8—TEST AND CALCULATED TOOTH PULSATIONS FOR TOOTH *D* AND A PERMEABILITY OF 13.6

tangential air gap widths opposite each other for the position of maximum and minimum reluctance, we can estimate the amount of the tooth pulsations. When Carter's coefficients for the stator and rotor teeth have already been calculated for other purposes, the effective width of the tooth may be obtained from the ratio $\lambda/g\ (= t_e)$ where λ is the tooth pitch and g is the Carter coefficient.

Referring now to Fig. 13 we have ~~the four~~ cases which are likely to occur in practise for induction motors. The stator tooth pulsations in per cent of the maximum flux can almost always be calculated by the formula (open stator slots).

$$P_s = \frac{\lambda_r - t_{er}}{t_{es}} 100 \qquad (2)$$

There are four cases for the rotor teeth depending on the relative dimensions. These four cases are covered by the following formulas:

Case 1 — Limits

$$P_{r1} = \frac{\lambda_s - t_{es}}{t_{er}} 100 \qquad (3)$$

P_{r1} cannot exceed 100

t_{es} is greater than t_{er}

Case 2

$$P_{r2} = \frac{\lambda_s - t_{er}}{t_{es}} 100 \qquad (4)$$

t_{es} is less than t_{er}

P_{r2} has a positive sign

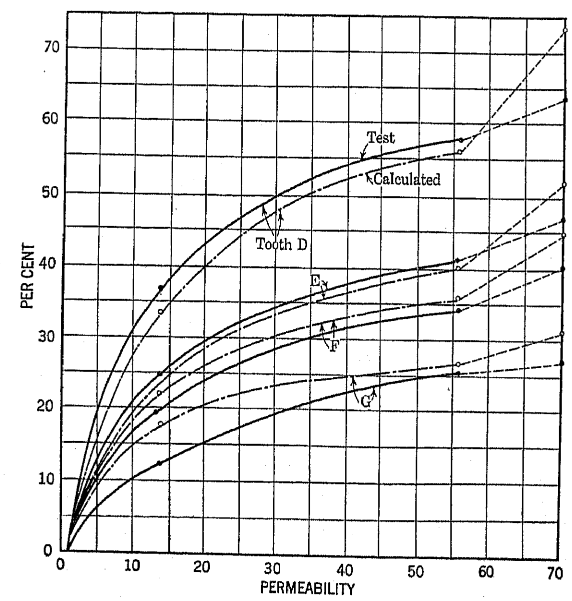

FIG. 9—TEST AND CALCULATED TOOTH PULSATIONS FOR VARIOUS TEETH AND PERMEABILITY AND AN AIR GAP OF 0.04 INCHES

Case 3

$$P_{r3} = \frac{t_{er} - \lambda_s}{t_{er} - \lambda_s + t_{es}} 100 \qquad (5)$$

t_{es} is less than $t_{er} - \lambda_s + t_{es}$

t_{er} is less than $2\,\lambda_s - t_{es}$

Case 4

$$P_{r4} = \frac{\lambda_s - t_{es}}{t_{er} - \lambda_s + t_{es}} 100 \qquad (6)$$

t_{er} is greater than $2\,\lambda_s - t_{es}$

t_{er} is less than $\lambda_s + t_{es}$

where,

P_s is the stator tooth pulsation in per cent of the maximum tooth flux

P_{r1}, P_{r2}, P_{r3} and P_{r4} are the rotor tooth pulsations for the four cases.

λ_s is the stator slot pitch

λ_r is the rotor slot pitch

t_{es} is the effective stator tooth width

t_{er} is the effective rotor tooth width.

Cases 1 and 2 are to be used when the rotor slot pit[illegible]ie [illegible]ully

8. Tooth Frequency Iron Losses in Slip Ring Induction Motors, D. B. Hoseason; *Electrician*, Sept. 7, 1923.

9. Electrical Machine Design. Alexander Gray; p. 44, fig. 40.

is less than the stator slot pitch and cases 3 and 4 when the reverse is true. The conditions for the four cases are shown graphically in Fig. 13. If the rotor slot pitch becomes greater than covered by case 4, a fifth and sixth case, etc., may be added if necessary but the above four cases will cover practically all commercial conditions. After the effective tooth widths are calculated it takes only a moment to determine which formula to use.

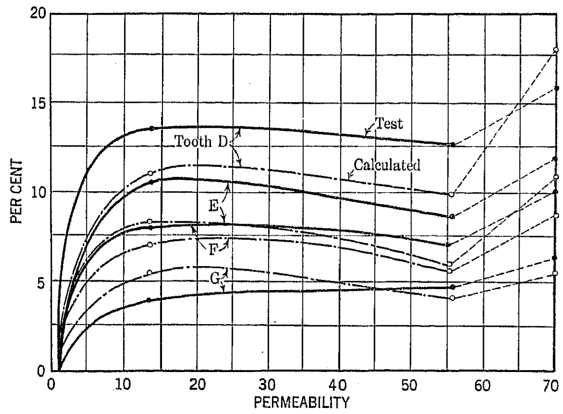

FIG. 10—TEST AND CALCULATED TOOTH PULSATIONS FOR VARIOUS TEETH AND PERMEABILITY AND AN AIR GAP OF 0.04 IN.

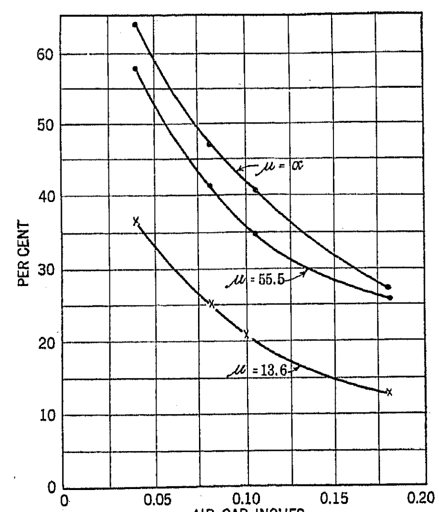

FIG. 11—TEST TOOTH PULSATIONS FOR VARIOUS AIR GAPS AND PERMEABILITIES FOR TOOTH *D*

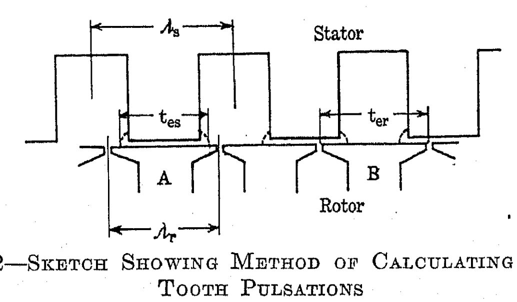

FIG. 12—SKETCH SHOWING METHOD OF CALCULATING ROTOR TOOTH PULSATIONS

These formulas do not give strictly correct results since they are based on assumptions which are not quite true. Their reliability will be discussed a little later. Fig. 14 shows the sort of pulsation curves that are obtained by their use. It will be noted that when passing from one formula to the next the curves are discontinuous. Approximately true results will probably be obtained by rounding off these curves at those positions. At the point of transition from one formula to the next, either formula will give the same result.

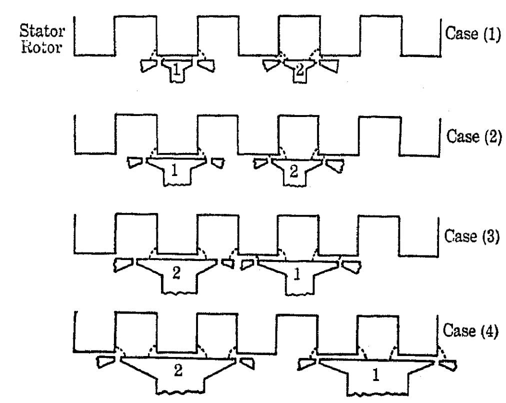

FIG. 13—SKETCH SHOWING METHOD OF DERIVING TOOTH PULSATION FORMULAS

The calculation of curves of this kind will yield a number of interesting points, some of which have been mentioned by Hoseason.[10] It should be noted that these formulas apply only to the case of infinite permeability.

Comparison between Calculated and Test Results. By

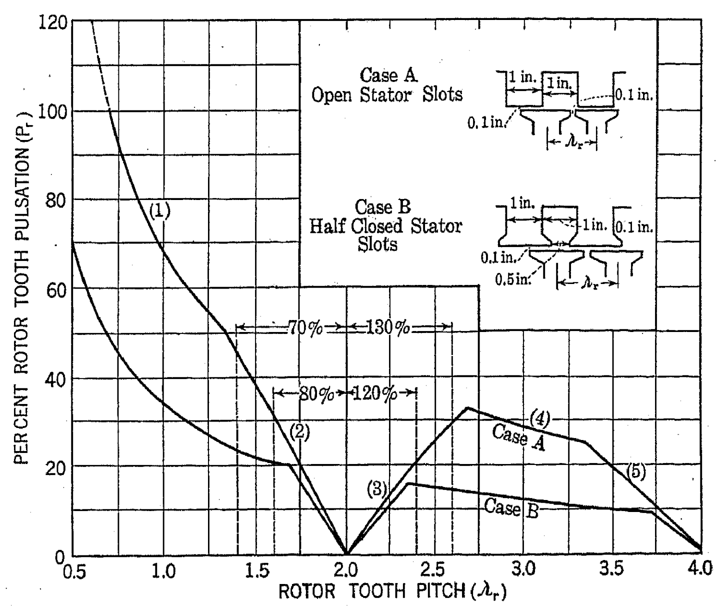

FIG. 14—SKETCH SHOWING EFFECT OF CHANGING ROTOR SLOT PITCH WITH REFERENCE TO STATOR SLOT PITCH

referring to Figs. 3-10, it will be seen how the test values compare with the pulsations as calculated by the above-mentioned methods. It will be noted that in general the calculated results are slightly higher but

10. Tooth Frequency Iron Losses in Slip Ring Induction Motors, D. B. Hoseason; *Electrician*, Sept. 7, 1923.

the shape of the curves checks very well. We feel quite confident that the formulas when properly applied may be used without any very large errors when the inductions are sufficiently low so that saturation effects are negligible.

Calculation of Saturation Effects. In order to calculate the effect of saturation on the pulsation values we made use of the following method, (see Fig. 15) which consists simply in adding the air-gap resistance to the tooth resistances. It was assumed that the specific resistance of the mercury was 1 and that the resistance of the electrode material was 1 divided by the permeability. It was also assumed that the vertical thickness was unity. The resistance of tooth D is then (Fig. 15, position 1).

$$R_1 = \frac{d_r}{t_r\, x\, \mu} \qquad (7)$$

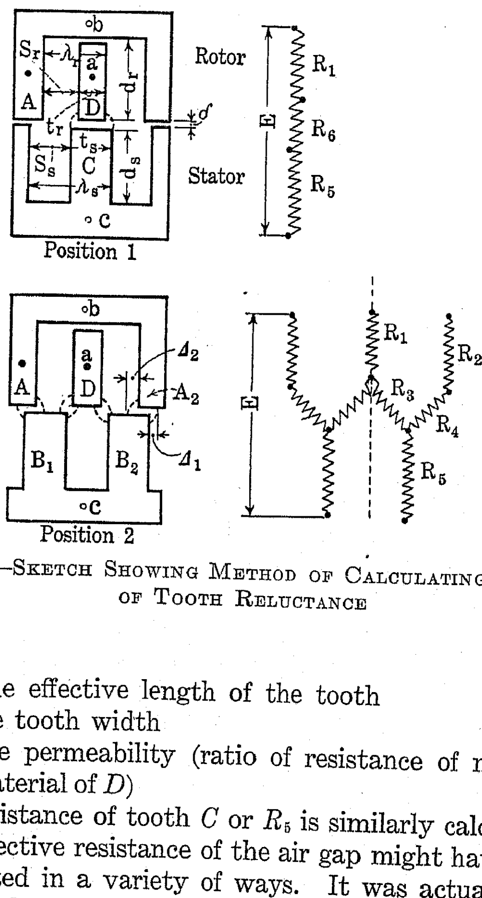

FIG. 15—SKETCH SHOWING METHOD OF CALCULATING EFFECT OF TOOTH RELUCTANCE

where,

d_r is the effective length of the tooth

t_r is the tooth width

μ is the permeability (ratio of resistance of mercury to material of D)

The resistance of tooth C or R_5 is similarly calculated. The effective resistance of the air gap might have been calculated in a variety of ways. It was actually calculated by using Carter's coefficients. The effective tangential width of the air gap since tooth D is narrower than tooth C (position 1) is then,

$$t_{er} \text{ or } \lambda_r/g_r$$

$$t_{er} = t_r + f_{sr} \text{ (see Gray p. 44)} \qquad (8)$$

λ_r is the slot pitch for $A - D$, and

g_r is the rotor tooth Carter coefficient.

The effective resistance of the air gap is then,

$$R_6 = \delta / t_{er} \qquad (9)$$

Position 2 for maximum reluctance is more complicated. The equivalent resistances are indicated at the right (Fig. 15). It will be seen that the right and left halves of the diagram are alike so we can use one-half only for the calculations.

R_1 is the same as above

R_2 is equal to R_1 for the particular case here considered

R_5 is the same as above

R_3 is obtained as follows, using the effective tooth width as calculated by Carter's method mentioned above.

$$R_3 = \frac{\delta \times 2}{t_{er} - \lambda_s + t_{es}} \qquad (10)$$

(see 11, case 1).

In order to calculate R_4 or the effective air gap resistance between A_2 and B_2, we have to determine the fringing for the two teeth and add this to the amount which the two teeth overlap, thus, (see Fig. 15, position 2).

$$\Delta_1 = \frac{t_{es} - t_s}{2} \qquad (11)$$

$$\Delta_2 = \frac{t_{er} - t_r}{2} \qquad (12)$$

$$\text{The overlap} = \frac{3\, S_s}{2} - \frac{3\, S_r}{2} = 0.187 \qquad (13)$$

$$R_4 = \frac{\delta}{\Delta_1 + \Delta_2 + 0.187} \qquad (14)$$

The equivalent resistance can now be calculated as indicated by Fig. 15. If now we assume that one volt is applied between the roots of the rotor and the roots of the stator teeth, then the maximum and minimum currents i_1 and i_1' in tooth D can be calculated as indicated and the pulsations would be proportional to these currents. In the case of teeth F and G where the resistance of the teeth has a larger influence on the results than in the case of D and E, the potential drop was taken between points a and c instead of c and b. Under these conditions the tooth resistances were taken only from the point a down (¾ in.) and a correction was made to take care of the resistance from point c to the roots of the B and C teeth.

The calculated curves of Figs. 7-10 were obtained by the above method.

Discussion of Results. Referring to Figs. 3-6, it will be seen that for infinite permeability the calculated results are in general somewhat higher than the test results and that the results as obtained by the use of Carter's coefficients are somewhat closer to the true results than those obtained by the Shand method. The differences, however, are not large and due to other uncertainties in calculating iron losses are probably quite accurate enough for estimating tooth pulsations. The reason that the calculated losses using Carter's coefficients are slightly high is probably due to the fact that uniform flux over certain distances is

assumed whereas in reality the flux does not terminate sharply but gradually shades off. It is surprising that the results check as well as they do.

When saturation effects come in, namely, with the copper and brass blocks and mercury, the checks between the calculated and test results are in general equally good. There are a few rather wide variations but these are due probably as much to testing errors as to inaccuracies in the method of calculation. At least the checks are close enough to show that the assumptions and methods are not in serious error. The testing for tooth G was specially difficult since the pulsations are small and an error of one per cent in reading the currents due to thermoelectric effects, an inaccuracy in setting the air gap or other causes would mean approximately a 10 per cent error in percentages. The apparatus was crude and the results could not be expected to check much better than they do.

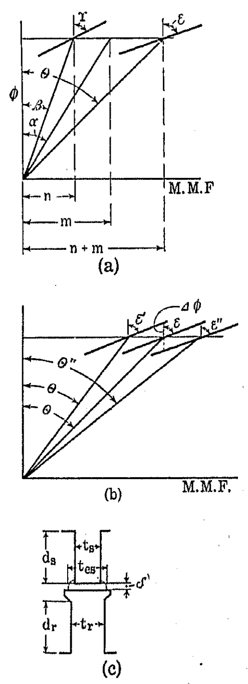

FIG. 16—SKETCHES SHOWING METHOD OF CALCULATING EFFECT OF SATURATION ON TOOTH PULSATIONS

Referring to Fig. 10 an actual increase in percentages of pulsation for the smaller permeability was noted both by test and calculation. This was due to the certain peculiarities of the testing and probably would not occur in any commercial machine.

Fig. 11 shows that for tooth D at least it is necessary for the permeability to be reduced to about 13 in order to reduce the pulsation percentage to one-half its value at infinite permeability. We shall discuss this further a little later.

Saturation Effects in Actual Machines. In order to calculate the saturation effects in the teeth of actual machines it would seem at first glance that it is simply necessary to add the reluctance of the teeth to the reluctance of the air-gap for the positions of maximum and minimum air-gap reluctance, calculate the total change in reluctance due to the change in air-gap reluctance for the tooth under consideration and then take this difference as a measure of the tooth flux pulsation. This procedure would be correct if the permeability of iron were constant. Since this is not the case, however, the method is far from valid. Again from permeability curves on commercial sheet iron it may be seen that it is necessary to go to inductions of over 120 kilolines per sq. in. before we reach a permeability as low as 100. According to the data just reported (see Fig. 11) a permeability of even as low as 50 does not very greatly affect the pulsation amplitude and yet we know from tests on actual machines that saturation effects begin to be noted at tooth inductions of about 70 kilolines per sq. in. where the permeability may be several thousand, and at 120 kilolines these saturation effects are quite large. The following analysis will make clear the reason why these saturation effects appear at such low flux densities and will also give a method of calculating them.

Referring to Fig. 16C let us assume two teeth opposite each other having the dimensions as indicated. These dimensions may be in any desired units provided the units are all the same; d_r is the effective length of the rotor tooth and is somewhat less than the actual length to take care of the wide tip which does not saturate: t_{es} is the effective tangential width of gap and is equal to t_s (actual stator tooth width) plus Carter's fringing constant times the stator slot width as above. Now referring to Fig. 16A the ordinate represents the total flux per tooth across the air gap and the abscissas the magnetomotive force necessary to force this flux through the various parts of the path from the root of a stator tooth to the root of a rotor tooth. The magnetomotive force m is that necessary to force the flux across the air gap from one tooth to the other and is equal to the flux times the air-gap reluctance R_δ where the air-gap reluctance equals the radial air-gap width δ divided by the effective tangential air-gap width t_{es}; n is the magnetomotive force necessary to force the flux through the stator and rotor teeth and is equal to $\phi \times R_f$, where R_f is the total tooth reluctance. The tooth reluctance must be calculated separately for a stator and rotor tooth and is equal to

$$\frac{d}{\mu \times t} \tag{15}$$

d is the effective length of tooth,
μ is the permeability corresponding to the maximum induction and t is the width of the tooth. The sum of the reluctance for the two teeth gives R_f.

Now referring to Fig. 16A, suppose we assume some arbitrary flux and plot a point corresponding to this flux and to the magnetomotive force $= \phi\, R_\delta$. Draw a line from this point through the origin and call the angle made by this line with the vertical α. Now the tangent of this angle is,

$$\frac{\phi \times R_\delta}{\phi} = R_\delta \tag{16}$$

and is proportional to the reluctance of the air gap. Similarly the tangent of the angle β is R_f and is proportional to the reluctance of the teeth. Suppose now we increase or decrease the flux ϕ. The line making the angle α (air-gap reluctance) will simply be extended. If, however, we consider the line making the angle β (tooth reluctance), when the flux is increased the line will not be extended but will follow a curve corresponding to the magnetization curve for the steel. In order to simplify this instead of plotting a magnetization curve, let us consider that the flux follows a straight

line, making the angle γ with the vertical. This angle γ is calculated in the same way as the angle β except that we use the incremental permeability μ_Δ[11] instead of the ordinary permeability. The incremental reluctivity $R_{f\Delta}$ is the sum of $\dfrac{d}{\mu_\Delta \times t_f}$ for the two teeth. This simply means that we are assuming that over the range of inductions covered by the tooth pulsations the magnetization curve is a straight line which is the line connecting the two tips of a minor hysteresis loop, having the same flux amplitude as the tooth pulsations and whse upper tip corresponds to the maximum tooth induction.

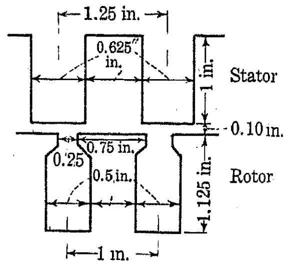

FIG. 17—SKETCH OF TEETH FOR ILLUSTRATING SATURATION EFFECT CALCULATIONS

Now if we combine the air gap and tooth reluctances we obtain a line making an angle θ with the vertical and the tangent of the angle will be $R_\delta + R_f$ and the tangent of the angle ϵ will be $R_\delta + R_{f\Delta}$.

Now referring to Fig. 16B the angle θ is the same as for 16A, namely, at the assumed flux the magnetomotive force equals $R_\delta + R_f$ where R_δ is the mean reluctivity of the air gap. If now we calculate the tooth pulsations by the appropriate formula (3)-(6) and make R_δ' one-half this per cent less than R_δ and R_δ'' the same amount greater we may calculate the tangents of the angles δ', δ'', ϵ', ϵ'', as shown by Fig. 16. Now if we draw a vertical line through the point of intersection of the line of θ and the assumed flux the length of this line $\Delta\,\phi$ (Fig. 16B) between the lines of ϵ', and ϵ'' will be the flux pulsation or will give the per cent pulsation numerically if the maximum flux is assumed to be 100.

In the above it is quite immaterial what the flux and magnetomotive force units are. In fact, it is perhaps convenient to make the tooth reluctance values equal simply to the tooth lengths in inches divided by the permeability and the tooth widths in inches. In order to make this analysis clearer a simple case will be assumed and the calculations gone through to illustrate the method.

Example. Refer now to Fig. 17.

$q_s = 6.25$ stator (S_s/δ)

$q_r = 2.5$ rotor (S_r/δ)

$t_{es} = 0.905$

$t_{er} = 0.916$

$$P_{r2} = \frac{1.25 - .916}{0.905} = 0.368 \text{ (see formula 4)}$$

Now from the derivation of formula 4 for P_{r2} we see that t_{es} represents the maximum effective contact area of the two teeth. Then the mean area equals:

$$0.905 - \frac{0.905 \times 0.368}{2} = 0.739$$

The above is on the assumption of infinite length of punchings axially.

This value 0.739 is t_{es} for Fig. 16C. Then,

$$R_\delta = 0.1/0.739 = 0.135$$

Now assume that the maximum tooth induction is 110 kilolines per sq. in. on a sine wave basis and let us assume no stator tooth pulsations. Also let us assume that due to saturation effects the rotor tooth pulsation is only one-half the calculated value of .368 or 0.184. This means that the true maximum rotor tooth induction will be

$$\frac{110}{1 - 0.184/2} = 121 \text{ kilolines,}$$

and the minimum will be 98 kilolines.

$$\text{Now } R_f = \frac{1}{295 \times 0.625} + \frac{1^*}{295 \times 0.5} = 0.0122$$

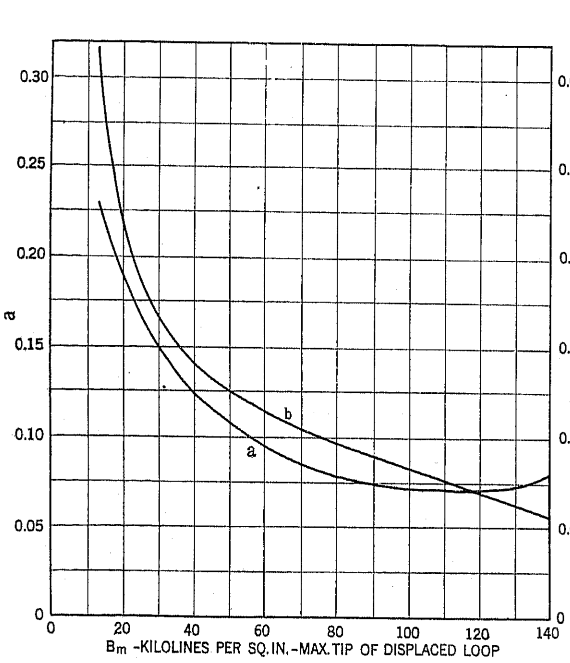

FIG. 18—CONSTANTS FOR INCREMENTAL PERMEABILITY CALCULATIONS

$\mu_\Delta = \mu_m\,(a + b \times \Delta\,B)$

(μ_m is the ordinary permeability corresponding to B_m)

The permeability value of 295 is an average value for *O H* electrical sheet at $B = 110$ kilolines.

$B_m = 121$

$\Delta\,B = 121 \times 0.184 = 22$

$\mu\,\Delta = 115\,(0.071) + 22 \times 0.0068) = 25.4$ (see Fig. 18)[13]

(115 is the μ corresponding to 121 kilolines)

11. Permeability. Thos. Spooner: A. I. E. E. JOURNAL, January 1923.

*12. Effective Length of rotor tooth taken as 1 inch.

13. Fig. 17 is derived from the data of Fig. 4, A. I. E. E. JOURNAL, p. 42, January 1923, but altered slightly at the high inductions to conform more closely to recent data and converted to English units.

$$R_{f\Delta} = \frac{1}{25.4 \times 0.625} + \frac{1}{25.4 \times 0.5} = 0.143$$

$$R_{\delta}' = 0.1/0.905 = 0.110$$

$$R_{\delta}'' = \frac{0.1}{0.905 \times 0.632} = 0.175$$

$$\begin{aligned} \text{Tan } \theta' &= 0.110 + 0.012 = 0.122 \\ \text{Tan } \theta'' &= 0.175 + 0.012 = 0.187 \\ \text{Tan } \epsilon' &= 0.110 + 0.142 = 0.252 \\ \text{Tan } \epsilon'' &= 0.175 + 0.142 = 0.317 \end{aligned}$$

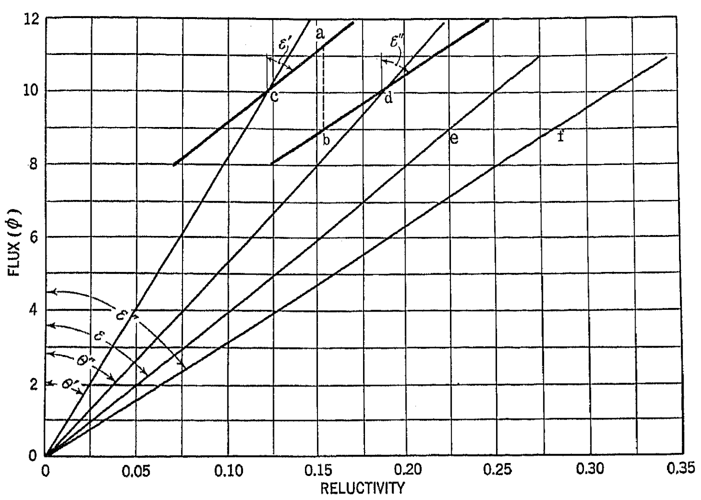

FIG. 19—DIAGRAM SHOWING METHOD OF CALCULATING EFFECT OF SATURATION FOR TEETH OF FIG. 18

$$P_r = \frac{11.25 - 8.95}{11.25} \times 100 = 20.4$$

Now referring to Fig. 19 for the vertical ϕ axis we may use any arbitrary scale we please but for convenience suppose we divide it into ten divisions. On the horizontal axis we have the reluctivity scale corresponding to the values as calculated above. On the line corresponding to the flux of 10 we plot the tangent θ' and θ'' and the tangent ϵ' and ϵ'' or reluctivity values, giving the lines $O - c$, $O - d$, $O - e$ and $O - f$, respectively. Now with a pair of triangles we transfer the lines $O - e$, $O - f$ so that they pass through the points c and d, respectively. Now at the midpoint between c and d, erect a perpendicular. The vertical distance between the points a and b gives the total flux pulsation in the teeth and divided by the maximum ϕ ordinate (point a) and multiplied by 100, gives the per cent flux pulsation or 20.4 as against 36.8 per cent if there had been no saturation effects. It will be noted that without taking into account the incremental permeability, the flux pulsation would be the difference between the line $O - c$, $O - d$ or nearly double the corrected value as just stated.[14]

This correction for saturation applies only for the teeth in the position of maximum induction. In the case of an induction motor where the flux varies approximately according to a sine wave, the saturation effects will be different for every flux value and this greatly complicates the correction. The actual use of this method is more difficult than indicated in the example due to the presence in commercial machines of tapered teeth, to appreciable leakage fluxes through the slots at high inductions and various other disturbing factors. We believe, however, that for careful machine design the method is valid and may be employed with confidence when the extra labor involved warrants its use. These pulsation calculations are correct only when short-circuited windings are not present. For the case of the squirrel-cage induction motor and the salient-pole machines with damper windings, corrections will be necessary for the counter-magnetomotive force of the short-circuited windings.

We have calculated saturation correction curves based on different relative tooth widths, lengths and air gaps for the case of induction motors. These curves have not been adequately checked experimentally and will not be included here. We hope, however, that they will prove to be reasonably accurate and if they are, will make a ready method of correcting for saturation effects in wound rotor induction motors.

14. If this calculated value had been much different from the assumed value of 18.4 per cent it might have been advisable to recalculate.

Discussion

For discussion of this paper see page 280.

Surface Iron Losses With Reference to Laminated Materials

BY T. SPOONER and I. F. KINNARD
Member, A. I. E. E. — Associate, A. I. E. E.
Both of the Westinghouse Electric & Mfg. Co.

Review of the Subject.—*Surfaces or pole-face losses are assumed to be governed by ten factors and the influence of each on the resulting losses is considered. After reviewing the work of the previous investigators an account is given of some rather extensive tests recently completed by the writers. These tests cover results obtained on an experimental salient pole machine and an experimental 3-phase induction motor. Data are given for various types and thicknesses of commercial sheet.*

For a given material and machine the surface losses are assumed to be a function of the air-gap induction, ratio of slot width to single air gap, tooth frequency and slot pitch or width. The laws of variation of surface losses with respect to these variables are determined from experimental results and are shown to be in general exponential. The relation between hysteresis and eddy-current losses and the effect of variations in thickness and resistivity of laminations is considered in some detail.

Simple methods are given for applying these results to actual design problems which involve plotting the various functions on double log paper, a slide rule being then sufficient for all calculations.

The appendix gives a description of a graphical method of separating the various types of core losses which exist in a polyphase induction motor.

Introduction

Surface losses, or pole-face losses as they are sometimes called, are common to nearly all types of rotating machines in which at least one member is slotted. In many machines they are responsible for a very appreciable percentage of the total no-load losses. It is often very desirable to be able to calculate their magnitude with a reasonable degree of accuracy and it is sometimes well to know the best way in which to reduce them.

It is the purpose of this paper to analyze as accurately as possible from the data which we have available the various factors affecting surface losses and to combine them into easily usable design formulas.

We shall define surface losses as those hysteresis and eddy-current losses which occur just below the surface of a magnetized smooth-core laminated material which is adjacent to a slotted member having a relative motion with respect to the first member. One of the most familiar examples of pure surface losses is in the poles of salient-pole machines having no damper windings. When this first member is slotted as well as the second the losses of the former are increased due to the greater penetration of the pulsating flux and to the higher flux density. The losses due to high-frequency pulsations penetrating through the whole length of a tooth will be known as tooth-pulsation losses. A discussion of this latter type of loss is beyond the scope of this paper.

There have been published a number of formulas for calculating pole-face or surface losses. Some of them have been based on theoretical considerations alone and some on empirical formulas derived from test data on experimental or commercial machines. Still others are based on theoretical considerations but the constants are derived from actual tests on machines. Some of these formulas are difficult to use due to their complication; some are based on insufficient or inaccurate test data and some of the older ones applied to material which is no longer in commercial use. Most of them either have not been verified by other observers or if they have, the constants are known to be in doubt, or erroneous. Finally, so far as we know, the experimental data which have been published do not show the relative magnitude of the hysteresis and eddy-current components which leaves us in doubt as to the best choice of material with reference to thickness and magnetic quality to be used for pole shoes and for similar applications. For these reasons and others to be mentioned later it was therefore thought worth while to make a rather thorough investigation of this subject with the idea of putting it on a simpler and more rational basis having in mind especially that it should be possible to predict the performance of any laminated material under these conditions of use from a knowledge of its fundamental electrical and magnetic characteristics just as we can predict the core loss of a transformer from an Epstein test on samples of the material entering into its construction. The experimental work is limited to the case of open slots only.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

Factors Affecting Losses

In analyzing this problem we wish especially to acknowledge our debt to Adams and his collaborators for the aid received from their classic paper on "Pole Face Losses."[1] We have to a large extent followed the trail blazed by them and their predecessors. In considering this problem we have taken into account the following factors.

1. Air gap induction B_{AG}
2. Field form
3. Ratio of slot width to single air gap q
4. Tooth frequency f_t
5. Tooth pitch λ or slot width σ.
6. Resistivity of material ρ.
7. Thickness of individual laminations t.
8. Hysteresis coefficient r.

1. Adams, Lanier, Pope, Schooley. Trans. A. I. E. E., page 1133 (1909)

9. Insulation between laminations
10. Effect of punching.

Surface losses are a function of the flux density, the frequency of pulsation and the quantity of material involved as is the case for the simpler problem of the alternating-current transformer. The additional complications are due to four things: (1) the very appreciable departure of the pulsating wave form from that of a sine wave; (2) the rapid decrease in the amplitude of pulsations from the surface inward; (3) the fact that the high-frequency pulsating fluxes are superimposed on the fundamental-frequency flux variations (namely, we have a case of displaced unsymmetrical hysteresis loops which produce increased hysteresis losses over those caused by symmetrical hysteresis loops of the same amplitude of pulsation); (4) due to the high frequency of the tooth pulsations and to the thickness of material commonly used, skin effects become quite appreciable.

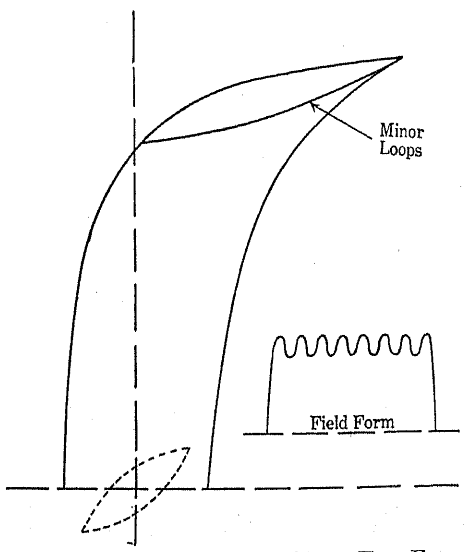

FIG. 1—HYSTERESIS LOOPS WITH FLAT TOP FIELD FORM

We have two general types of field form, *i. e.*, the flat top as given by a salient-pole machine with uniform air gap and the sine as usually approximated in the induction motor. With chamfered poles we may have almost any form in between. The flat-top field form produces a major hysteresis loop in the smooth-core member and near the surface there is superimposed a series of unsymmetrical hysteresis loops as shown by Fig. 1. These minor loops are all of approximately the same amplitude for a given depth of penetration and occur at the tips of the major loops. As we penetrate deeper away from the air-gap surface these minor loops decrease rapidly in amplitude. For a sine wave distribution of flux we have the following condition (see Fig. 2). Superimposed on the major loops are a series of minor loops changing in amplitude in proportion to the displacement from zero induction.

The flux density is determined chiefly by the average air-gap induction B_{AG}. Of course for a sine-wave flux distribution the maximum flux density is greater than for a flat top distribution for the same average air-gap induction. The frequency f_t or number of minor hysteresis loops is determined by the number of teeth which pass a given position per second. We have preferred to use tooth frequency rather than air-gap velocity as is used by some of the previous investigators since it seems to correspond better to our habits of thought when considering alternating-current iron losses. It is also more convenient when considering surface losses in connection with tooth pulsation losses as must be done in the case of induction motors, for instance. The magnitude of the flux pulsations in the air gap is chiefly determined by the ratio of slot width to radial air gap (equals q). The depth of penetration of the pulsating fluxes is chiefly a function of the slot pitch λ or perhaps more accurately the slot width σ.

In other words, the first five items of the factors affecting losses give us a measure of the three fundamental variables, induction, frequency and volume of material as previously outlined.

In considering the quality of the material which for the transformer is determined by the Epstein or some similar test we must consider items 6, 7 and 8. The sixth item, resistivity of the material ρ determines, together with item 7, the thickness of laminations t, the eddy-current loss to be expected, assuming perfect insulation between laminations. It must be remembered that these two factors also govern the skin effect as produced by the screening currents of Mr. Adams' previously-mentioned paper. These effects can by no means be neglected for commercial laminated poles. Item 8, the hysteresis coefficient governs the hysteresis loss. This in turn is affected by the screening currents and by the amplitude of the displacement of the minor high-frequency hysteresis loops from the normal position.[2,3,4] Items 9 and 10, the insulation between laminations and the effect of punching, are incidental to the process of manufacture and will be considered in detail later.

We shall make no attempt to derive theoretical formulas for surface losses but shall be content to combine the various factors by empirical means based on numerous tests to give a working formula. Due to the many variables, we believe that this is the only satisfactory mode of attack. We have, however, been guided by the able theoretical analyses of Rudenberg, Adams, Carter and others in separating and combining these various factors most effectively.

PREVIOUS WORK

We wish to discuss briefly the work of some of the most prominent of the previous investigators along this

2. The Effect of Displaced Magnetic Pulsations on the Hysteresis Loss of Sheet Steel. L. W. Chubb and Thos. Spooner, TRANS. A. I. E. E. (1915) page 2671.
3. The Unsymmetrical Hysteresis Loop, John D. Ball. TRANS. A. I. E. E. (1915) page 2693.
4. Tooth Frequency Losses in Rotating Machines, Thos. Spooner. A. I. E. E. JOURNAL 1921, page 751.

line, pointing out some of the limitations of the various analyses. Much of the pioneer work was done by Rudenberg[5] and Potier,[6] in establishing a sound fundamental theory on which to base and analyze the results of experimental work. Their original formulas, however, were for solid poles which is beyond the scope of this paper. Their theoretical formulas for the magnitude of pole-face losses in solid poles formed a basis for the laminated-pole formulas of Adams and others.

Later Wall and Smith[7] obtained some most interesting test results on pole-face losses for laminating material by an ingenious use of a special salient pole machine in which they measured the temperature of their poles after they had been subjected to surface loss conditions and then brought them to the same temperature with the machine unexcited by means of imbedded electrical heaters. The known heater input gave a measure of the surface losses. Their pole-face-loss formulas are given

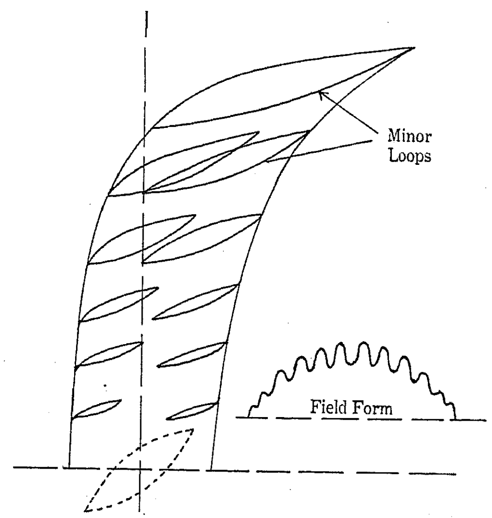

FIG. 2—HYSTERESIS LOOPS SINE-WAVE FIELD FORM

a little later in comparison with others. As pointed out by Adams their pole-face-losses were in error due to the fact that because of an unfortunate relation of pole-face width and slot pitch high-frequency pulsations penetrated through the whole stator core, thus giving incorrect results.

Adams has probably given us the most complete and accurate surface-loss formulas at present available. He derived these formulas based on the work of Rudenberg and Potier as previously mentioned and then checked his formulas by means of a large number of tests on a special salient pole machine driven only by electrica means and fitted successively with several rotors and sets of poles. The pole-face losses were segregated by testing with the same poles set for various air gaps. His actual working formulas which were based on his theoretical formulas are really empirical. These will be given later.

Mr. Lamme[8] derived a pole-face formula based on tests on a large number of commercial machines. His formula has the advantage that it is based on many tests on commercial machines rather than on a few tests on a single special machine and has the disadvantage that it is not based on all of the fundamental factors which affect surface losses and may therefore give inaccurate results on machines which depart much from the normal.

Mr. Hanssen[9] by taking the test results for numerous induction motors calculated the fundamental-frequency losses, subtracted these from the test values and obtained constants for empirical curves between watts per square inch of surface and a factor, f, where

$$f = \frac{B\,K\,S}{\delta\,P\,100}\text{, where} \qquad (1)$$

B = maximum density in air gap,
K = slot width,
S = total number of teeth,
δ = air gap,
P = total number of poles.

A different curve has to be used for each applied frequency. It is obvious that this formula gives simply mean values for the machines tested and includes both surface and tooth-pulsation losses, the surface losses being those obtained with a smooth-core rotor and the tooth-pulsation losses being the additional losses due to the presence of the rotor teeth.

Carter[10] has derived surface-loss formulas from theoretical considerations only. Due to the complexity of the problem, however, it is probably impossible, at present any way, to derive an accurate solution for surface losses from theoretical considerations alone and that this is so can be shown by a comparison of Carter's formulas with the known characteristic of surface losses as will be done later. Carter did one thing, however, which, so far as we know, had not been attempted by anyone else; namely, he has derived a formula for the hysteresis loss as distinct from the eddy-current loss. Previous theoretical formulas have been based on eddy-current losses alone.

Latour[11] has not, so far as we know, specifically attacked this problem of surface losses but he has recently derived some very valuable formulas for hysteresis and eddy-current losses for laminated material where skin effect is appreciable. His work was in connection with radio frequencies but we have checked

his formulas experimentally for frequencies of a few hundred and thousand cycles per second and have found them to agree qualitatively very closely with the test results. They are very valuable in explaining some of the test data which we shall later discuss.

Space does not permit of a resumé of the work of previous investigators so we shall have to be content to refer to their original articles and would specially recommend the discussion of damping and screening currents as given by Adams since he offers a very clear picture of the mechanism of surface losses. For laminated materials such as are used for commercial machines the damping currents may be neglected, namely, the depth of penetration of the pulsating flux is only slightly affected by tooth frequency and is determined almost completely by the dimensions of the slots, air gap, etc. The screening currents, however, crowd the flux toward the surface of the individual laminations so that looking at a cross section of the laminations the flux near the air-gap surface at any instant will be as shown by Fig. 3. This is the familiar skin effect and results in decreased eddy-current losses and corresponding increased hysteresis losses over those which would exist if the skin effect were inappreciable. Since the hysteresis loss is comparatively a small percentage of the total surface losses, usually the net result of skin effect is a smaller loss than would occur if it were not present.

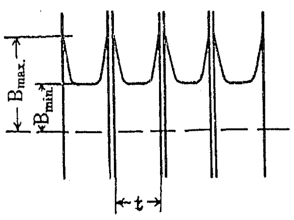

Fig. 3—Flux Distribution Due to Skin Effect in Plane at Right Angles to Plane of Laminations

The previously-mentioned investigators are not the only ones who have done valuable work along these lines but are the only ones whose work has been seriously considered in connection with our own investigation. These various formulas which are given below have all been reduced as far as possible to the same variables in order that they can be more readily compared.

Adams (theoretical)

$$S = 3.3 \times 10^{-7}\, a\, k^2\, t\, \rho^{-1/2}\, \mu^{-1/2}\, B^2 f_t^{1.5} \qquad (2)$$

Carter (theoretical)

$$S_e = \frac{\pi}{24}\, t^2\, \rho^{-1/2}\, \mu^{-1/2}\, (B^1)^2\, f_t^{1.5} \qquad (3a)$$

$$S_h = \frac{1}{3.2\,\pi}\, \rho^{1/2}\, \mu^{-1/2}\, (n + n^1 B^{1.9})\, (B^1)^{1.6} f_t^{0.5} \qquad (3b)$$

Adams (empirical)

$$S = K_1\, B^{2.3 \text{ to } 2.4} f_t^{1.55}\, q^{1.22 \text{ to } 1.5}\, \lambda^{1.05} \qquad (4)$$

The different exponents correspond to different thicknesses of laminations. The first exponents correspond to 0.014 in. material and the last to 0.06 in.

Wall and Smith (empirical)

$$S = K_2\, B^{2.1} f_t^{1.5}\, q^{3.5} \qquad (5)$$

Lamme (empirical)

$$S = \frac{K_3\, \sigma\, E^2}{C_f\, W_s\, g\, L} \sqrt{\frac{S_c}{R_s\, g}} \qquad (6)$$

(See page 8 for Hanssen's formula).

S = total surface loss per unit air-gap area.

S_e = the same except that it refers to eddy-current loss only.

S_h = the same except that it refers to hysteresis loss only.

a and k = constants depending on the relative slot, tooth and air gap dimensions.

K_1, K_2, K_3 = constants depending upon the thickness and magnetic and electrical quality of the material.

t = thickness of the individual laminations.

ρ = resistivity.

μ = mean permeability.

B = average induction over the pole face.

B^1 = amplitude of tooth pulsation (see Carter[10] for the relation of B and B^1).

f_t = tooth frequency in cycles per second.

λ = slot pitch.

r and r' are hysteresis coefficients; n' takes care of the increased loss due to the displacement of the hysteresis loop from its normal position.

$$q = \sigma / g = \frac{\text{slot width}}{\text{single air gap}}$$

e = generated voltage.

C_f = field-form constant.

W_s = armature windings in series.

L = width of poles.

V = peripheral velocity.

Scope of Experimental Work

Our experimental work was divided into two parts; (1) pole-face losses for salient pole machines; (2) surface losses for induction motors. The salient-pole losses were obtained on a special four-pole railway motor supplied with various sets of poles of different materials so arranged that the air gap could be varied at will. The induction-motor losses were obtained on a special induction motor provided with an open-slot stator and several rotors of the same material, but having different diameters.

It might be stated here that no tests were made on solid pole material due to the fact that such poles are practically never used in modern machines except in the case of turbo-generators and for interpoles. This is due chiefly to the fact that solid poles have much higher losses and that the construction of laminated poles is generally cheaper.

Test Apparatus

Railway Motors. The salient pole machine was mounted on ball bearings and direct-connected by a flexible coupling to a small variable speed d-c. motor. The latter had ordinary sleeve bearings. Two armatures were provided for the railway motor having the following general dimensions.

TABLE A

	Armature A.	Armature B.
Diameter	9 in.	9 in.
Length	7 in.	7 in.
Number of slots (open)	31	60
Slot width at air gap	0.370 in.	0.220 in.
Slot pitch at air gap	0.911 in.	0.471 in.
Slot depth	1.184 in.	0 8 in.

Neither armature had any vent ducts but armature *A* had three 5/8-in. band-wire slots 1/16 in. deep. Armature *B* was smooth. There were no windings on the armatures except certain exploring coils to be mentioned later. Several sets of poles were constructed for this machine made of the following materials.

0.125-in. Bessemer unenameled
0.0625-in. " enameled
0.0281-in. " unenameled
0.0281-in. " enameled
0.0172-in. 0.9 per cent silicon unenameled
0.0172-in. 0.9 per cent " enameled

These poles were shortened so that an adjustment of 1/2 in. could be made in the air gap by means of shims. The pole dimensions are given by Fig. 4.

Induction Motor. The induction-motor set consisted of a special ball-bearing induction motor direct-connected to a ball-bearing, adjustable-speed, d-c. motor. The latter was arranged to be driven by means of a storage battery. The general dimensions are as follows:

TABLE B.

Stator punchings	O.D. = 19in.	I.D. = 14 in.	
Length	= 6 in.		
Number of slots (open)	= 60 in.		
Slot width at air gap	= 0.346 in.		
Slot pitch at air gap	= 0.711 in.		
Slot depth	= 1.6 in.		
Rotor Punchings			
Diameter rotor No. 1	= 13 17/32 in.	Single air gap (mils)	= 31.5
" " No. 2	= 13 1/2 in.	" " " "	= 47
" " No. 3	= 13 7/16 in.	" " " "	= 78
" " No. 4	= 13 3/8 in.	" " " "	=109.5
" " No. 5	= 13 1/4 in.	" " " "	=172

The stator and rotor punchings were made of enameled 0.0172, 0.9 per cent silicon sheet steel. All of the punchings were obtained from the same lot of steel. Special pains were taken to remove the burs from the punchings before enameling. The three-phase stator windings were arranged in 12 sections and could be connected for 110, 220 and 440 volts, 60 cycles and 4 poles. Fractional-pitch windings were used so as to give an approximate sine-wave distribution of flux. The rotors were supplied with a few small longitudinal slots in the surface 1/16 in. square. Suitable exploring coils were placed in these slots and brought out to slip rings.

Methods of Test

Salient Pole Machine. The method of test consisted in placing a set of poles in the machine obtaining the friction and windage losses with no field current and then gradually increasing the field current and noting the increased input to the d-c. drive motor. These tests were repeated for various speeds and air gaps. By extrapolating the curves between loss and air gap to infinity air gap the magnitude of the pole-face losses was estimated. This was done for each set of poles as noted above. Of course, corrections were made for brush loss and $I^2 R$ loss in the windings of the driving motor. The armature inductions of the machine under test were determined by means of exploring coils on the armature covering approximately a pole pitch. The terminals of these coils were brought out to slip rings and the voltages measured by means of an a-c. voltmeter. It was assumed that for a given voltage on this exploring coil and a given frequency that the fundamental-frequency armature losses were a constant except as noted later. The total pole fluxes were determined ballistically by means of exploring coils surrounding the poles and connected to a fluxmeter. The air-gap inductions were obtained by dividing the total flux-per-pole by the gross area of the pole. Also readings were taken of the a-c. voltage generated in a coil wound on an armature tooth. This will be discussed more fully later.

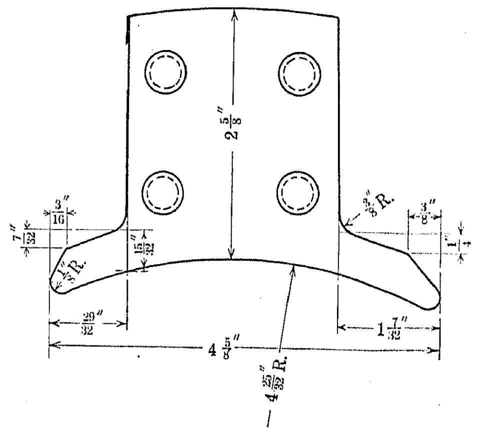

Fig. 4—Salient Pole Punchings

Pulsation Losses. In order to find out whether a pulsation of the total flux existed through the poles and frames of sufficient magnitude to cause any appreciable iron loss, which would appear as pole-face losses, the following special test was made: A single turn of wire was placed around a pole and connected to an oscillograph that had been previously calibrated. By this means it was found that for a 0.100-in. air gap and an

air gap induction of approximately 55 kilolines per sq. in. the pulsating fluxes were entirely negligible.

The method of test has the advantage over the method of direct electrical drive in that there are no $I R$ drops in the machine under test to be observed and no eddy-current losses in the copper. Also there are no flux distortions due to armature current. There is of course the disadvantage that we have greater windage and friction losses due to the extra armature and bearings and also the losses in the drive motor. Moreover, the particular drive motor we were using did not have ball bearings although the main motor under tests did. It would have been preferable if both machines had been fitted with ball bearings. However, the conditions of test were so well controlled that results could be duplicated very closely from day to day and differences of 2 watts from one time to another could readily be detected.

Induction Motor. Two methods of test were used for determining the induction motor losses.

1. Three-phase alternating current was applied to the stator, the rotor driven at various speeds below and above synchronism and the a-c. and d-c. inputs noted.

2. Direct current of a certain value was applied to one phase of the stator with one-half this current reversed in the other two phases. The rotor was then driven by the d-c. motor and the input to this motor noted for various speeds and stator excitations.

In both cases the input to the d-c. motor was observed for each speed without stator excitation. This consisted of friction, windage and losses in the d-c. drive motor. When the load was increased, the armature voltage of the d-c. drive motor was kept constant and the usual corrections made for the increased brush and $I^2 R$ losses.

The a-c. supply was obtained from a three-phase, 440-volt generator connected directly to the stator of the induction motor through suitable switching apparatus. The supply voltage was varied by altering the field of the a-c. generator. The a-c. generator was direct-connected to a d-c. drive motor and the a-c. supply frequency was adjusted by varying the field of this motor. For method 1, the a-c. input to the test motor was measured by means of a single-phase precision wattmeter introduced successively into the three phases. The potential circuit of the wattmeter was connected between the line and the motor neutral and was automatically shifted from one line to the next when its current coil was shifted. The a-c. input to the induction motor was equal to the sum of the three wattmeter readings. These meter readings included the losses in the voltmeter and shunt circuit of the wattmeter. These instrument losses together with the $I^2 R$ losses of the induction motor windings were subtracted from the sum of the wattmeter readings to give the net input.

For both methods of test the losses were based on average air-gap induction as determined by a pole pitch coil placed in the small slots on the surface of the rotor. This coil was connected through slip rings to a rotating commutator and d-c. voltmeter. For method 1, the rotor was held stationary in various positions and the a-c. stator voltage varied. The maximum readings of the d-c. voltmeter gave a measure of the average air-gap induction. The different positions of the armature were necessary due to an appreciable eccentricity between the rotor and the stator. For method 2, the rotor was revolved at 1800 rev. per min. and the average air-gap induction calculated as before from the readings of the d-c. voltmeter. For one rotor the a-c. values with d-c. excitation were checked by ballistic results obtained with the same rotor coil connected to a fluxmeter and the readings noted when the rotor was slowly revolved. As a matter of interest the d-c. field form was obtained ballistically by means of a coil placed in two rotor slots 0.2 in. apart. This coil was placed opposite a tooth, the d-c. exciting current reversed and the deflection of a ballistic galvanometer connected to the coil noted. This was done for each tooth giving the flux density opposite the tooth. Data were also obtained with the coil opposite the slots. Similar data were obtained by means of an oscillograph connected to a pole pitch coil or a radial coil with the stator excited by d-c. and the rotor revolved. These tests will be discussed in greater detail later.

In order to separate the various losses of method 1 (a-c. applied to the stator) an approximate method was developed as follows: A definite three-phase voltage was applied to the stator and the rotor revolved at various speeds below and above synchronism. The a-c. and d-c. inputs were noted, the results corrected for friction, windage, $I^2 R$ losses, etc. and then plotted. From the characteristics of the resulting curves plotted between input and rotor speed, the fundamental-frequency stator and rotor iron losses could be calculated and subtracted from the total input, thus leaving the surface losses. This method is described in detail in Appendix 1.

For method 2, (d-c. excitation) we have present no stator losses but only the rotor losses. After subtracting the friction and windage losses in the d-c. drive motor, the remaining losses as determined at 600, 1200 and 1800 rev. per min. for the five rotors having different diameters were plotted against air gap and the results extrapolated to infinity air gap. Assuming that the fundamental-frequency losses for all of the rotors were identical, the difference between these extrapolated values and the total rotor losses equalled the tooth-pulsation losses. This assumption is correct with a small adjustment for the different size of rotors except as the tooth pulsation losses may affect the fundamental-frequency losses and as the rotor losses may be affected by burs, difference in stacking pressure, etc. for the different rotors. There should be no appreciable

difference in materials as the rotors were all punched from the same lot of steel.

The a-c. method of test has the advantage that a separation of losses may be made with a single rotor and air gap. There is the disadvantage, however, that the testing methods are complicated; the method of calculation is somewhat tedious and the surface losses themselves are in general only a small portion of the total losses, thus requiring great accuracy of measurement. The d-c. method has the advantage of simplicity of measurement and calculation with the surface losses representing a considerable proportion of the total losses but has the disadvantage of requiring several rotors or some other means of varying the air gap and when several rotors are used the uncertainty as to the amount of the fundamental-frequency losses for the various rotors.

Test Results.

Salient Pole Machine. After obtaining the pole-face loss results by the method outlined above the losses were plotted on double-log paper against each of the four variables B_{AG}, f_t, q and λ, where

B_{AG} = air gap induction,
f_t = tooth frequency,
q = ratio of slot width to air gap,
λ = tooth pitch.

From the average slope of the curves the mean exponent for each variable was determined. In general, these functions gave approximately straight lines, indicating that the variations were truly exponential except for the values of q. As will be noted later the ratio of variation of q varies, decreasing as q increases. Of course, these various functions are not altogether independent of each other but for a first approximation they may be considered to be so. In fact, the dependence of one function upon another is surprisingly small. It is obviously impossible to reproduce even a small part of these curves here but the exponential values may be summarized as follows:

TABLE C.
Exponents

Material	B_{AG}	f_t	q	λ
0.0172 M. A.	2.2	1.7	1.7	1.1
0.0281 Bessemer	2.4	1.6	2.15	1.3
0.0625 "	2.6	1.6	2.2	1.3
0.125 "	3.1	1.6	2.3	1.3

Range of variables: B_{AG} = 25 -60 kilolines per sq. in.
f_t = 600-1800 cycles.
q = 2.2-4.1
λ = 0.471-0.911 inches.

From this information we may therefore write the surface loss equation for 0.0625 Bessemer, for instance, as follows:

$$W_s = K \times B_{ag}^{2.6} f_t^{1.6} q^{2.2} \lambda^{1.3} \tag{7}$$

This is quite similar to the formulas used by Adams. Such an equation will give a good estimate of pole-face losses over a considerable range of the several variables, but it is not in convenient form to use.

Derived Design Curves. We therefore suggest that the variables be plotted on double-log paper, thus greatly facilitating their use. For instance, see Fig. 7. In order to draw such a set of curves let us assume that the surface loss for the following conditions equals 1.2 watts per sq. in. of the surface:

B_{AG} = 49.5 kilolines per sq. in.
f_t = 500 cycles per second
q = 2.85
λ = 1.17

Now place a point at an ordinate of 1 and an abscissa of 49.5 and draw a straight line having a slope of 2.6. This gives the B_{AG} function. Similarly place a point at an ordinate of 1 and an abscissa, say, of 500 and draw a line having a slope of 1.6. This gives the frequency function. Similarly the q and λ functions may be drawn. Finally the known loss of 1.2 watts per sq. in. give the constant of the equation and we have

$$W_s = 1.2 \times K_{B_{AG}} \times K_f \times K_q \times K_\lambda, \tag{8}$$

where the K factors signify the respective ordinates for

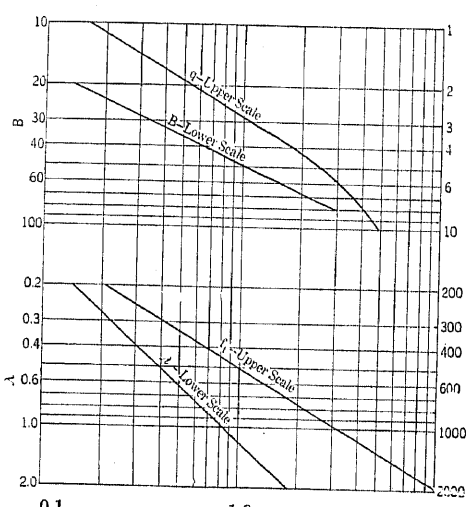

FIG. 5—SURFACE-LOSS CALCULATION CURVES FOR 0.0172 IN., 0.9 PER CENT SILICON STEEL
$W_s = 0.20\ K_{B_{AG}} \times K_{f_t} \times K_\lambda$

any desired value of B_{AG}, f_t, q and λ as read from the curves.

If desired the constant 1.2 may be eliminated by placing the reference point for one of the curves at an ordinate of 1.2 instead of 1. Similarly if the curves do not fit well on the sheet or overlap they may be shifted up or down at will and the constants changed accordingly. Or if one curve is shifted up and another shifted down an equal amount, no change in the constant need to be made.

Figs. 5–8 give the calculation curves for 0.0172 0.9 per cent silicon sheet, 0.0281, 0625 and 0.125 Bessemer sheet steel, respectively. These are all placed on the same basis so that for the reference conditions the constant of each equation is proportional to the actual surface losses for each class of material.

It will be noted that the q curves go to much higher values than were covered by the test results. These

curves were extrapolated from the induction-motor data and from test data by other observers. It is obvious that q can not have a constant exponent since as the air gap approaches zero, q approaches infinity while the pole-face losses approach a constant value. Therefore the exponent of q would actually begin to decrease if q were taken sufficiently large. We believe that the curves as shown are a very fair estimate of the way in which the pole-face losses actually vary with q.

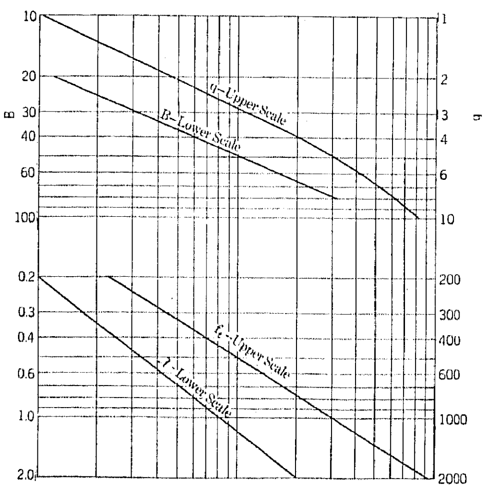

FIG. 6—SURFACE-LOSS CALCULATION CURVES FOR 0.0281-IN. BESSEMER STEEL

Separation of Hysteresis and Eddy-Current Losses. It is obvious that if we wish to estimate the effect of changes in the magnetic quality of the materials entering into our poles, it is necessary to know the relation between the hysteresis and eddy-current coponents. In order to make an estimate of the relative values of these two components the pole-face losses for a given set of poles were reduced to watts/cycle and the results plotted against frequency. Fig. 9 gives a typical set of data. The intercepts on the vertical axis give a measure of the hysteresis components. In spite of the fact that in general there is present an appreciable skin effect causing the curves to be concave downward the extrapolation to zero frequency can be made fairly accurately.

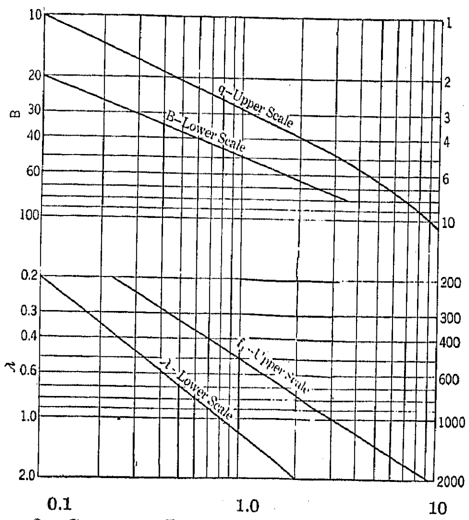

FIG. 8—SURFACE-LOSS CALCULATION CURVES FOR 0.125-IN. BESSEMER STEEL

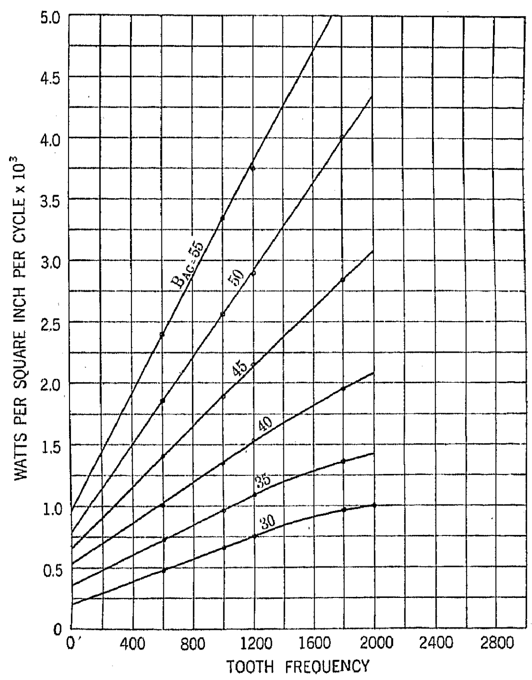

FIG. 9—SURFACE-LOSS IN WATTS-PER-CYCLE AGAINST FREQUENCY FOR 0.0625-IN. BESSEMER STEEL, SHOWING RELATION BETWEEN HYSTERESIS AND EDDY LOSSES

$q = 4.1$ in.

$\lambda = 0.47$ in.

The skin effect causes the hysteresis losses to increase somewhat faster than the first power of the frequency and the eddy-current losses to increase somewhat more slowly than the square of the frequency. This will be discussed in greater detail later.

From similar curves to those shown in Fig. 9 we have obtained the following average results for the relative hysteresis and eddy-current losses.

TABLE D.

Material			Total loss watts sq. /in.	Per cent Hysteresis	Per cent Eddy
0.0172 M. A.	$q = 4.2$	$\lambda = 0.471$	0.385	25	75
0.0281 Bess. (enameled)	$q = 3.7$	$\lambda = 0.912$	1.30	47	53
0.0281 " (unenameled)	$q = 3.7$	$\lambda = 0.912$	1.68	31	69
0.0625 " "	$q = 3.7$	$\lambda = 0.912$	3.7	35	65
0.0625 " "	$q = 3.0$	$\lambda = 0.471$	1.0	26	74
0.0625 " "	$q = 4.1$	$\lambda = 0.471$	1.9	35	65
0.125 " "	$q = 3.7$	$\lambda = 0.912$	8.1	20	80

In all cases $B_{AG} = 45$ and $f_t = 1000$.

Effect of Gage. In order to study the effect of gage, Fig. 10 has been plotted. This shows the relation between surface losses and thickness of individual laminations for various gages of Bessemer sheet steel and for various air-gap inductions. The points at zero thickness were obtained by the previously explained multiple-frequency method of separation, assuming that the zero thickness losses equal the zero frequency losses for the 0.0281 material. This is not strictly correct but the

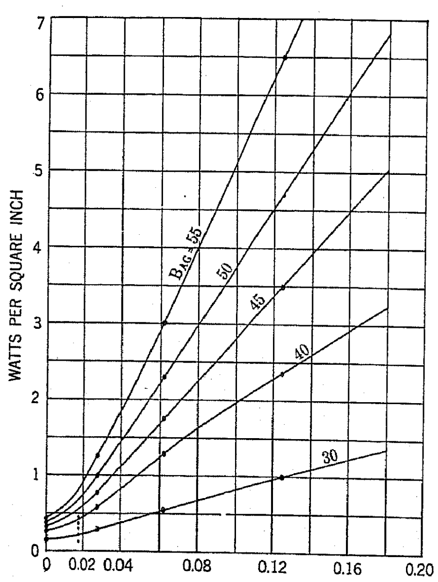

FIG. 10—RELATION BETWEEN SURFACE LOSSES AND THICKNESS OF LAMINATIONS FOR BESSEMER STEEL

$f_t = 620\sim$
$q = 3.7$ in.
$\lambda = 0.912$ in.

curves are accurate enough for most purposes and show an interesting relation about which little has hitherto been published. It should be noted that for quite thick material the rate of increase of pole-face losses with gage is approximately equal to the first power, while for thin gage material the rate of increase is approximately as the square of the thickness of the individual laminations. The vertical row of dots at a gage of 0.017 is for 0.0172 0.9 per cent silicon sheet steel. It will be noted that the 0.9 per cent silicon losses fall far below the Bessemer loss curves. This thin sheet has a considerably higher resistivity and considerably lower hysteresis loss than Bessemer steel which accounts for these differences.

Effect of Pole Chamfering. Fig. 11 shows some pole-face data for a set of standard poles and also for the same poles in which the air gap was 0.1 in. at the center and the tips machined off to give an air gap of approximately 0.2 in. It will be noted that pole-face losses are approximately the same for both the unchamfered and chamfered poles. In order to obtain these data certain

Full lines before chamfering. Dotted lines after chamfering.

corrections had to be made in the armature losses. We shall not go into detail here in regard to these corrections but believe that they were made with a fair degree of accuracy.

Effect of Enameling. The net gain from enameling was very slight, ranging from 15 per cent in one case to zero in others. It may be noted from Table D, however, that enameling evidently results in decreased eddys and increased hysteresis.

Induction Motors. The method of handling the surface-loss test results as obtained by the test procedure outlined above was the same as for the salient-pole-machine data. The four functions B_{AG}, f_t, q and λ were plotted on double-log paper against surface losses and the average exponents determined with the following results for 0.0172 0.9 per cent silicon sheet steel.

TABLE E.

Function	Test Range	Exponent
B_{ag}	4-40	1.9
f_t	100-2700	1.55
q	2.01-11.	2.3-0.93
λ	0.711	1.1 (assumed)

0.2 in. apart. The points marked by crosses were obtained from measurements on oscillograms taken as previously described. The calculated curve marked by the dots was obtained from Carter's formula[10]. It will be noted that the oscillograms and calculated results check very closely indeed. The ballistically

observed pulsations are low, due to the fact that the exploring coils spanned an appreciable arc of the rotor surface and therefore did not show quite as deep dips in the flux wave as would have been shown by a very narrow coil.

DISCUSSION OF RESULTS

Accuracy of Results. It is obvious that since these surface-loss data are obtained as the difference between two large quantities which may be several times the

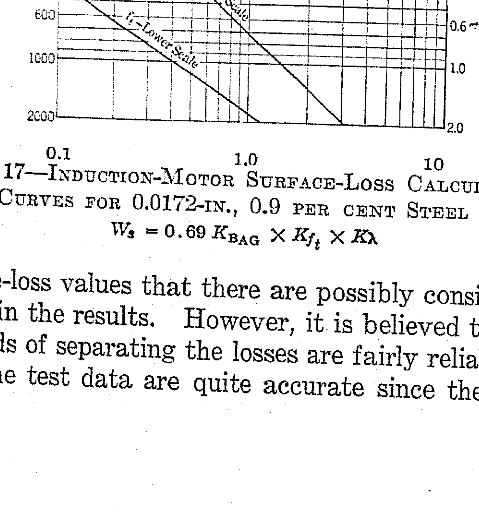

FIG. 17—INDUCTION-MOTOR SURFACE-LOSS CALCULATION CURVES FOR 0.0172-IN., 0.9 PER CENT STEEL

$W_s = 0.69\, K_{BAG} \times K_{f_t} \times K\lambda$

surface-loss values that there are possibly considerable errors in the results. However, it is believed that the methods of separating the losses are fairly reliable and that the test data are quite accurate since they were taken under exceptionally good laboratory conditions with great pains taken to have all instruments accurately calibrated. When there was the slightest doubt about the accuracy of a test run it was repeated. Care was taken in the preparation of the laminations and it is believed that the test results represent approximately the best conditions which may be expected from the various materials. When extrapolations of the test data have been necessary they have been made as carefully as possible, taking into account not only our data but other available data as well. There should be no large errors due to these extrapolations. The greatest chance for uncertainty is in connection with the use of these data for large machines where the slot pitch is large. It is possible that under these conditions our extrapolations may be somewhat inaccurate as no reliable test data were available covering large slot pitches. For the thicker laminated pole material it is possible that there were some errors

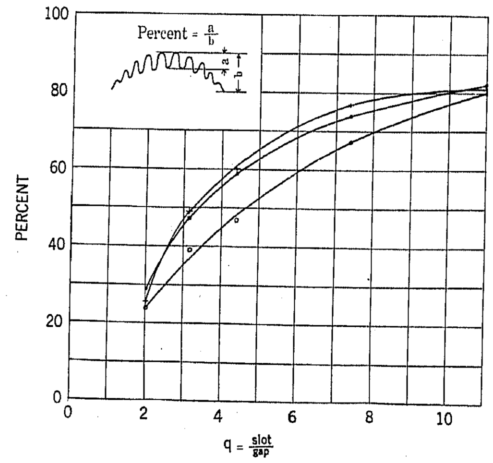

FIG. 18—CURVES SHOWING HIGH-FREQUENCY FLUX PULSATION AT AIR GAP

• Calculated (Carter's formula)
O Ballistic tests
+ Oscillographic tests

at the high inductions and high frequencies due to heating effects. However, under these conditions the test results were obtained very rapidly and it is believed that no serious errors have been introduced due to this cause.

Comparison with Previous Results. No comparisons will be attempted between our results and those of other observers except in the case of Adams data, due to the fact that the conditions of test were so different that comparisons are practically impossible. We shall, however, make some comparisons between the exponents of the various variables as obtained by previous investigators and our own. Referring to the formulas 2, 3, 4, 5 and 6 and to Tables C and E of our data it will be noted that there is a very close agreement in regard to the exponent of B, both from actual tests and from theoretical considerations, the average exponent being approximately 2. There is also a very

great uniformity in the exponent of frequency, the average result being about 1.5. q does not appear in Carter's formulas. A direct comparison cannot be made with Adams' theoretical formula because he uses the product of a and k in place of q. In Adams' empirical formula his q exponents are about an average of our extreme values. Due to the fact that he assumes a constant q exponent, his formulas give results which are too high for small and for large values of q, while a very good check is obtained for average values of q. The q exponent for Wall and Smith's empirical curve is much too high as pointed out by Adams. This is due to the fact that under their peculiar test conditions

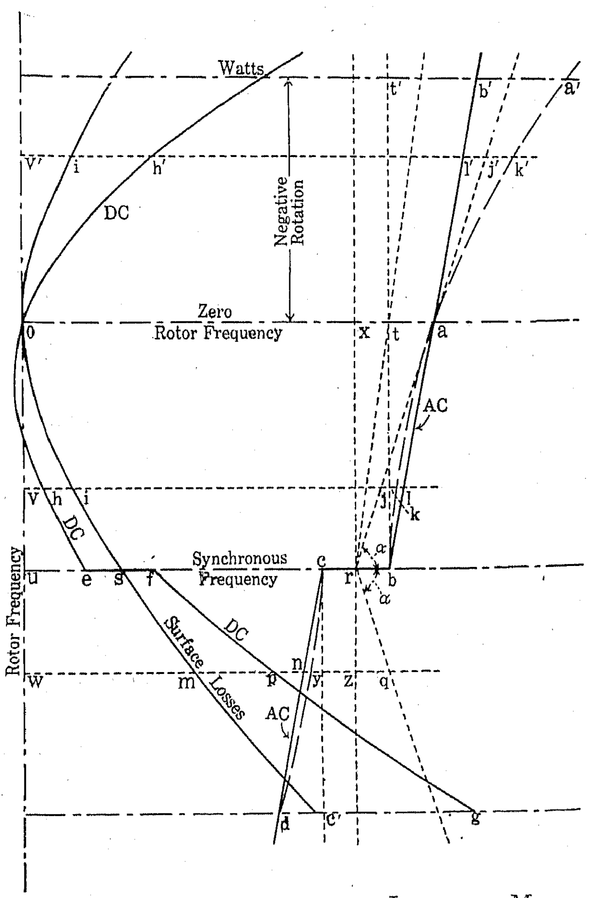

FIG. 19—METHOD OF SEPARATING INDUCTION MOTOR CORE LOSSES

Curve marked $A\ C$ is input to stator
Curve marked $D\ C$ is input to rotor

large flux pulsations existed in the poles and frame of the machine which were included in the estimated pole-face losses. Our exponent of λ is slightly higher than given by both of Adams' formulas. In his theoretical formulas he gives λ to the first power and in his empirical, λ to the 1.05. λ does not appear in the Wall and Smith formulas and although it appeared originally in the Carter formulas it cancels out when f_t is substituted in this formula for V by the relation,

$$f_t = K\,V/\lambda \tag{9}$$

Adams' formula as well as Carter's used V (peripheral velocity) rather than f_t (tooth frequency) and we reduced his V to the latter value in order to obtain his exponent of λ. With respect to the Adams' and Carter theoretical formulas there is an agreement for the eddy-current losses for the ρ exponent and the μ exponent. With regard to the thickness, however, Adams has an exponent of 1 and Carter of 2. It has been shown by our experimental data and may be shown from theoretical considerations that the exponent of t is a function of the thickness of the material. Therefore both formulas are approximately correct in this respect, depending upon the range of thickness covered. The Carter formula for hysteresis loss has too small an exponent for frequency. This should range from 1 to 1.5, depending upon the skin effect.

Latour's[11] formulas for high-frequency losses throw some valuable light on this discussion. They are as follows for hysteresis and eddy losses, respectively.

$$W_h = \frac{\omega^2\, a \sin\tau}{4\, m\, \rho} \quad \frac{\dfrac{\sinh 2\, m\, \alpha\, a}{\alpha} + \dfrac{\sin 2\, m\, \beta\, a}{\beta}}{\cosh 2\, m\, \alpha\, a - \cos 2\, m\, \beta\, a}\, B^2 \text{ app} \tag{10}$$

$$W_e = \frac{\omega^2\, a}{4\, m\, \rho} \quad \frac{\dfrac{\sinh 2\, m\, \alpha\, a}{\alpha} - \dfrac{\sin 2\, m\, \beta\, a}{\beta}}{\cosh 2\, m\, \alpha\, a - \cos 2\, m\, \beta\, a}\, B^2 \text{ app} \tag{11}$$

where

$2\, a$ = thickness of laminations in centimeters.

ρ = resistivity of laminations in abohms.

$$2\, m^2 = \frac{4\, \pi\, \mu\, \omega}{\rho}$$

$$\alpha = \sqrt{1 + \sin\tau}$$

$$\beta = \sqrt{1 - \sin\tau}$$

$$\sin\tau = n \times 4\, \mu$$

It is difficult to draw any conclusions from such formulas as these, but fortunately when the laminations are thick enough, or the frequency high enough to make $\sinh 2\, m\, \alpha\, a$ nearly equal to $\cosh 2\, m\, \alpha\, a$, the eddy losses are then proportional to $\dfrac{\omega^2\, a}{4\, m\, \rho}$ and the hysteresis losses to the same value times $\sin\tau$. We reach this condition for 0.0172 0.9 per cent silicon steel at a frequency of the order of 500 cycles. Now under these circumstances if we can assume constant permeability the eddy losses vary as follows:

$$W_e \text{ varies as } t,\ \rho^{-1/2},\ \mu^{-1/2},\ f^{1/5}$$

It will be seen that this checks Adams' theoretical

formula 2 for all the factors. Similarly the hysteresis loss varies as follows:

$$W_h \text{ varies as } t,\ \rho^{-1/2},\ \mu^{-1/2},\ f^{1/5}$$

It will be seen that this checks Carter's formula **3b** in no respect.

We believe that it is necessary to have a factor corresponding to either the slot pitch or the slot width in these formulas, since it is obvious that the depth of penetration of the flux is a function of this factor. The wider the slot, the deeper the flux penetration, other things being equal. Adams' formulas are the only ones containing this factor when proper corrections are made, consequently we believe his formulas are the only ones which are capable of giving approximately correct results.

No comparisons have been made between Mr. Lamme's and Mr. Hanssen's formulas and the others because of the very large differences in the type of formulas. Mr. Hanssen's formula applied only to induction motors and includes both surface and tooth pulsation losses.

Comparison Between Salient Pole and Induction Motor Losses, and Between A-C. and D-C. Induction Motor Losses

A comparison between the salient-pole and induction-motor losses can be made only for the 0.0172 material since this was the only material tested in both types of machine. Assuming the following conditions, calculations have been made by the surface-loss formulas as obtained by the two methods of test.

TABLE F.

$B = 30$

$f_t = 930$

$q = 3.7$

$\lambda = 0.711$

$K = 0.81$

$W_s = 0.69 \times 0.333 \times 0.36 \times 2.6 \times 1 \times 0.81 = 0.174$ (Fig. 17)

$W_s = 0.20 \times 0.343 \times 0.283 \times 1.59 \times 0.575 = 0.177$ (Fig. 5)

The comparisons between these formulas is made on the assumption that the salient pole machine data are for a flat-top flux wave and the induction-motor data for a sine-shape flux wave. Assuming that the losses vary as the square of the flux density, for the same average induction the salient-pole conditions should give 81 per cent of the loss for the induction-motor conditions. Therefore this factor ($K = 0.81$) has been introduced into the induction-motor formula. The check between these two formulas is remarkably good, especially considering the fact that the two sets of data were obtained on such widely different types of machines, and that the results were obtained and calculated by two different observers. The check will not be quite as good at high inductions because a somewhat different B exponent has been assumed for the induction motor conditions than for the salient-pole conditions.

The comparison between the a-c. and d-c. test results as shown by Figs. 14 and 15 is not quite as good as we would have liked to see. It is believed that the d-c. losses are somewhat low due to the fact that the rotor giving the largest air gap had somewhat higher fundamental-frequency losses than the other rotors due probably to a different condition of the dies or greater stacking pressure, etc. Since all of the surface losses obtained under d-c. conditions are influenced by the extrapolation for the fundamental-frequency losses, it is evident that if this large-air-gap rotor had high losses the estimated surface losses would be too low. We have considered that the a-c. loss results are more nearly correct than the d-c. loss results and for most of our calculations have used them in preference to the d-c. results. Considering the very wide variations which may occur in different machines due to different conditions of shop practise this discrepancy is not serious.

A considerable number of large a-c. and d-c. salient-pole machines have been tested for losses under commercial conditions with two or more air gaps and the difference in losses under the two conditions compared with the difference in pole-face losses as calculated by our formulas. The check results were not especially good due, we believe, chiefly to the notoriously inaccurate results which may be expected from ordinary test-floor conditions. However, the differences were in some cases higher than the calculated and sometimes lower, the mean results checking fairly well. We believe that in general pole-face losses may be calculated much more accurately than they can be determined by ordinary test-floor methods.

Advantages of Method of Presenting Final Results. As previously mentioned the exponential formulas as derived by Adams and others are too complicated for ordinary routine design calculations. The time involved in looking up logarithms is prohibitive except in certain special cases. We believe that our method of presentation, making use of curves on double-log paper, Figs. 5-8, so simplify the calculations that there can be no reasonable objection to using functions of this form. No log tables are necessary and all the calculations can be made in a few moments by means of a slide rule when the necessary factors are given. These four fundamental factors are usually already known by the designer since he needs them for other purposes or they can be calculated readily from data which he already has at hand.

Relation Between Hysteresis and Eddy-Current Losses. Referring to Table D on page 24, giving the relation between hysteresis and eddy-current losses for the various classes of material considered, it is seen that the average hysteresis loss amounts to approximately 30 per cent of the total surface losses. If similar data were obtained on samples of these materials for the same range of frequency by means of an Epstein apparatus, using symmetrical pulsations of flux in the ordinary way it would be found that these hysteresis losses instead of being 30 per cent would be very much less. This increase in hysteresis-loss percentage under surface-

loss conditions is due to the fact that the high-frequency hysteresis loops are displaced from their normal position. It has been shown by previous investigations[2,3,4] that such displacements of the hysteresis loops produce very greatly increased hysteresis losses. Moreover, as will be shown a little later the skin effect when present still further increases these hysteresis losses. The eddy-current losses are unaffected by displacement but are simply a function of the maximum amplitude of pulsation. The skin effect when present decreases these eddy-current losses.

Factors Affecting Hysteresis Losses. To elaborate somewhat on the effect of displacement as previously mentioned, Fig. 1 shows approximately the effect of displacing a hysteresis loop of given magnitude from its normal position to a fairly high value of displacement. The symmetrical dotted loop has the same B amplitude as the displaced minor loop. If the amplitudes of pulsation are not too high the displaced hysteresis loss may be calculated approximately for ordinary open hearth steel by the following formula due to Ball[3].

$$W_h = (1.06 \times 10^{-3} + 0.344 \times 10^{-10} B_m^{1.9}) B^{1.6} \times \frac{f}{d \times 7.92} \qquad (12)$$

where,

W_h = the hysteresis loss in watts per cu. in.
f = frequency
d = density
B_m = the mean displaced induction
B = ½ the amplitude of pulsation.

So far as our available data go the effect of displacement on hysteresis is not very different for various kinds of materials. If we are dealing with another class of material we simply increase or decrease the hysteresis loss as calculated by the above formula according to the known difference in the hysteresis characteristics of the material from normal open hearth steel. The relative specific hysteresis loss for Bessemer and 0.9 per cent silicon steel are on the average about 2 to 1. We know the magnitude of flux pulsation at the surface of induction-motor rotors as shown by Fig. 18. We do not, however, know the relative depth of penetration of flux for various conditions and are at present unable to accurately calculate the surface losses from a knowledge of the specific quality of the material. However, knowing the surface hysteresis losses for a given set of conditions we can quite accurately predict the losses for another class of material having a different specific hysteresis loss.

Factors Affecting Eddy-Current Losses. As previously stated the eddy-current losses are a function only of the amplitude of flux pulsation regardless of the displacement of the pulsating hysteresis loops. Various formulas have been developed for calculating eddy-current losses from a knowledge of the thickness and resistivity of the electrical sheet. These all give eddy-current losses which are too low, the actual losses being in general anywhere from 50 to 200 per cent greater at normal frequencies. However, knowing the eddy-current losses for a given sheet the losses for another thickness or resistivity of sheet may be calculated in the usual way, unless the material has abnormally large grain size in which case the actual eddy-current losses will be considerably higher in general than anticipated.[12] Therefore knowing the surface eddy-current losses for a given class of material the losses to be expected for another thickness or resistivity of the material may be calculated with a fair degree of accuracy provided we take into account skin effect as will be explained in the next paragraph.

Skin Effect with Special Reference to Thickness of Material. By the aid of certain formulas recently developed by Latour it is now possible to calculate accurately the effect of frequency on hysteresis and eddy-current losses for materials of various thicknesses and resistivities. These formulas were developed for use at radio frequencies. However, we have checked them at audio frequencies and have found that the shape of the curves as calculated by them is fairly close to results obtained by test although the absolute value may be somewhat different. The hysteresis formula is based on the assumption that hysteresis loss varies as the square of the induction. This is approximately true at an induction of about 70 kilolines per sq. in. (14 kilogausses) only for commercial materials. Below this induction the hysteresis ratio of variation decreases to approximately a constant value of 1.6 and above it increases quite rapidly to much higher values. In order to use these formulas accurately the hysteresis loss should be determined from loss curves for the material in question at the particular induction at which it is desired to work. Also for surface loss calculations the hysteresis loss should be increased according to the displacement factors as previously noted. With these precautions the formula may be used to calculate the increased hysteresis losses to be expected with increased frequency due to skin effect. It should be noted, however, that for the condition of displaced hysteresis loops the permeability value to be used is not that of the material under normal conditions, but the average permeability as given by the upper and lower tips of the displaced hysteresis loops. For fairly high values of displacement this permeability may be quite low. For a comparatively small amplitude of displaced loop and a displacement, say of 64.5 kilolines per sq. in. (10 kilogausses) the permeability will be of the order of 100.

In calculating eddy-current losses this same precaution in regard to permeabilities must be taken. Moreover, the eddy-current losses as obtained by the formula may have to be increased somewhat to get actual values especially at the lower frequencies. This increase may be determined by measuring the eddy-current loss of this particular material in the Epstein apparatus and

12. Grain Growth in Silicon Steel, W. E. Ruder. *Trans. A. I. M. E.* October, 1913, p. 2820.

then calculating the eddy-current loss by the formula under the same conditions. Referring to Fig. 16 the combined effects upon the hysteresis and eddy-current losses of skin effect may be noted. The curves show a very marked concave tendency downward with increasing frequency. This is due to the fact that the increase in hysteresis loss due to skin effect is very much less than the relative decrease in eddy-current loss. For the thicker materials the skin effect may cause the eddy-current losses to be of the order of one half those to be expected by applying the ordinary square law to the frequency. Referring to Fig. 10 and formula **11** it will now be seen why these curves at the higher frequencies show surface losses increasing approximately as the first power of the thickness of laminations instead of the square. If the formula is used for thicknesses and frequencies which will give $\cosh 2\, m \alpha a$ and $\sinh 2 m \alpha a$ approximately equal, it is seen that the eddy-current losses increase approximately as the first power of the thickness rather than the square as previously mentioned. A comparison of the surface loss constants for the three thicknesses of Bessemer steel, Figs. 6, 7 and 8, indicate that these constants are approximately proportional to the thickness of laminations. It is largely on account of this skin effect that with the thicker materials (see Table D, page 24) the eddy-current losses do not change very greatly in percentage as the thickness increases. It should be understood that Table D, page 24, gives results for comparatively low frequencies only. It is evident that at higher frequencies the hysteresis values will be somewhat higher and the eddy-current losses lower than given by the table. Skin effect will probably account for the fact that the B exponent of surface loss is higher for the thick material than for the thin (see Table C). The thicker the material the greater the skin effect. Now as the induction increases the effective permeability decreases, thus producing a relative decrease in the skin effect which means increased eddy loss. We believe that it is chiefly due to this effect that we have a B exponent of 3.1 for 0.125 Bessemer sheet as against a value of 2.4 for the 0.0281 material.

Depth of Penetration of Pulsating Flux. As previously stated we do not know exactly the way in which the high-frequency pulsations of flux decrease as we penetrate below the surface. However, from the loss characteristics of unsymmetrical hysteresis loops as known from another investigation the results of which it is hoped we may be able to present at a later date, the depth of penetration may be calculated if we assume a certain law of attenuation. For instance, if we assume that the flux pulsations decreases linearly with the distance below the surface we can show that in order to obtain the losses which actually exist the effective penetration must be something over an inch. The work of Hele-Shaw[13] indicates that under some conditions the pulsations may actually extend from one pole to the next through the rotor iron.

Effect of Unequal Slot and Tooth Widths. This investigation has been confined to the case of open slots. When considering the case of partly closed slots two main factors must be considered: (1) the effect of the narrow slot on the depth of penetration of the pulsating flux; (2) the decreased flux density opposite the tooth tips.

1. Where the slot and tooth widths are unequal it would probably be much more accurate to use the slot width σ instead of the slot pitch λ in the double log curves. This would automatically take care of the first factor.

If it is desired to use the λ curve it is only necessary to multiply the value of the slot width σ by 2 and then look up the K value corresponding to $2\,\sigma$. This procedure is probably not permissible when saturation effects are of any magnitude.

2. In order to correct for the change in flux density Carter's fringing coefficients may be used. The correction to be applied to B_{AG} will be as follows.

$$B_{AG}\ (\text{cor.}) = \frac{B_{AG} \times \lambda_1}{g_1} \qquad \textbf{(13)}$$

where λ_1 = tooth pitch
g_1 = gap factor

By this formula a correction is made to the induction corresponding to the actual effective width of tooth as compared with the effective width on the assumption that the tooth and slot widths are equal. After applying formula **13** it is then only necessary to use the new value of B_{AG} in connection with the original B_{AG} curve.

It will be noted that in the salient-pole test machine the tooth and slot widths are not equal although open slots were used. For small differences from unity ratio no serious error is introduced for normal salient pole inductions due to the fact that the teeth have begun to saturate, thus making the pulsation amplitude less than for lower values of induction. We see therefore that if the tooth is wider than the slot the saturation effect is less and the amplitude of pulsation greater, thus largely compensating for the difference from unity of the tooth to slot ratio.

Effect of Saturation. For the inductions ordinarily used in induction motors probably saturation effects are not large but for salient pole machines where the inductions ordinarily run much higher, we undoubtedly have large saturation effects. As the teeth begin to saturate the amplitude of the high-frequency pulsations at the air gap begin to decrease. This results in a smaller surface loss than would otherwise occur. It is well known that as we go to high inductions hysteresis losses increase much faster than the square of the induction. When we consider also that the amplitude of pulsation increases with the induction it is easy to see that the hysteresis pulsation losses may increase as the fourth or fifth power of the induction under certain conditions. However, we find that the surface losses

13. Hydrodynamical and Electromagnetic Investigation regarding the Magnetic Flux Distribution in Tooth Core Armatures, H. S. Hele-Shaw, A. Hay, P. H. Powell. I. E. E. Vol. 34, page 21 (1904).

actually increase only as some power between the square and the cube and that the slope of the double-log curve between loss and air-gap induction is usually nearly straight. This means that the tendency for the rate of change of losses with induction to increase is counterbalanced by the effect of saturation in reducing the amplitude of pulsation. Of course, if it were possible to go to sufficiently high inductions the surface losses would actually begin to decrease.

Insulation between Laminations. It has been shown that by enamelling the laminations of pole material there is a slight decrease in surface losses. Apparently the eddy losses are decreased and the hysteresis losses increased by nearly an equal amount. Evidently if some of the laminations are in electrical contact with each other in spots long path eddy currents are set up which tend to damp out the pulsating flux. The increase in losses due to these long-path eddys just about equals the decreased loss due to hysteresis and the short-path eddys. Of course if the contact between laminations were very good the result would be increased surface losses for we would approach the condition of solid poles. That the unenameled poles do not have higher losses is due to the fact that the sheets have a fairly high resistance scale and are not pressed together very tightly at the air gap.

Effect of Punching. For material which has not been annealed subsequent to punching there will be quite appreciable increased hysteresis losses due to the punching strains. These strains may affect the quality of the material for a distance of $\frac{1}{8}$ in. or more from the punched edges depending on the thickness, nature of the material, and sharpness of the dies. In this area the hysteresis losses may be increased very considerably, appreciably affecting the surface losses since the greater part of the surface losses occur quite near the surface. However, since the resistivity of the material is affected but very slightly by annealing and the eddy losses are much the larger part of the surface losses, annealing will not very greatly decrease the surface losses.

Summary

An attempt has been made to separate the various factors which govern the surface or pole-face losses of laminated material in rotating machines and to determine the way in which these losses vary with each factor. By a separation of the hysteresis and eddy-current components it has been shown that while the eddy losses are responsible for the larger part of the surface losses the hysteresis losses are very appreciable and can not be neglected. As a basis for this analysis test results were obtained on a salient pole machine supplied with various sets of poles arranged for variable air gap and on a special three-phase induction motor supplied with a number of smooth-core rotors having slightly different diameters. The rotors of the two machines contained no windings except exploring coils and were direct-connected to d-c. drive motors, the input to which gave the losses for the various conditions of test. By a suitable separation of the fundamental-frequency losses from the total losses the surface losses were given. This was done either by varying the air gap and extrapolating to infinity air gap (zero surface losses) or by a special method for the induction motor described in detail in the appendix.

The surface losses were assumed to be a function of four main aproximately independent variables, namely air-gap induction B_{AG}, tooth frequency f_t, ratio of slot width to air gap q and the slot pitch λ. These losses are approximately an exponential function of B_{AG}, f_t and λ but the ratio of variation of losses with q decreases as q increases. As a rough approximation the surface losses vary as the square of the air-gap induction, as the 1.5 power of tooth frequency, from the second to the first power of q with increase in q, and as the first power of the slot pitch. These losses can most readily be represented as a function of these variables by plotting on double-log paper, three of the functions being straight lines. Knowing these four variables which the designer can determine very readily the surface losses can be calculated in a few moments by a simple multiplication on a slide rule. This avoids the use of logarithms in spite of the fact that the functions are exponential.

It is shown that by plotting the surface losses in watts/cycle against frequency it is possible to obtain an approximate separation of the hysteresis and eddy components. The hysteresis loss at 1000 cycles is about 30 per cent of the total surface losses for all the materials investigated. Due to the skin effect this separation may be somewhat inaccurate since the hysteresis loss increases faster than the first power of the frequency and the eddy loss less rapidly than the square of the frequency. Due to the uncertainty as to the effective permeability it is impossible to accurately calculate this skin effect. The net result of skin effect is decreased losses since the decrease in eddy losses is considerably greater than the increase in hysteresis losses. Due to the fact that the high-frequency pulsation hysteresis loops are usually greatly displaced from the normal symmetrical position, the hysteresis losses are much higher than would be the case for symmetrical loops for the same frequency and amplitude.

In addition then to the four factors B_{AG}, f_t, q and λ which govern surface losses for any given material and are a function of the design of the apparatus we have the four fundamental factors: Hysteresis coefficient n, resistivity ρ, thickness of individual laminations t and the effective permeability μ which are determined by the nature of the laminated material. The factor n governs not only the hysteresis loss but according to Latour's formulas when skin effect is appreciable also affects the eddy losses somewhat. The eddy losses are inversely proportional to ρ for small frequencies but for high frequencies are inversely proportional to the square root of ρ. Also the eddy losses are proportional to the

square of t for low frequencies and thin material and to the first power of t for high frequencies or thick material. With a given flux density for low frequencies μ is not a factor, but for high frequencies the eddy losses are inversely proportional to the square root of μ and the hysteresis losses directly to the square root of μ. The permeability also influences the attenuation of the pulsating flux but we have no data in regard to this factor and it is probably not very different for the different classes of commercial materials.

It is shown that for chamfered poles approximately correct results may be obtained by assuming that the air gap is that corresponding to the minimum gap. The change in field form largely compensates for the increased gaps at the tips of the poles.

Enamel on the individual laminations of salient poles only slightly decreases the surface losses although it may materially affect the relative hysteresis and eddy losses. In most cases it is an extra manufacturing expense which would be unwarranted.

Due to the hardening of the material near the edges caused by punching the hysteresis surface losses are undoubtedly increased unless the punchings are subsequently annealed. We have no specific data in regard to this effect with reference to surface losses but would expect an increase in hysteresis losses due to punching of from 5 to 10 per cent.

It is believed that the surface-loss curves here presented may be used with considerable confidence at least for open slots where the slot and tooth widths are approximately equal. Our results check those of Adams and his collaborators with a reasonable degree of accuracy although they used different methods of test. Again our results for the salient pole machine and for the induction motor check very well with each other although the methods of test and the conditions for the two types of machines were quite different. In other words we believe that our curves are based on all of the important fundamental factors which govern surface losses. Finally, the check results which we have on commercial machines show a fair average check although some of the individual machines show considerable discrepancy between calculated and test results. This, we believe, however, is due largely to inaccuracies in the commercial testing rather than in the formulas.

From the calculation curves given we believe it is possible to predict from the fundamental characteristics of a new material, namely, n, ρ, t and μ, the surface losses to be expected under any normal conditions of use. Even a simple Epstein test under standard conditions should give sufficient data for an approximate estimate for the surface loss constant.

It is hoped that this paper will bring out further test data on surface losses in order that a more accurate check on existing formulas may be obtained so that this type of loss may be calculated with the same degree of accuracy and confidence with which we now calculate transformer losses.

Appendix

This method depends upon the fact that when the rotor of a polyphase induction motor with the stator excited is driven from an external source there is a sudden decrease in stator input when the rotor goes through synchronism. This decrease is equal to twice the rotor hysteresis loss at zero speed. There is, of course, an equal increase in input to the motor which drives the rotor. For a more complete discussion of these phenomena see Alger and Eksergian.[14] Now at synchronous speeds if we add one-half this sudden change in input to the net input to the driving motor just before synchronism is reached we have the surface losses of induction motor for this particular rotor speed and induction. By changing the frequency of the stator applied voltage and noting the input to the rotor just below and above synchronism, data may be obtained for surface losses for any rotor speed. However, since we desired fundamental-frequency stator and rotor loss data as well as surface-loss results we found it more convenient to keep the stator frequency constant and make the separation of losses by the procedure above to be described. As a matter of interest the discussion covers negative as well as positive rotor rotation and it has been found that surface loss results check very well for both directions of rotation. If the surface pulsation frequency is high with reference to the fundamental frequency there should be no appreciable difference, the surface losses depending then only on the tooth frequency.

Referring to Fig. 19 the following points should be noted before considering it in detail:

1. This diagram refers to any polyphase induction motor with the rotor driven by an external source of power. The curve marked d-c. refers to the input from this external drive.
2. It holds for one given applied stator-frequency and voltage, the rotor-frequency being the only variable.
3. Instrument losses and $I^2 R$ losses in the stator windings are subtracted from the observed a-c. input before plotting.
4. Friction, windage, armature $I^2 R$ and brush $I^2 R$ losses are subtracted before plotting the d-c. input (assuming a d-c. motor drive).
5. The ordinates are a-c. and d-c. input in watts. The abscissas are rotor speeds plotted in terms of stator-frequency, namely, for a stator applied frequency of 60 cycles and a four-pole stator, the rotor speed at synchronism will be 1800 rev. per min., but would be plotted as 60. If desired rotor speeds in rev. per min. could be used for abscissas.

Now considering the sketch in detail, the full line $b' \, a \, b \, c \, n \, d$ represent the a-c. input to the stator ($I^2 R$ losses subtracted as noted above) where $b' \, a \, b$ is parallel to $c \, n \, d$. The d-c. input (minus friction, wind-

age, etc. as noted above) is $h' \, o \, h \, e \, f \, p \, g$. It will be noted that there is a discontinuity in the input curve at synchronous frequency. The decreased a-c. input ($b \, c$) is of course equal to the increased d-c. input ($e \, f$). This sudden change in wattage is equal to twice the product of the rotor torque (due to rotor hysteresis) and the synchronous frequency, namely, it is equal to twice the rotor-hysteresis loss at zero rotor speed. The points r and s bisect $b \, c$ and $f \, e$ respectively. $x \, r \, z$ and $t' \, t \, b$ are drawn parallel to the x axis so that $t \, x$ equals $b \, r$. The lines $t \, r$ and $a \, r$ are straight lines. $r \, q$ is drawn making an angle with the vertical equal to the angle between $a \, r$ and the vertical. Now $t \, x$, $b \, r$, $r \, c$, $f \, s$ and $s \, e$ each equals the rotor hysteresis loss at zero rotor speed and $a \, t$ is the corresponding eddy-current loss. This eddy-current loss will include any copper losses which may be due to circulating currents in the rotor windings if these happen to be closed, also eddy-current losses in the rotor and stator copper. The sum of the stator-hysteresis and eddy-current losses are equal to $x \, o$, or $r \, u$ and are practically constant for all rotor speeds. For any rotor speed below synchronism (positive or negative rotation) the actual rotor-hysteresis loss is equal to the vertical intercept between $t \, r$ and $x \, r$, that is, it is directly proportional to $1\text{-}\omega_r$ where ω_r is the rotor frequency expressed in terms of synchronous frequency. It therefore decreases from $t \, x$ at zero speed to zero at synchronous rotor speed. Above synchronous frequency it again increases at the same rate with frequency at which it decreased. For negative rotation it increases at the same rate as indicated by extending $r \, t$ back to the left.

Before discussing this diagram further it will be well to define a few useful terms.

The *apparent* fundamental-frequency rotor-hysteresis loss is the product of the fundamental-frequency rotor-hysteresis torque and the synchronous frequency. This is a constant and is represented by the vertical distances $t \, x$, $b \, r$, $r \, c$, etc.

The *true* fundamental-frequency rotor-hysteresis loss as noted above is zero at synchronous rotor-frequency and increases uniformly with the frequency on either side of that point. It is represented by the difference between $t \, r$ and $x \, r$.

The *fictitious* fundamental-frequency rotor-hysteresis loss is equal to the difference between the true and the apparent hysteresis loss and is represented by the vertical distance between lines $t \, r$ and $t \, b$ or what is the same thing, the vertical distance between $a \, r$ and $a \, b$. It will be noted that for negative rotation the fictitious hysteresis loss is changed in sign.

The *apparent* fundamental-frequency rotor-eddy-current loss is equal to the eddy-current torque multiplied by the synchronous frequency. It is represented by the vertical distance between the lines $b' \, a \, b$ and $t' \, t \, b$, for rotor frequencies at the left of synchronous speed and is represented by the difference between $c \, c'$ and $c \, n \, d$ at the right of synchronous speed (negative slip). It will be noted that the apparent eddy-current loss increases at a constant rate with rotor frequency at the left of synchronous frequency and decreases at a constant rate for rotor frequencies at the right of synchronous frequency. This is due to the fact that the rotor torque is zero at synchronous frequency, but increases linearly with the slip frequency.

The *true* fundamental-frequency rotor-eddy-current loss increases as the square of the slip or in proportion to $(1-\omega_r)^2$ where ω_r is expressed in terms of synchronous frequency. Knowing the true eddy-current losses as represented by $a \, t$ at zero rotor frequency, the true eddy-current loss for any other frequency may be calculated by assuming this square law. $a' \, k' \, a \, k \, b$ was calculated on this basis. The true eddy-current loss is then the vertical distance between $a' \, k' \, a \, k \, b$ and $t' \, t \, b$. For frequencies above synchronous speed (negative slip) $c \, y \, d$ is drawn as the reverse of $b \, k \, a$ and the true eddy-current loss is the vertical distance between $c \, c'$ and $c \, y \, d$.

The *fictitious* fundamental-frequency rotor-eddy-current loss is the difference between the apparent eddy-current loss and the true eddy-current loss. It is the vertical distance between lines $b' \, a \, b$ and $a' \, k' \, a \, k \, b$. It will be noted that this difference reverses sign at zero rotor frequency. For frequencies above synchronism (negative slip) the fictitious eddy-current loss is the vertical distance between $c \, y \, d$ and $c \, n \, d$.

It is at first rather confusing to note that although the true rotor-hysteresis loss is decreasing with increasing rotor frequency between zero rotor frequency and synchronous rotor frequency, the apparent rotor-hysteresis loss (product of rotor hysteresis torque and synchronous frequency) as represented by the difference between $t \, b$ and $x \, r$, is a constant. A similar confusion exists in considering the true and apparent eddy-current losses. This action may perhaps be made clearer by considering that the stator is revolving at synchronous speed and that the rotor hysteresis torque is represented by friction between the stator and rotor. As long as the rotor speed is below the stator speed the hysteresis torque will be positive and constant. Above synchronous speed the torque will be constant and negative, thus accounting for the sudden change in apparent hysteresis loss. A similar analogy may be used for the eddy-current effects. In this case, however, the coefficient of friction is not constant but is assumed to vary and is directly proportional to the slip frequency being zero at synchronous speed.

In order to separate the surface losses from the other losses let us examine the conditions at a rotor speed represented say by the vertical line $l \, v$ and let us remember that the surface losses must be supplied by the rotor[14]. The rotor itself is driven partly by the input to the drive motor and partly by means of energy transferred across the air gap from the stator. Let us also

14. Induction Motor Core Losses, Alger and Eksergian, JOURNAL A. I. E. E., October 1920, p. 906.

remember that the total a-c. and d-c. inputs as shown by Fig. 19 are equal to the sum of the stator and rotor iron losses. We have, therefore, only to subtract the known stator losses, plus the known fundamental frequency-rotor losses from the total input to give the surface losses. This can most easily be done graphically. In addition to the stator losses and the true fundamental frequency rotor losses the a-c. end is supplying fictitious hysteresis and eddy-current losses which later losses must be subtracted from the a-c. input and added to the d-c. input to give the surface losses. The fictitious hysteresis loss is represented by the difference between lines $t\,b$ and $t\,r$ or by the difference between $a\,b$ and $a\,r$ as mentioned above and is equal to $l\,j$ for the chosen rotor speed. The fictitious eddy-current loss is $l\,k$. Therefore to find the true surface loss $i\,v$, add $l\,j$ plus $l\,k$ (equals $i\,h$) to $h\,v$. This can be done most readily by means of a pair of dividers.

For negative rotation a similar procedure is used. Assume a rotor frequency as represented by $k'\,v'$. Then the fictitious hysteresis loss is represented by the difference between the apparent and true hysteresis loss as before and is equal to $j'\,l'$. The fictitious eddy-current loss is $k'\,l'$. It will be noted that here the true hysteresis and eddy-current losses are greater than the apparent losses. Therefore the fictitious values must be subtracted from the d-c. input since the d-c. drive motor is supplying some of the fundamental frequency a-c. losses. Therefore the true surface loss is $i'\,v' = h'\,v' - (j'\,l' + k'\,l')$.

For rotor frequencies above synchronism (negative slip) the d-c. motor is supplying not only the surface losses but the true rotor losses plus a part of the stator losses. In other words the d-c. end is supplying the true and apparent fundamental-frequency rotor hysteresis losses and the true and apparent eddy losses. Let us consider the rotor frequency $q\,w$. Then $q\,z$ represents the true rotor-hysteresis loss plus the apparent rotor eddy-current loss (reversed) and $z\,y$ represents the apparent rotor-hysteresis loss plus the true rotor eddy-current loss. Therefore in order to obtain the surface loss $m\,w$, $q\,y$ (equals $p\,m$) must be subtracted from $p\,w$. $y\,n$, or course, corresponds to the fictitious eddy-current losses as did $l\,k$ for the lower rotor frequency.

As a check on this method surface loss data were calculated as above for a given rotor, using test data obtained with applied stator frequencies of 20, 40 and 60 cycles. The results are as follows:

TABLE G.

Rotor Frequency	Surface Losses			Stator Frequency
	20	40	60	
20	29	29	28	
30	54.3	52.5	52	
40		77	81	
50		115	114	
60		147	150	

The stator voltages were of course altered in proportion to the applied frequency in order to keep the inductions constant. These checks which are well within the accuracy of the test methods show that reliable results may be obtained with a single stator frequency rather than using stator frequencies corresponding to the rotor frequencies at which data are desired.

Discussion

TOOTH PULSATIONS IN ROTATING MACHINES
(Spooner) and
SURFACE IRON LOSSES WITH REFERENCE TO LAMINATED MATERIALS
(Spooner and Kinnard)

Philadelphia, Pa., February 6, 1924

G. E. Luke: These two papers on iron losses are very worthy papers in that their purpose is to give the designing engineers a knowledge of the stray losses which occur in a machine. These stray losses are very large in the case of some induction motors and in the case of turbo-generator and other high speed electric machines. The old d-c. machines had solid pole faces; the losses on those were large. The only thing that limited them and kept them down within reasonable value was the fact that they used large air gaps. But as the designs were improved, the air-gap was brought down, particularly with the use of the commutating pole, and it was necessary to reduce these pole-face losses; this necessitated a laminated structure.

These papers give a valuation of those losses and how they can be reduced by changing the size of the laminations or by insulating the laminations in the pole. The tooth-pulsation losses are of especial importance because they occur in the tooth zone where the losses are the greatest, due to the copper loss and the high densities found there, and they may be appreciable; sometimes larger than the fundamental loss.

These losses are important first, as regards efficiency; probably of greater importance, though, with regard to heating of the machine. In other words, they limit very seriously the output of the machine as far as temperatures go, and if we can evaluate those losses, it will give the designing engineer a better idea of what his machine will do. In mechanical engineering we have a figure which we call "factor of safety;" it might be called "Factor of ignorance" because it is a figure which takes into account imperfections in design or material.

In electrical engineering we have a similar figure which we use in the magnetic circuit. We obtain losses on the raw material and multiply by that factor, which takes into account the stray losses, and if we can reduce that factor we will put the design on a higher plane and be able to predetermine the performance of any machine to a higher degree of accuracy.

P. L. Alger: I wish to comment on Messrs. Spooner's and Kinnard's paper on surface losses, making two points particularly. One point concerns the relation of the paper to the previous art; and the second concerns the application of the dimensional theory to the results of the paper.

Articles have been published in recent years giving methods for calculating the line-frequency losses and demonstrating their practical accuracy. Mr. Spooner's article now gives us methods for calculating surface losses with reasonable accuracy. Recent papers by Rosenburg and others have given methods for calculating the losses in the adjacent metal parts. These three types of loss, together with the pulsation losses, make up practically the whole core loss of commercial machines. Therefore, if we may hope to have a paper upon pulsation losses, as good as Messrs. Spooner's and Kinnard's paper on surface losses, in the near future, we ought to be able to calculate core losses with satisfactory accuracy. I hope such a paper will be forthcoming before long.

The second point I wish to make is that if you make use of the dimensional theory (which states that the quantity measured is not be affected by any change in the units employed), by applying it to Messrs. Spooner's and Kinnard's results, you may derive some rather interesting conclusions. They find, for example, that the total loss varies approximately as the 2.5 power of the density, when the different exponents for the different conditions are averaged. If this is so and if it is assumed that in calculating these losses theoretically the only factors to be considered in addition to those which they have varied are the resistivity, the thickness of the laminations, and the saturation value of density, then it must follow from the dimensional theory that the loss will vary as the minus 0.5 power, or the inverse square root, of the saturation value of density. Thus we have a measure of the gain it is possible to make by changing the saturation value of the density. Similarly, assuming their exponents to be correct for the variation of the loss with the frequency and with the tooth pitch, it follows that the loss should vary approximately as the minus 1.5 power of the resistivity. The ordinary theory, based upon a constant permeability shows an exponent for the resistivity of minus 0.5. This variation as the minus 1.5 power makes the resistivity very much more important in reducing the losses than we would expect from the conventional theory.

Finally, it may be shown that the losses must vary about as the 1.7 power of the lamination thickness, if the exponents derived for the other variables are really true. Since their tests on variations in lamination thickness show the square law to hold at low thicknesses and the first power law to hold at greater thicknesses, it also follows that their exponents for density and tooth pitch cannot be true over the whole range.

In brief, the whole range of their experiments may be coordinated, made more reasonable, and extended by applying the dimensional theory to their results.

I have prepared a table of the exponents derived in this manner which gives the values expected for the several cases.

TABLE OF EXPONENTS

Experimental					Deduced		
Material	B_{AG}	f	λ	q	B_{SAT}	ρ	t
.0172 M. A.	2.2	1.7	1.1	1.7	− .2	−1.3	1.9
.0281 Bessemer	2.4	1.6	1.3	2.15	− .4	−1.4	1.7
.0625 "	2.6	1.6	1.3	2.2	− .6	−1.4	1.7
.125 "	3.1	1.6	1.3	2.3	−1.1	−1.4	1.7
Solid Steel*	2.5	1.5	..	1.4	− .5	−1.5	..
.0172 M. A. (Induction Motor)	1.9	1.55	..	..	0.1	−1.45	..

*Taken for unpublished experiments. The other figures are from tables *C* and *E* in Messrs. Spooner and Kinnard's paper.

I. F. Kinnard: In closing this paper, I have no further remarks to make, excepting to explain in a little more detail Fig. 11 on page 270. You will note that this is a comparison between the losses obtained, using chamfered poles and ordinary poles with a uniform gap. The basis of the comparison was using minimum air gap; that is, in the case of the chamfered poles we used minimum air gap at the center and average induction. The reason for this I think I can make clear:

Assume a uniform air gap, and a non-uniform gap due to chamfered poles. For the reason that in both cases, we are using average air gap induction over the entire pole face, it is easy to see that in the case of the chamfered poles the losses are increased somewhat due to the greater flux density at the center. These higher losses are satisfactorily accounted for, if, instead of using average length of gap in our formulas, we use the minimum gap in all cases.

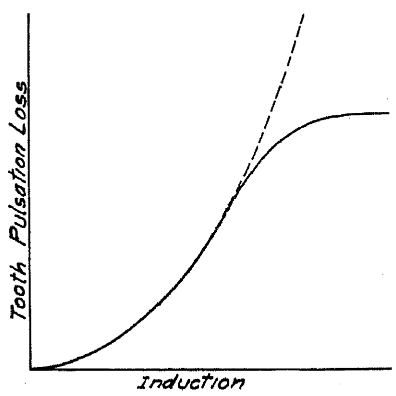

FIG. 1—TOOTH PULSATION LOSSES SHOWING EFFECT OF SATURATION

Although this is an approximation, it is sufficiently accurate for practical purposes.

T. Spooner: I would like to say a word in regard to the practical effect of saturation on tooth pulsation losses. In the paper we did not mention losses specifically but this investigation was made, of course, with the definite purpose of applying the results to the calculation of losses. Suppose we plot from experimental results tooth pulsation losses against air gap induction, we shall obtain a curve similar to Fig. 1. If there were no tooth saturation, the curve would continue as shown by the dotted line but due to the reduction of tooth pulsations caused by saturation, the rate of increase of loss decreases and if the induction were carried high enough, the losses may actually decrease.

Saturation is then an important factor in reducing tooth pulsation losses. This, of course, applies only to induction motor rotors with no windings or with slip ring windings, but does not apply to squirrel cage rotors.

Methods for Testing Current Transformers

BY FRANCIS B. SILSBEE

Associate, A. I. E. E.

Physicist, Bureau of Standards

Review of the Subject.—*In the sale of electric power especially in large amounts at high voltages, current transformers are universally used to operate the meters from the readings of which the bills are made out. While the secondary currents of such transformers reproduce fairly faithfully on a smaller scale the conditions of current strength and phase existing in their primary circuits, meter engineers are realizing more and more the importance of checking up the accuracy of this link in the chain of measurements.*

Many possible methods have been suggested for testing the accuracy of current transformers. Some are delightfully simple and inaccurate while others involve relatively intricate connections and sensitive apparatus, but give correspondingly more exact results. The present paper gives a critical discussion of the various possible methods with data as to the advantages and disadvantages of each, in order to serve as a guide to the meter engineer in selecting the method best suited to the particular working conditions of accuracy, speed, volume of testing, and intelligence of labor, existing in his plant. In all eleven distinct methods are described, and supplementary suggestions are made concerning various types of detecting instruments, etc.

INTRODUCTION

As a result of the continued growth of electric power systems, and the improvement in accuracy of metering methods which has accompanied it, more and more attention is being given both by utility companies and public service commissions to the testing of the instrument transformers which are almost invariably involved in the measurements on which large amounts of electric energy are bought or sold. The choice of which testing method to adopt in any given case depends very greatly upon a variety of conditions, such as the volume of testing work to be done, the accuracy required, the skill of the staff available for making the measurements, and the working conditions such as steadiness of the supply voltage, freedom from stray magnetic fields, etc.

It is the purpose of the present paper to assist the meter engineer in choosing a testing method by assembling in convenient form brief descriptions of the various methods which are now available for testing current transformers, and indicating the advantages and disadvantages of each method.

There will be given first a brief classification of the available methods, together with a discussion of the more important properties of the electrodynamic type of instrument used in many of the testing methods. This will be followed by a brief description of each method with an indication of its advantages and disadvantages, and its probable accuracy, and later by a more detailed discussion of the various forms of detecting instruments which may be used with many of the methods. In Appendix A is given a bibliography which, though by no means complete, lists the more important methods for testing current transformers. The numbers in parenthesis scattered through the text refer to the articles in the bibliography where the particular subject referred to will be found discussed in more detail.

GENERAL CONSIDERATIONS

A typical vector diagram for a current transformer is shown in Fig. 1. If the primary current I_1 is divided by the nominal ratio of the transformer, and reversed in direction, we obtain the vector I', which is here represented as being slightly larger than the secondary current I_2 and as lagging behind it by a small angle β. The ratio of the effective values of I_1 to I_2 is defined as the current ratio of the transformer, while the ratio of the effective values of I' to I_2 is defined as the ratio factor and is the quantity by which the nominal ratio of the transformer must be multiplied in order to obtain the true current ratio. The phase angle of the transformer is defined as the angle by which the secondary current leads the reversed primary current. In order to determine the performance of a current transformer completely as part of a measuring equipment, it is necessary to know the values of ratio and of phase angle for all the conditions of use. Unfortunately these two values depend to a considerable extent upon the frequency, the secondary burden, and the value of

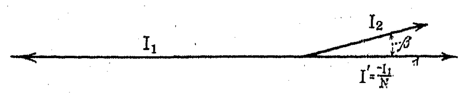

FIG. 1

the currents flowing in the transformer windings, and it is therefore necessary to duplicate all of these conditions when the transformer is tested. Since all testing methods require the insertion of some additional apparatus into the secondary circuit, it becomes a matter of very considerable importance in accurate work to insure that proper allowance for this has been made and that the transformer is tested with a burden closely equivalent to that on which it is used in service. It is convenient to determine the ratio and phase angle at secondary current values of 0.5, 1, 2, 3, 4 and 5 amperes since interpolation between these points is satisfactory for determining intermediate values. It is found that well-made transformers having several primary windings which may be connected in series or parallel have substantially the same ratio factor and phase angle with all connections. In transformers of the hole type in which the primary is inserted by the user of the transformer, this constancy of ratio and

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

phase angle is not as perfect as in the preceding case, but the variation in these quantities seldom exceeds 0.3 per cent in ratio and five minutes in phase angle.

In the use of a current transformer for the measurement of current, phase angle is, of course, of no importance and it is necessary to measure only the ratio of the transformer. On the other hand, when the transformer is used with a wattmeter or watthour meter on circuits of power factor other than unity, the effect of the phase angle becomes of importance. The effect of this angle has been worked out by Robinson (28) and others (10, 21, 24, 26), and can be expressed by the equation

$$P = \frac{P' R \cos(\theta + \beta)}{\cos\theta} = P' [R(\cos\beta - \tan\theta \sin\beta)] \quad (\mathbf{1})$$

where P = true power in primary circuit
P' = apparent power as observed in the secondary circuit
$\cos\theta$ = apparent power factor as observed in the secondary circuit
R = ratio of current transformer
β = phase angle of current transformer

In some cases where it is known that the transformer will be used on circuits having a particular power factor, it is desirable to make the test in such a manner as to determine not the ratio and phase angle separately, but the particular combination of these two quantities which is included in the brackets in the right hand member of equation (**1**.) This type of test gives the over-all correction factor which must be applied to power or energy measurements at the particular circuit power factor. Any of the methods described below which use electro-dynamic instruments or watthour meters in the measurement, permit of this type of test.

Methods for testing instrument transformers may be classified (6) into (A) absolute and (B) relative methods as shown in Table I. In the absolute methods the

TABLE I

ratio and phase angle of a single transformer are determined directly from the observations, while in the latter the constants of the transformer under test are compared with those of a standard transformer of the same nominal ratio which has been previously tested by an absolute method. The absolute methods are suitable for two classes of work (*1*) in standardizing laboratories when the highest accuracy is needed in testing transformers which are to be used as standards and (*2*) in relatively crude measurements under emergency conditions when the standard transformers needed for the relative methods are not available. As is usually the case with any type of measurements, the relative methods are in general simpler and require less sensitive and delicate apparatus for the same accuracy than do the absolute methods, and are therefore to be preferred in most cases.

The methods of either type may be further classified as (a) deflection or (b) balanced methods. In the former the magnitude and phase (or their equivalents) of both the primary and secondary currents are observed separately and the ratio and phase angle computed from these observations. In the latter the effects of the two currents to be compared are opposed and only their vector difference is measured. In the true null methods this difference is completely balanced against a known vector, while in other balance methods of what may be called the "semi-null" type the vector difference is obtained from the deflections of suitable instruments. As in other types of measurement the

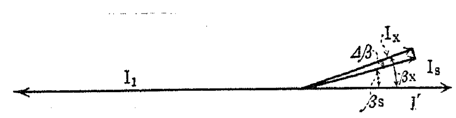

FIG. 2

balance methods have decidedly greater accuracy than the deflection methods and the semi-null methods are usually slightly quicker to operate than the null methods.

Fig. 2 shows a vector diagram applicable to any relative method of testing. The primary current I_1 passes through the primary coils of both transformers and produces currents I_s and I_x in the secondary coils of the standard and test transformers respectively. The differential current ΔI or some effect proportional to it can be measured in terms of I_s. The observations then give the ratio I_s to I_x and the phase difference $\Delta\beta$ between these vectors. The true ratio $\frac{I_1}{I_x}$ is found by multiplying I_s/I_x by R_s (the ratio, I_1/I_s, of the standard transformer). The true phase angle $\beta_x = \Delta\beta + \beta_s$.

In order to avoid repetition later it may be well at this point to review briefly the principal properties of two-circuit electrodynamic instruments (indicating wattmeters and electrodynamometers) since these are often used in transformer testing. Instruments of this type are used for two main purposes (1) as a guide in setting the proper phase relation between the currents in two different circuits, and (2) to measure currents or

It is the purpose of the present paper to assist the meter engineer in choosing a testing method by assembling in convenient form brief descriptions of the various methods which are now available for testing current transformers, and indicating the advantages and disadvantages of each method.

There will be given first a brief classification of the available methods, together with a discussion of the more important properties of the electrodynamic type of instrument used in many of the testing methods. This will be followed by a brief description of each method with an indication of its advantages and disadvantages, and its probable accuracy, and later by a more detailed discussion of the various forms of detecting instruments which may be used with many of the methods. In Appendix A is given a bibliography which, though by no means complete, lists the more important methods for testing current transformers. The numbers in parenthesis scattered through the text refer to the articles in the bibliography where the particular subject referred to will be found discussed in more detail.

GENERAL CONSIDERATIONS

A typical vector diagram for a current transformer is shown in Fig. 1. If the primary current I_1 is divided by the nominal ratio of the transformer, and reversed in direction, we obtain the vector I', which is here represented as being slightly larger than the secondary current I_2 and as lagging behind it by a small angle β. The ratio of the effective values of I_1 to I_2 is defined as the current ratio of the transformer, while the ratio of the effective values of I' to I_2 is defined as the ratio factor and is the quantity by which the nominal ratio of the transformer must be multiplied in order to obtain the true current ratio. The phase angle of the transformer is defined as the angle by which the secondary current leads the reversed primary current. In order to determine the performance of a current transformer completely as part of a measuring equipment, it is necessary to know the values of ratio and of phase angle for all the conditions of use. Unfortunately these two values depend to a considerable extent upon the frequency, the secondary burden, and the value of

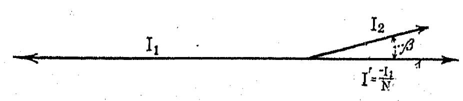

FIG. 1

the currents flowing in the transformer windings, and it is therefore necessary to duplicate all of these conditions when the transformer is tested. Since all testing methods require the insertion of some additional apparatus into the secondary circuit, it becomes a matter of very considerable importance in accurate work to insure that proper allowance for this has been made and that the transformer is tested with a burden closely equivalent to that on which it is used in service. It is convenient to determine the ratio and phase angle at secondary current values of 0.5, 1, 2, 3, 4 and 5 amperes since interpolation between these points is satisfactory for determining intermediate values. It is found that well-made transformers having several primary windings which may be connected in series or parallel have substantially the same ratio factor and phase angle with all connections. In transformers of the hole type in which the primary is inserted by the user of the transformer, this constancy of ratio and

phase angle is not as perfect as in the preceding case, but the variation in these quantities seldom exceeds 0.3 per cent in ratio and five minutes in phase angle.

In the use of a current transformer for the measurement of current, phase angle is, of course, of no importance and it is necessary to measure only the ratio of the transformer. On the other hand, when the transformer is used with a wattmeter or watthour meter on circuits of power factor other than unity, the effect of the phase angle becomes of importance. The effect of this angle has been worked out by Robinson (28) and others (10, 21, 24, 26), and can be expressed by the equation

$$P = \frac{P' R \cos(\theta + \beta)}{\cos \theta} = P' [R(\cos \beta - \tan \theta \sin \beta)] \quad (1)$$

where P = true power in primary circuit
P' = apparent power as observed in the secondary circuit
$\cos \theta$ = apparent power factor as observed in the secondary circuit
R = ratio of current transformer
β = phase angle of current transformer

In some cases where it is known that the transformer will be used on circuits having a particular power factor, it is desirable to make the test in such a manner as to determine not the ratio and phase angle separately, but the particular combination of these two quantities which is included in the brackets in the right hand member of equation (1.) This type of test gives the over-all correction factor which must be applied to power or energy measurements at the particular circuit power factor. Any of the methods described below which use electro-dynamic instruments or watthour meters in the measurement, permit of this type of test.

Methods for testing instrument transformers may be classified (6) into (*A*) absolute and (*B*) relative methods as shown in Table I. In the absolute methods the

TABLE I

ratio and phase angle of a single transformer are determined directly from the observations, while in the latter the constants of the transformer under test are compared with those of a standard transformer of the same nominal ratio which has been previously tested by an absolute method. The absolute methods are suitable for two classes of work (*1*) in standardizing laboratories when the highest accuracy is needed in testing transformers which are to be used as standards and (*2*) in relatively crude measurements under emergency conditions when the standard transformers needed for the relative methods are not available. As is usually the case with any type of measurements, the relative methods are in general simpler and require less sensitive and delicate apparatus for the same accuracy than do the absolute methods, and are therefore to be preferred in most cases.

The methods of either type may be further classified as (a) deflection or (b) balanced methods. In the former the magnitude and phase (or their equivalents) of both the primary and secondary currents are observed separately and the ratio and phase angle computed from these observations. In the latter the effects of the two currents to be compared are opposed and only their vector difference is measured. In the true null methods this difference is completely balanced against a known vector, while in other balance methods of what may be called the "semi-null" type the vector difference is obtained from the deflections of suitable instruments. As in other types of measurement the

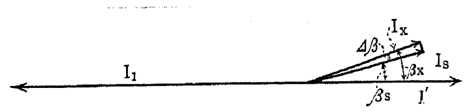

FIG. 2

balance methods have decidedly greater accuracy than the deflection methods and the semi-null methods are usually slightly quicker to operate than the null methods.

Fig. 2 shows a vector diagram applicable to any relative method of testing. The primary current I_1 passes through the primary coils of both transformers and produces currents I_s and I_x in the secondary coils of the standard and test transformers respectively. The differential current ΔI or some effect proportional to it can be measured in terms of I_s. The observations then give the ratio I_s to I_x and the phase difference $\Delta \beta$ between these vectors. The true ratio $\frac{I_1}{I_x}$ is found by multiplying I_s/I_x by R_s (the ratio, I_1/I_s, of the standard transformer). The true phase angle $\beta_x = \Delta \beta + \beta_s$.

In order to avoid repetition later it may be well at this point to review briefly the principal properties of two-circuit electrodynamic instruments (indicating wattmeters and electrodynamometers) since these are often used in transformer testing. Instruments of this type are used for two main purposes (1) as a guide in setting the proper phase relation between the currents in two different circuits, and (2) to measure currents or

differences of currents, such as ΔI of Fig. 2. The fundamental equation for the deflection of an instrument of this type is

$$I_f I_m \cos\theta = k\,D \qquad (2)$$

where I_f is the current in the fixed coil, I_m is the current in the moving coil, θ is the phase displacement between these two currents, D is the deflection and k is a constant of the instrument. As the phase of one of the currents, say I_m, is rotated with respect to that of the other current, the deflection of the wattmeter will rise from zero to a maximum value and then decrease through zero to a negative maximum and then return to its original value. An indication of zero on the instrument corresponds to the value of $\cos\theta = 0$ in equation (2) and hence to $\theta = 90$ deg. It may be noted that the accuracy of locating the zero position is much greater than that of locating the maximum, and therefore the former method should always be used where possible as a means of setting phase. If full-scale deflection of the instrument corresponds to 150 divisions, then an error of one division at the zero mark corresponds to an error in the phase relation between the currents of only 0.4 deg. while the same error at the maximum position corresponds to 6.5 deg.

When used for the purpose of current measurement, one coil is excited by sending through it a current of known magnitude and phase, while the current to be measured is sent through the other coil. The instrument then becomes in effect an ammeter and serves to measure the component of the current in the second coil which is in phase with that in the first. When the fixed coil is excited and the current to be measured is sent through the moving coil, we have the equation

$$I_m \cos\theta = \frac{k\,D}{I_f} \qquad (3)$$

If an ordinary wattmeter, the scale of which is graduated in watts, is used with a separate exciting current I_f in the fixed coil, the value of the constant k is given by $k = w/R_v$ where R_v is the resistance in ohms of the voltage circuit and w is the watts per division. If, on the other hand, the voltage circuit is excited with an auxiliary voltage V, the component of fixed coil current in phase with this voltage is given by

$$I_f \cos\theta = \frac{w\;D}{V} \qquad (4)$$

In order to determine completely any current such as I_f or ΔI of Fig. 2, two readings are necessary in which the wattmeter is excited from two sources of current of different phase. After such readings have been obtained it is possible by graphical construction or by trigonometry to determine both the magnitude of the unknown current and its phase relation to either of the auxiliary current sources. From two pairs of such measurements of I_1 and I_2 or of ΔI and I_2, the vector relation of I_1 to I_2 can be obtained in terms of these readings, and gives the desired constants of the transformer. The mathematical treatment of the relations involved is given in Appendix B. The resulting equations are rather complicated and burdensome in the general case, but fortunately they reduce to very simple forms when one of the auxiliary currents is in phase with the secondary current of the transformer under test and the other auxiliary current is in quadrature therewith. It is therefore advisable wherever possible to insert some form of phase shifting device in the circuits supplying the auxiliary current in order that one of them may be brought into phase with the secondary current of the transformer. The use of the general equations of Appendix *B* should be limited to exigencies when such a phase-shifting arrangement is not available.

In cases which frequently arise in practise where the auxiliary circuits exciting the dynamometer are obtained from a three-phase system, the angle φ in Appendix *B* becomes 60 deg., and the solution reduces to equations

$$R = \frac{A_1}{A_2 \cos\beta} \text{ or } (1 + A/A_2)\ \frac{1}{\cos\beta} \qquad (5)$$

$$\tan\beta = \frac{2\,(B_1 - N\,B_2) - 1.732\,(A_1 - N\,A_2)}{A_1} \qquad (6)$$

$$= \frac{2\,B_\Delta - 1.732\,A_\Delta}{A_2 + A_\Delta} \qquad (6)$$

The symbols used in this and the following equations are defined in Appendix *B*. It will be seen that these are fairly simple if one of the currents can be brought into phase with the transformer secondary current, and the need for a two-phase source of current can be avoided by using these equations instead.

Equation (3A) of Appendix *B* is

$$R\,(\cos\beta - \tan\theta\sin\beta) = A_1/A_2 \qquad (3A)$$

It will also be noticed that the left hand member of this is identical with the factor given by equation (1) above for the correction to the wattmeter or watthour meter operating at a circuit power factor $\cos\theta$. Consequently any of the wattmeter methods may be used with the auxiliary voltage, making an angle θ with the transformer currents to determine the over-all correction factor for that particular power factor.

It appears from the preceding paragraph that all of the testing methods which involve wattmeters or watthour meters in the measurement have the following advantages and disadvantages in common:

Advantages:

(1) They automatically check the polarity marking.

(2) They permit of test giving combined effect of ratio and phase angle at any specified power factor.

(3) The instruments used are of simple and generally available types except when high sensitivity is desired.

Disadvantages:

(1) They require an auxiliary source of voltage.

(2) If phase angles are to be measured this must be a polyphase source preferably two-phase.

(3) It is highly desirable to provide for shifting the relative phase of the auxiliary voltages.

ABSOLUTE METHODS

The term "absolute" may be applied to those methods in which the constants of a single transformer can be determined directly without reference to any standard transformer of the same nominal ratio.

Two-Ammeter Method. (6, 17, 24, 28) By far the simplest possible absolute method is the use of two ammeters, one to measure the primary current and the other to measure the secondary current. The ratio of the transformer is given directly by the ratio of the ammeter readings. Of course the phase angle cannot be determined by this method. The accuracy is limited by the calibration errors of the two instruments and by the accuracy with which they can be read simultaneously. With carefully calibrated instruments it is possible to obtain an accuracy of ½ per cent at full rated current, but because of the non-uniform scales of all a-c. ammeters the accuracy falls off to a very poor value at lower currents. This source of inaccuracy can be reduced only slightly by changing the range of the ammeter used in the primary circuit. This expedient is not feasible in the case of the secondary ammeter since the burden imposed on the transformer by inserting in its secondary circuit the coils of an ammeter of lower range than 5 amperes is excessive, so that the results obtained when such lower range ammeters are used are decidedly different from the performance of the transformer when in actual service. Other objections to this method are that its range is limited by the available range of self-contained a-c. ammeters which is about 500 amperes, the method gives no check on the polarity marking of the transformer, and the results give only the ratio of the transformer and not its phase angle.

Two-Wattmeter Method. (6, 17, 23, 24) In this method the current coils of two wattmeters of appropriate range are connected in series with the primary and secondary circuits of the transformer respectively, and the voltage circuits of the wattmeters are connected in parallel with one another and to one or the other phase of an auxiliary source of voltage. If the auxiliary voltage is in phase with the secondary current, the ratio of the watt readings gives the ratio of the transformer. If the phase of the auxiliary voltage is approximately in quadrature with the primary current, the phase angle of the transformer is given by

$$\tan \beta = \frac{B_1 - N B_2}{A_1} = \frac{W_1 - N W_2}{E I_2} \qquad (7)$$

where W_1 and W_2 are the readings of the primary and secondary wattmeters respectively. I_2 is the secondary current, E the effective value of the auxiliary voltage, and N the nominal transformer ratio (see Appendix B).

This method is also simple and quick, and after a set up has once been checked out, it serves to check the polarity of other transformers which may be tested with it. Furthermore, by exciting the voltage circuits of the wattmeters from an auxiliary voltage which is displaced in phase by an angle θ from the transformer currents, the resultant readings give directly the combined error due to ratio and phase angle when used on a circuit of power factor $\cos \theta$. As in the preceding method the range is limited by the range of available wattmeters which is about 200 amperes. The accuracy may be as high as 0.2 per cent at full current and drops off only in proportion to the current instead of dropping off in proportion to the square of the current as in the preceding method. A disadvantage which it has in common with most other methods using electrodynamic instruments as detectors is that it requires a polyphase auxiliary source of voltage.

We now come to the class of absolute balance methods in which some effects of the primary and of the secondary currents are balanced against one another as a means of determining their ratio and phase displacement.

Mutual Inductance Method. (13) In this method the primary and secondary currents respectively are sent through the primary windings of two large mutual inductors. These are chosen so that the value of each mutual inductance is inversely proportional to the nominal value of the current which it carries, and hence the secondary electromotive forces induced are approximately equal. The secondary coils of the two mutual inductors are connected in series opposition so that the difference in the induced e. m. f. is applied to a detector. A fine adjustment is provided on one of the mutual inductances so that an exact balance can be obtained. In order to compensate for the phase angle of the transformer, a small resistance of a few hundredths of an ohm is connected in series with the secondary circuit of the transformer under test, and the voltage drop across a variable portion of this is inserted into the detector circuit.

This method is suitable for precise laboratory work and can be made exceedingly accurate. It is also easy to construct the mutual inductors with a considerable number of individual coils which may be connected in series or parallel. It is thus possible to obtain a wide range of values of mutual inductance and consequently a wide range of transformers can be tested.

On the other hand, it is very essential that the inductors be astatic since any electromotive forces induced in their secondary windings by a stray field would introduce an error directly in the ratio determination. This feature has been very successfully obtained in the apparatus designed by Fortescue, and now used by the Westinghouse Co. In this equipment a range of from 5 to 5000 amperes is obtained, and the mutual inductors have been made astatic by the use of toroidal coils for

both primary and secondary. Such a uniformly wound toroid produces no external magnetic field, and consequently will have no electromotive force induced in it even when placed in a strong external field providing the conductor producing this field does not pass through the opening of the toroid. By using a relatively large number of turns in the secondary coils, it is possible to obtain a secondary electromotive force as great as 4 volts, and an accuracy of 0.01 per cent can be obtained even while using a rugged and relatively insensitive detector. In the equipment mentioned above the necessary burden inserted in the secondary coils of the transformer by the testing equipment varies from 0.1 to 0.3 of an ohm impedance, depending upon the connections which are used. Complete astaticism requires that the marble core on which the coils are wound shall be machined very accurately to dimensions, and as a result the entire equipment is rather expensive, and so far as the writer is aware has not been duplicated in any other laboratory.

In any such apparatus it is important to make certain that the secondary electromotive force from the mutual inductor is in quadrature with the primary current.

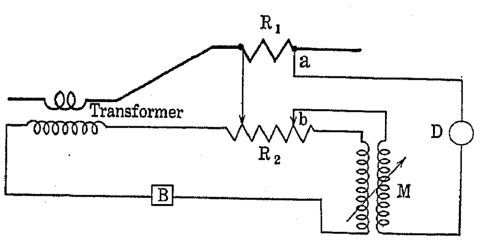

Fig. 3

Often this relation does not exactly hold in cases where the primary circuit consists of conductors of large cross section such as are necessary when heavy currents are to be measured. Fortunately the same toroidal construction which makes the inductor astatic also contributes to reduce this phase defect. (31).

Resistance Method. (1, 6, 9, 19, 20, 21, 24, 25, 28, 29, 30, 33). This method is perhaps more generally used than any other absolute method for the precise testing of current transformers. In its various modifications it is used by the National Standardizing Laboratories of the United States (1), England (33), France (19), and Germany (25), and also by several commercial and university laboratories. The primary and secondary currents are passed through four-terminal resistance standards of such value that the potential drops across the two are equal, and in most equipments of the order of one volt. The potential terminals of the shunts are then connected in series with the detector instrument so that the $I R$ drops are in opposition. The phase angle of the transformer is determined in several different ways at the various laboratories, depending upon the type of detector used. In one group of laboratories the unbalanced e. m. f. resulting from the fact that the primary and secondary currents are not in phase is balanced by inserting in the detector circuit a third source of e. m. f. in quadrature with the primary current. This e. m. f. may be obtained in several ways, the simplest of which is from the secondary of a small mutual inductor (1, 9, 30), the primary of which is connected in either the primary or the secondary circuit of the transformer under test. The compensating electromotive force may be obtained if preferred from a separate phase of the generator supplying the test current (19), or from a shunt circuit containing a condenser connected across the potential terminals of the primary resistor (29). With any of these arrangements the resistances and the quadrature electromotive forces are adjusted until the detector shows a condition of balance and the ratio and phase angle are then computed from the settings by the formulas

$$R = R_2/R_1 \tag{8}$$

$$\tan \beta = \frac{\omega M}{R_2} \text{ or an equivalent formula.} \tag{9}$$

In the second group of methods the effect of the phase angle is determined by the residual deflection of the detecting instrument after the $I R$ drops have been balanced and the detector has been excited from an auxiliary source in quadrature with the transformer currents (20, 25, 28). Slight modifications in the method as described are introduced by the type of detector which is used, but these will be discussed in a later paragraph. The method is capable of an accuracy of 0.01 per cent and can easily be made direct reading except for possible corrections to the values of the primary and secondary shunts. By suitably changing the nominal values of these shunts the method can be made very flexible, and the range can be extended indefinitely. The detector can be made sufficiently sensitive so that the voltage across the shunts is only 0.25 volt at full current, and the burden introduced into the secondary circuit can be kept as low as 0.1 ohm.

The principal objections to this method are the fact that it requires a sensitive and therefore delicate detecting instrument, and that the shunts must be carefully constructed to minimize residual inductance, and to avoid skin effect. The construction of non-inductive shunts for currents up to 1000 amperes is relatively simple but becomes increasingly difficult beyond that point (31). Precautions must also be taken to avoid errors from capacity currents which may circulate through the detector from the primary source of current.

The Baker Test Ring Method. (4) Instead of balancing the electromotive force produced by a pair of mutual inductances or a pair of resistances, as was done in the previously described methods, this method opposes the magnetomotive forces produced by the primary and secondary currents. A special test ring of well laminated transformer steel is provided with primary and secondary windings quite similar to those

of a current transformer. A third winding is placed next to the iron core and has a large number of turns (about 6000). The primary and secondary currents of the transformer under test are led through the corresponding coils around the test ring in such a direction that their magnetomotive forces are in opposition. Any departure of the currents from their nominal ratio produces a slight flux in the ring which in turn induces an electromotive force in the third winding. This third winding is connected to one coil of a wattmeter or other type of electrodynamic instrument, the other coil of which is excited from any suitable auxiliary source. The number of turns through which the secondary current of the transformer circulates is then varied until the indication of the wattmeter is reduced to a minimum. Since the number of turns of the secondary coil can be varied only in integral steps, the procedure in using the apparatus is to record the reading of the wattmeter for two different values of secondary turns near the point which gives the minimum reading. Thus, for example, if the balance point lies between 179 and 180, the readings of the wattmeter for both of these numbers of secondary turns is observed. The wattmeter is then excited from some other aux-

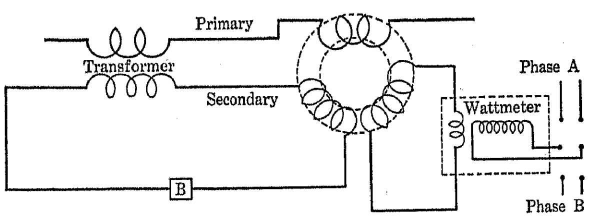

FIG. 4

iliary voltage having a different phase from the first, and a similar pair of readings is taken. From these readings it is possible by a simple graphical construction to lay off on the drawing board the relative location of the primary and secondary current vectors with respect to the auxiliary voltages, and by interpolation between the observed points to determine the ratio and phase angle.

This method has the advantage of requiring only simple and inexpensive apparatus, and of being quite flexible in range since the primary winding on the test ring usually consists of only a few turns which can be easily changed. The computation of the results is, however, somewhat complicated and liable to lead to blunders and the accuracy is not as high as that of the two previously described laboratory methods. Furthermore, as in all methods employing electrodynamic instruments, a separate polyphase auxiliary source is required.

The burden which the apparatus adds to the secondary circuit of the transformer consists of the resistance of the secondary coil of the test ring, which in most cases can be several hundredths of an ohm and in addition there is an effective burden resulting from any electromotive force induced in the coil by the flux arising from lack of perfect balance of the magnetomotive forces.

Relative Methods

If a standard current transformer with known ratio and phase angle and of the same nominal ratio as the transformer which it is desired to test is available, it then becomes feasible to use any one of several additional methods which have certain advantages over those previously described. Of course any of the absolute methods can be used to compare a transformer with a standard transformer of the same nominal ratio, but only those will be mentioned here in which the fact that the nominal ratios of the transformers are the same, permits of a notable simplification or increase in accuracy.

Interchanged Ammeter Method. (6, 24) A simple relative method of testing transformers is analogous to the two-ammeter absolute method first discussed, and consists in connecting two transformers with their primaries in series and with a 5-ampere ammeter and any other desired burden in the secondary circuit of each transformer. Simultaneous readings are then taken of the two secondary ammeters. The ammeters are then interchanged and a second set of readings taken. The ratios of the two transformers are then inversely proportional to the average readings of the ammeters connected to them.

It will be seen that interchange of the ammeters, which is made possible by the fact that transformers have the same nominal ratio, eliminates any error arising from a difference in calibration of the two instruments, and the absolute calibration of either instrument is of only minor importance in the test.

Of course this method gives only the ratio of the transformers and not their phase angle, and the accuracy falls off very badly at low values of the current. For the reason previously mentioned, it is not possible to use low range ammeters in making the test at the lower points on the curve. In actual tests with this method it is very important so to arrange the circuits that the secondary windings of the transformers are not open-circuited while current is flowing in the primary when the two ammeters are interchanged. A switch connected directly across the terminals of each transformer which can be used to short-circuit it while changes are being made in its secondary circuit is a valuable addition to any current transformer testing set-up.

Interchanged Wattmeter Method. (6, 24) This method bears the same relation to the two-wattmeter absolute method as the interchanged ammeter method does to the corresponding absolute method. It is quite simple to check the polarity of the transformers and by using an excitation for the voltage circuits of the wattmeters having a specified phase relation to the transformer currents, the results give directly the

relative performance of the transformers on a circuit of that particular phase displacement. The accuracy, however, is limited to the accuracy of reading the wattmeters and is rather poor with small currents.

Interchanged Watthour Meter or the Agnew Method. (3, 6, 10, 11, 16, 21, 24) This method is very similar to that just described except that a pair of induction watthour meters are used instead of the two electrodynamic wattmeters. The advantage of these meters is that by obtaining their registration over a run of several minutes duration, it is possible to obtain readings of greater percentage accuracy than can be done on the scale of an indicating instrument. This method was originally described by P. G. Agnew (3) and has been the subject of a number of other papers which have suggested slight improvements. At least one of the watthour meters which are used must have graduations marked on the disk, or be of the so-called "rotating standard" type in order that fractions of a revolution may be read off. It is usually desirable to operate the meters at a speed somewhat greater than normal since their accuracy is not impaired and the time of the test is shortened. This condition can be obtained by moving the drag magnets of the meters nearer the axis or by shunting them. By careful work an accuracy of better than 0.1 per cent can be obtained by this method, but the long time required for obtaining the readings of the watthour meters at each point renders the method somewhat slow. The computations involved are rather long but can be considerably simplified by the use of formulas and methods published by Craighead and Weller (10) or by Crothers and Kartak (11).

The three preceding methods are all of the deflection type, inasmuch as the entire primary and secondary effects are observed separately and compared in the computation. The advantages of relative methods of testing appear more definitely, however, in the balance methods, since we here have quantities of substantially equal magnitude and phase to be balanced.

Differential Wattmeter Method. (35) This method is based upon the principle of opposing the magnetic fields due to the secondary currents supplied by the standard and test transformers respectively. The secondary currents are sent through duplicate current windings of a wattmeter in such a direction that their magnetic effects are opposite. The moving coil of the wattmeter is then excited from an auxiliary source of voltage which may be either in phase or in quadrature with the currents in the transformers. A comparison of the indications of this instrument with that of an ordinary 5-ampere wattmeter connected with its current coil in the secondary circuit of one of the transformers and its voltage coil in parallel with that of the differential instrument serves to give the ratio and phase angle of the transformer from the equations (11) and (14) or (15) of Appendix B.

The equality of the two-current coils can be checked by a second observation in which they are interchanged or by connecting them in series opposition and sending current through them from a single transformer. This method is simple and, like other electrodynamic methods, can be used to check polarity and to obtain the effective ratio at any desired circuit power factor. The disadvantage of the method is that it requires a somewhat special instrument which can have relatively few turns in the current coils so that the sensitivity is low. As a result if an ordinary 10-ampere range wattmeter which has two current coils in parallel is used with the coils separated, the sensitivity will be of the order of 1 per cent per division at 5 amperes. It is, however, often possible to overload the current coils of a wattmeter and a suspension-type dynamometer instrument is amply sensitive to give an accuracy as great as 0.01 per cent. As a rough factory check on the performance of transformers to determine any serious mistakes in construction it is probable that this method is very useful.

Modifications of this method which hardly require separate consideration are (1) the use of a polyphase

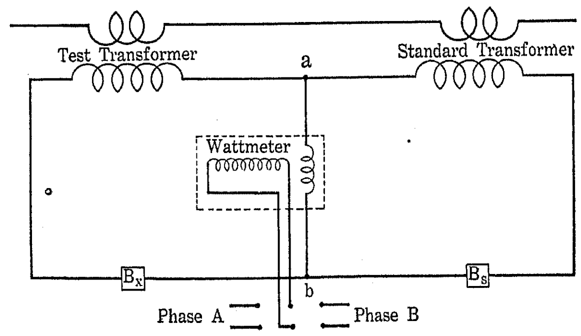

FIG. 5

wattmeter with its elements connected in opposition, and (2) the use of a differentially-wound watthour meter from which the light load compensation has been removed (35).

Bridge Circuit Method. (6, 12, 32). Instead of subtracting the magnetic effects due to the standard and test transformers, it is simpler to subtract the currents directly. This can be done by connecting the standard and test transformers with their primaries in series and with their secondaries also in series in such a direction that both transformers tend to circulate current in the same direction through both secondary burdens, as shown in Fig. 5. A "bridge" circuit is then connected between the points *a* and *b* with the result that any difference in the secondary currents of the two transformers tends to flow across this bridge and can be measured by a suitable detecting instrument placed in the bridge circuit.[1] The detector in the bridge circuit

1. This method was first described by W. A. Folger and was published in the *Proceedings* of the Pennsylvania Electrical Association in 1916, where, however, it is not widely available. It was suggested independently by the author in 1917 and published as part of Scientific Paper No. 309 by the Bureau of Standards.

can be a fairly sensitive low-range pivoted wattmeter excited from a suitable auxiliary source.

When the difference in the secondary currents of the two transformers is ΔI and the impedance of the detecting coil circuit is Z, the effective burden on one transformer is increased and that on the other transformer is decreased by an amount $Z \times \frac{\Delta I}{I}$. When the transformers are nearly equal in ratio this quantity is negligible, but when comparison is made between transformers of very different performance, the shift of the burden may become appreciable. It can be minimized by keeping the impedance of the detecting coil as low as possible. It has been found that the current coil of a one-ampere wattmeter or the voltage coil of a 30-volt wattmeter makes a satisfactory detecting circuit. It is convenient to shift the spring holders of such an instrument so as to put the zero in the middle of the scale. The scale can then be made to read directly the percentage difference in ratio of the transformers. This procedure also places the moving coil more nearly in the

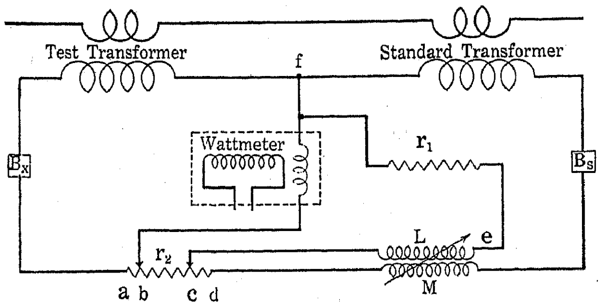

Fig. 6

position where it has zero mutual inductance with the fixed coil, and the slight errors caused by such inductance are reduced. With care this method is capable of an accuracy of 0.1 per cent in ratio and 3 minutes in phase angle.

Null Bridge Method. (32) This method is a modification of the one just described in which the uncertainty in the secondary burden resulting from impedance of the detecting instrument, and also the slight errors which may be produced by mutual inductances between the two coils of the detecting instrument have been eliminated. As shown in Fig. 6 this method makes use of a second bridge circuit, *c e f* which is made to carry the difference in current of the two transformers. The differential current is caused to circulate through this bridge circuit instead of through the detector by suitable adjustment of the resistance r_2 and mutual inductance M. When a balance is obtained the ratio and phase angle of the test transformer are given in terms of those of the standard transformer by the following equations:

$$R_x/R_s = 1 + a + b^2/2 - b\,c\;.\;.\;. = 1 + a \text{ approx.} \qquad \textbf{(10)}$$

$$\tan(\beta - \beta) = b + a\,c = b \text{ approx.} \qquad \textbf{(11)}$$

$$\text{when } a = r_2/r_1 \quad b = \frac{\omega M}{r_1} \quad c = \frac{\omega L}{r_1}$$

Unless the transformers differ widely in performance only the first terms of these formulas are of importance, and the slide wire resistance r_2 can be made to read directly the difference in ratio of the two transformers. The detecting instrument in this case may be either a vibration galvanometer or a separately excited electrodynamic instrument. In the latter case it is desirable, though not absolutely essential, that the phase of the exciting current be adjusted to coincide with that of the currents in the transformer. The magnitude of the exciting current, however, need not be known since the detector is used only as a null instrument.

In any testing method it is theoretically possible to determine the algebraic sign of the phase angle from the direction of the deflection. It is, however, in almost all cases much easier to determine this sign from a simple test based on the fact that adding non-inductive resistance in the secondary of a current transformer tends to increase the ratio and, except in very extreme cases, tends to advance the phase of the secondary current. Hence if the addition of such resistance increases the phase-angle reading the angle was originally positive before the resistance was added. If the addition of resistance decreases the phase-angle reading or reverses its direction, then the angle was originally negative. A similar test with any relative method shows which of the two transformers has the greater ratio.

Detectors

In the deflection methods the measurement is of course made directly by commercial pivoted instruments, and no unusual or sensitive detectors are needed. In the balance methods, however, special types of detector are used either as null instruments or in some cases also as deflection instruments, which serve to measure a small difference between two larger currents.

The absolute methods in general require relatively highly sensitive and therefore somewhat delicate instruments. To bring out more clearly the difference between relative and absolute methods, the case of the resistance method may be compared with the bridge circuit method. In the typical case of the resistance method the available voltage drop across the shunts is fixed at say 0.25 volt in order to keep down the burden inserted in the secondary circuit. At a secondary current of 0.5 ampere the voltage drop is only 0.025 volt, and if the ratio is to be determined to an accuracy of one part in 10,000 the detector must be sensitive enough to indicate an unbalance of 2.5 microvolts. This practically necessitates a suspension type instrument, and most detectors of this sensitivity are read by a mirror and scale arrangement.

In contrast with these, the relative methods require

in general detectors of much lower sensitivity. Thus, for example, in the case of the bridge circuit method, to obtain an accuracy of one part in 10,000 at one-tenth of rated current, the detector must show a visible indication when 50 microamperes pass through it. To compare this with the preceding case we must see what resistance the detector may have without loading the transformers with more than the assumed burden of 0.05 ohm. Even if the transformers under comparison differ in ratio by as much as 5 per cent, a current of only 0.25 ampere will flow through the bridge circuit at full current. The bridge may therefore have as much as 1 ohm resistance without adding more than 0.25 volt drop at the transformer terminals. With this resistance a sensitivity of 50 microamperes corresponds to 50 microvolts, which is 20 times the voltage which the detector for the absolute method would have to detect. Because of this relationship it is feasible to use pivoted wattmeters, such as those intended for measurements on circuits of low power factor. There are also on the market certain suspension types of pointer galvanometers which are fairly rugged, and which are decidedly more sensitive than is usually necessary, consequently by the use of such galvanometers the burden inserted in the secondary circuit can be made less than the 0.05 ohm assumed above.

For the absolute methods requiring high sensitivity, the available types of detectors are (1) the vibration galvanometer, (2) the separately excited electrodynamometer, (3) the separately excited quadrant electrometer, and (4) the d-c. galvanometer used with a synchronous rectifying commutator.

The direct-current galvanometer with rectifying commutator (7, 30), can be made the most sensitive of these instruments, and for the sensitivity required in the absolute testing methods, a fairly rugged galvanometer can be used. There are, however, a number of possible sources of error connected with its use which require a little care in their elimination. The friction of the brushes on the commutator tends to produce local heating, and thus spurious thermoelectric currents in the circuits. This error can, however, easily be eliminated by using as a zero point the reading of the galvanometer when the a-c. side of the commutator is short-circuited. Hunting of the synchronous driving motor, necessity of shifting the brushes to the proper commutating plane, and the irregularities in contact resistances are also sources of annoyance. This method also of course requires a synchronous source of fairly constant voltage from which to operate the driving motor.

A vibration galvanometer (34) can also be made very sensitive and has the great advantage that when it indicates a balance, the observer is certain that no currents of fundamental frequency are circulating in the galvanometer circuit. This is in contrast to the other forms of detector which are not sensitive to currents in quadrature with the phase of their exciting current or with the phase of the rectifying brushes. While the vibration galvanometer balances the fundamental components of the voltages produced by the primary and secondary currents in the transformer, any serious distortion of the wave form by the transformer is indicated by a blurring of the image of the lamp filament as reflected from the galvanometer mirror. No auxiliary source of voltage is required when the vibration galvanometer is used.

On the other hand, such galvanometers are mechanically rather delicate and are sensitive to mechanical disturbances, such as are caused by moving machinery in other parts of the building, so that they must be mounted on some type of vibration-free platform. Furthermore, very high sensitivity is only available over the particular narrow band of frequency to which they are tuned, and they are therefore not at all suitable for use where the frequency of the test circuit is liable to fluctuation. Another disadvantage in the use of a vibration galvanometer is that the observer cannot tell from its indications whether an observed lack of balance is due to the incorrect setting of resistance or of inductance. This objection is, however, more theoretical than actual since a relatively small amount of practise enables the observer to judge, by the rate at which the deflection of the galvanometer varies with the motion of his control handles, which variable requires adjustment; and the time required to obtain a balance with the vibration galvanometer is probably less than with the other types of instrument.

The separately excited electrodynamometer (26, 28) can be made amply sensitive for absolute methods of current transformer testing by using an instrument of the suspension type. With it the methods can be used in which the phase angle of the transformer is obtained by reading the deflection of the instrument when it is excited in quadrature with the primary current. When excited in one phase it is of course sensitive only to lack of balance in that phase, and the observer knows instantly which control to adjust. The direction of the deflection also indicates in which direction the adjustment should be made.

On the other hand, this instrument requires an auxiliary polyphase source of voltage for exciting its fixed coil, and in most methods it requires a phase shifting device for adjusting the phase of its auxiliary voltage. When it is used to measure phase angle by its deflection, it must be calibrated by some auxiliary circuit.

The separately-excited quadrant electrometer (25, 33) is very similar in its functions to the electrodynamometer, and is used to a considerable extent in Europe where such instruments are used in other branches of instrument testing work. So far as the author is aware it has not been used in this country for transformer testing. In order to obtain sufficient sensitivity for current transformer testing, the instrument has to be of

a highly refined and sensitive type, and is suitable for use only under the best laboratory conditions.

Supply of Current

Any testing equipment for current transformers must be able to supply the full-rated primary current to the transformer. Since it is usually undesirable to draw such a large current from the 110-volt supply available in the laboratory, a stepdown transformer is generally used. For this purpose it is sometimes feasible to use an additional current transformer supplied on its 5-ampere winding and delivering heavy current through what was intended to be its primary winding. In tests by the relative method in the field where it is possible to connect the two transformers in series by connecting the standard transformer across a disconnecting switch or some other gap in the line, it is quite feasible to use the actual load on the circuit as a source of primary current. Moderate fluctuations in this current will not seriously interfere with the measurement since the relative ratio and phase angle of the transformers change only slightly for a considerable change in operating current.

The wave form of the supply circuit is not of much importance because most current transformers reproduce very faithfully, in their secondary, even a very distorted primary current wave, consequently the ratio of the fundamental components of the currents is very nearly the same as the ratio of the root-mean-square values, and tests by the various methods described in this paper give substantially the same results. It is usually convenient to read the current in the transformers by means of an ammeter in the secondary circuit. Because of the small deflection of a-c. ammeters on low currents, however, it is often desirable to insert an ammeter in the primary circuit to measure the current when the secondary current is one ampere or less.

The low resistance of the primary circuit which carries the heavy current and the appreciable reactance of the primary windings of the transformers combine to produce a considerable phase shift in the primary current as compared with the source of voltage which supplies the stepdown transformer. For this reason it is very desirable to employ some form of phase-shifting device so that the auxiliary voltages used in exciting the detector instruments can be adjusted to be in phase or in quadrature respectively with the primary current. Such a shift of phase is essential in cases where the phase angle is determined by reading the deflection of the electrodynamometer instrument, or in cases where the test is used to give the combination of ratio and phase angle corresponding to the effective ratio of the transformer on a circuit of specified power factor. In the null method the need for a phase shifter is not so urgent but nevertheless it adds greatly to the convenience and speed of operation.

Brooks Type Transformer

The methods which have been discussed above are directly applicable only to transformers of the usual type with single primary and secondary windings. When used with compensated transformers of the Brooks type (8) certain modifications are necessary. These transformers have both a main and an auxiliary secondary coil and the method of test must be such as to compare the vector sum of the currents in the two secondary coils with the primary current, or with the secondary current of a standard transformer.

The resistance method can easily be modified by inserting into the detector circuit the voltage drop across a third shunt, which is connected in series with the auxiliary coil of the Brooks transformer. Since under normal conditions the current supplied by the auxiliary coil is only a small fraction of the main secondary current the third shunt need not be adjusted to have precisely the same resistance as the main secondary shunt, but may be left at the nominal value of the latter.

The interchanged watthour meter and differential wattmeter methods can be applied to a Brooks transformer if the instruments used are provided with an additional winding to receive the auxiliary coil current. Care must, however, be exercised to avoid introducing an excessive mutual inductance within the instrument between the main and auxiliary secondary coils since this will affect the performance of the transformer. This effect of mutual inductance is probably sufficient to make the Baker test ring method inapplicable for such transformers.

The bridge circuit method can be applied to the Brooks type transformer by connecting the auxiliary coil directly across the terminals of the detector. Since the e. m. f. across the detector is small this does not seriously affect the operation of the transformer. Trouble arises, however, in the null bridge method if there is any contact resistance at the slide wire since the $I R$ drop of the auxiliary current flowing through this contact is likely to affect the detector indications. This source of error can be avoided by using a detector which has an additional coil magnetically equivalent to that used as the "bridge" but insulated from it. Even with this modification the null bridge method does not measure the true effective ratio of the Brooks transformer with rigorous accuracy. The errors, however, are very small since they involve the product of the small percentage difference of the transformers under comparison, multiplied by the small percentage compensation that the auxiliary coil supplies to the main secondary coils.

The fact that transformers of this type have such very small ratio and phase-angle errors over a wide range of current renders them very useful as standards for use with the relative testing methods.

Miscellaneous and Indirect Methods

In addition to the direct methods of measurement described above, certain others have been suggested as being of value in special cases. For instance an a-c. potentiometer (14) may be used to measure separately the voltage drops across the shunts as used in the resistance method, and the resulting triangle of vectors can be solved to give the ratio and phase angle. A power-factor-meter or phase-meter (15) can be used to measure the phase of the primary and secondary currents respectively with respect to a polyphase voltage system, and the difference gives the phase angle of the transformer. Suitable modification of the instrument may be made so that the pointer magnifies the angular displacement by a factor of 5 or more.

In the case of transformers of very large primary current rating it is sometimes necessary to resort to the indirect process of measuring the magnetizing and core loss components of the exciting current of the transformer and computing the ratio and phase angle of the transformer from these data (5). Numerous formulas are available (2, 5, 18, 21, 22, 27) for making this computation, but the results are liable to considerable error because of lack of knowledge of the leakage reactance of the secondary winding. The presence of this reactance makes the terminal secondary voltage of the transformer when in normal operation differ materially from the induced voltage due to the core flux; and thus makes it difficult to determine at what flux density the transformer normally operates. In cases of this kind it is usually preferable to insert a number of primary turns, and thus reduce the primary current rating for the purpose of the test.

Summary

The foregoing survey of the available methods shows that the two-ammeter and two-wattmeter methods are the simplest and least accurate. The relative methods all combine considerable accuracy with fairly simple and rugged apparatus, and are probably to be preferred (1) for testing in the field or station where laboratory facilities are limited and (2) for production tests where large numbers of transformers of the same nominal ratio are to be inspected. The balanced absolute methods are of the highest accuracy but are applicable mainly in the laboratories of government and educational institutions and of the large manufacturers and central stations where they can be applied to the testing of transformers which are later to be used as standards for some relative method.

TRIGONOMETRIC RELATIONS IN CURRENT TRANSFORMER TESTING WITH ELECTRODYNAMIC INSTRUMENTS

Case I. Deflection Methods. As an example of deflection methods we may consider a test by the two-wattmeter method in which I_1 and I_2 are measured by two wattmeters. The voltage circuits of the instruments are excited first on phase A giving readings (reduced to a current basis) of A_1 and A_2 respectively. The voltage circuits are then excited from phase B and the corresponding readings are B_1 and B_2. The vector diagram is shown by Fig. 7.

Let θ = angle by which A leads I_2
φ = angle by which B leads A
R = ratio of transformer
β = phase angle of transformer
N = nominal ratio

Then
$$R = I_1/I_2 = \frac{A_1 \cos\theta}{A_2 \cos(\theta + \beta)} \quad \textbf{(1A)}$$

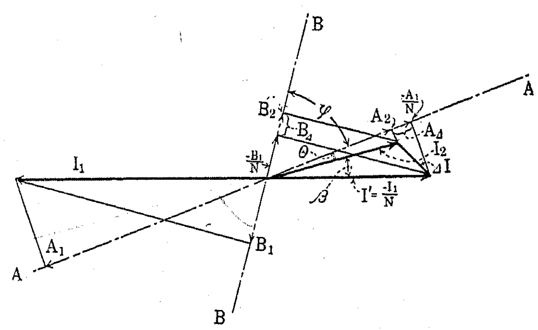

FIG. 7

$$= A_1/A_2 \frac{1}{\cos\beta - \tan\theta \sin\beta} \quad \textbf{(2A)}$$

or
$$R(\cos\beta - \tan\theta\sin\beta) = A_1/A_2 \quad \textbf{(3A)}$$

and
$$A_1 \cos(\varphi + \theta + \beta) = B_1 \cos(\theta + \beta)$$

whence
$$\tan\beta = \frac{\cos\theta - A_1/B_1 \cos(\theta + \varphi)}{\sin\theta - A_1/B_1 \sin(\theta + \varphi)} \quad \textbf{(4A)}$$

In the general case θ can be determined from the current I_2 as measured by an ammeter and the wattmeter reading A_2 by the equation

$$\cos\theta = A_2/I_2 \quad \textbf{(5A)}$$

similarly
$$\cos(\varphi + \theta) = B_2/I_2 \quad \textbf{(6A)}$$

After θ has been computed from (**5A**) it can be used in (**6A**) to compute φ and these two values can be inserted in (**4A**) to compute β. The values of β and θ can then be used in (**2A**) to compute the ratio. This intricate process is fortunately very greatly simplified if the phase of the auxiliary source can be shifted to make $\theta = 0$, and if the other auxiliary phase comes from a symmetrical

2-phase or 3-phase system so that $\varphi = 90$ deg. or 60 deg. respectively.

For $\theta = o$ eqs. (**2A**) and (**4A**) reduce to

$$R = \frac{A_1}{A_2 \cos \beta} = A_1/A_2 \text{ approx.} \tag{7A}$$

$$\tan \beta = \frac{-B_1 + A_1 \cos \varphi}{A_1 \sin \varphi} \tag{8A}$$

which is equivalent to

$$\tan \beta = \frac{-(B_1 - N B_2) + \cos \varphi \, (A_1 - N A_2)}{A_1 \sin \varphi} \tag{8B}$$

since $B_2 = A_2 \cos \varphi$ when $\theta = o$

For a 2-phase system $\varphi = 90$ deg. and (**8B**) reduces to

$$\tan \beta = \frac{-B_1 + N B_2}{A_1} \text{ or } = \frac{-B_1}{A_1} \tag{9}$$

since the adjustment of θ to zero should make the reading $B_2 = o$.

For a 3-phase system $\varphi = 60$ deg. and (**8A**) reduces to

$$\tan \beta = \frac{-2\,(B_1 - N B_2) + 1.732\,(A_1 - N A_2)}{A_1} \tag{10A}$$

Case II. Balance Methods. As an example of balance methods we may consider a test made by the bridge circuit method. Here observations are made on the secondary current obtaining A_2 and B_2 as in Case *I*; and on the differential current ΔI obtaining A_Δ and B_Δ. See Fig. 7. The ratio is then given by

$$R = \frac{N\,(1 + A_\Delta/A_1)}{\cos \beta - \tan \theta \sin \beta} \tag{11A}$$

$$\tan \beta = \frac{B_\Delta + A_\Delta \cos \varphi - A_\Delta \sin \varphi \tan \theta}{(A_2 + A_\Delta) \sin \varphi + \tan \theta\,(B_\Delta + A_\Delta \cos \varphi + A_2 \sin \varphi \tan \theta)} \tag{12A}$$

For $\theta = o$ the equations reduce to

$$R = \frac{N}{\cos \beta}\,(1 + A_\Delta/A_1) \tag{13A}$$

$$\tan \beta = \frac{B_\Delta + A_\Delta \cos \varphi}{(A_2 + A_\Delta) \sin \varphi} \tag{14A}$$

For a 2-phase system $\varphi = 90$ deg. and (**13A**) reduces to

$$\tan \beta = \frac{B_\Delta}{A_2 + A_\Delta} \tag{15A}$$

For a 3-phase system $\varphi = 60$ deg. and (**13A**) reduces to

$$\tan \beta = \frac{2\,B_\Delta + 1.732\,A_\Delta}{A_2 + A_\Delta} \tag{16A}$$

Since in practise it is possible for the angles θ and φ to vary slightly from their nominal values, it is of importance to consider what errors will be introduced into the results by such effects. The magnitude of such errors also depends in absolute methods on the phase angle of the transformer and its departure from nominal ratio, and in the case of relative methods on the difference in phase angle and ratio of the test and standard transformer. These differences will be assumed to have the rather extreme values of 2 deg. and 4 per cent respectively in the following computations:

The error in ratio caused by using the simple equations (**7A**) or (**13A**) in place of (**2A**) amounts to only about 0.06 per cent for an error of 1 deg. in θ, and is roughly proportional to β and to θ for small values of these angles. Since the ratio is determined entirely by readings on phase A, an error in the angle will have no effect on the ratio. The error in phase angle when using equations (**8B**), (**9A**), (**10A**) or (**14A**), (**15A**), (**16A**) in place of equation (**4A**) caused solely by an error of 1 deg. in θ, but with φ having its correct value amounts to 2.3′ and is roughly proportional to θ and to the departure from standard ratio. However, if equation (**8A**) is used an error of 1 deg. in θ will enter directly as an error of 1 deg. in β. If θ is approximately adjusted to zero, an error of 1 deg. in φ will make an error of 2.3′ in β when the test is made on a 2-phase system. On a 3-phase system the error may be greater or less than this depending on the phase relation of ΔI to phase A and in the worst case for the specified limits amounts to 3.5′.

An inspection of equations (**7A**) and (**11A**) shows the great difference in accuracy between the absolute and relative methods when the same instruments are used in both. An error of 1 per cent in reading A_1 or A_2 in eq. (**7A**) will produce an error in the ratio of 1 per cent. In eq. (**11A**) on the contrary the term A_Δ/A_2 is only 0.04 on the assumption previously made. Therefore, an error of 1 per cent in either A_Δ or A_2 will produce an error of only 0.04 per cent in the ratio. An error of 1 per cent in the readings will in most instances produce an error of 1 per cent in the phase angle. Since this angle seldom exceeds 2 deg. or 120′ the error caused by the reading would only be 1.2′ in such a case.

Discussion

I. M. Stein (Philadelphia): On the first and second pages of Dr. Silsbee's paper, a figure of 0.3 per cent is given, as being a maximum for the ratio error in "loop-through" types of current transformers. A number of people are using this type of transformer for standards, and accordingly, the figure given is of particular interest.

We know that there is a difference in the construction of transformers of the "loop-through" type, some being very poor and some very good, a great deal depending upon the way the secondary winding is distributed around the core, and something depending upon whether there are any joints in the laminated core.

If the figure is a maximum for the poorest type, there is not so much to worry about. If it is the figure representing the variations which may be expected in the best type, then it would seem a rather large error for a standard, and I should like to learn from Dr. Silsbee whether the best transformers of that type show errors as large as 0.3 per cent.

Referring now to the vibration galvanometer—the paper indicates in two places that the vibration galvanometer is a delicate instrument.

It is probably true that a number of vibration galvanometers are very delicate, particularly if made to cover a very wide range of frequencies, and perhaps if made considerably more sensitive than is necessary for ordinary measurements on current transformers.

I am familiar with vibration galvanometers that are extremely

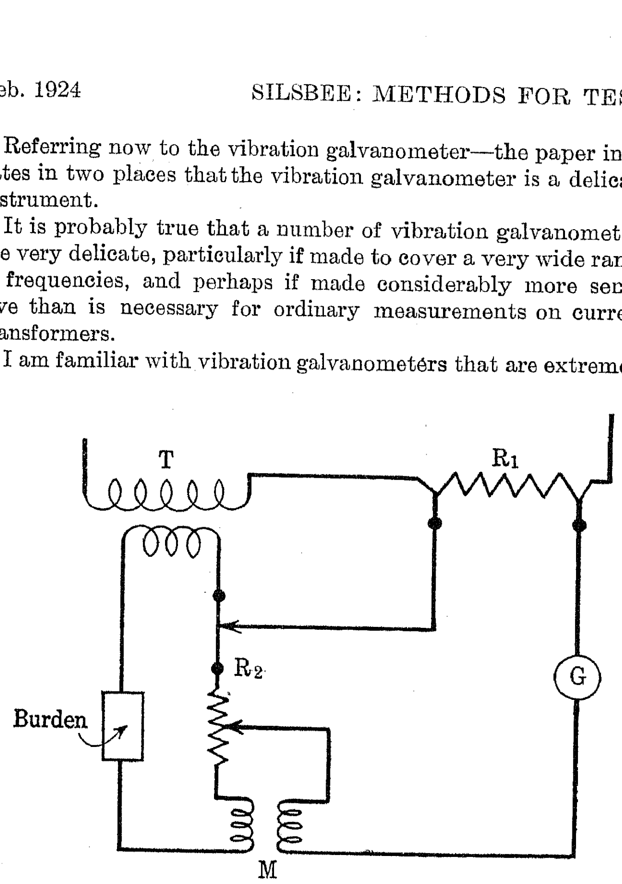

Fig. 1

rugged in construction. They are more rugged than the galvanometer that is used in portable testing sets, the suspension being about twenty-five times as strong as those of the portable galvanometer. I don't think Dr. Silsbee meant to indicate any delicate construction in the vibration galvanometer. I should like to know what interpretation should be placed on his referring to the vibration galvanometer as a delicate instrument.

In connection with the absolute-resistance method, the paper states that precautions must be taken to avoid errors due to

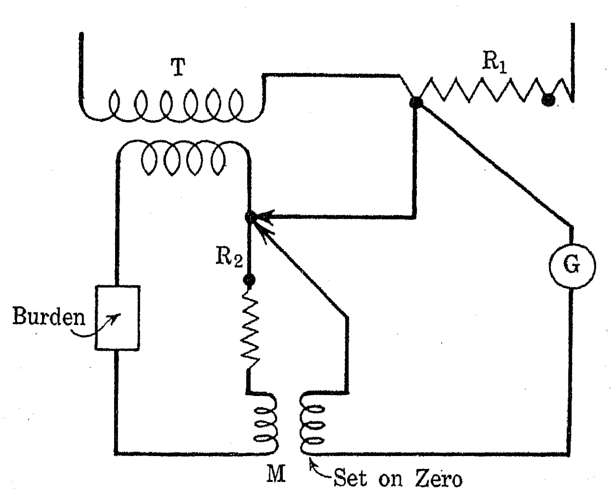

Fig. 2

capacity current which may circulate through the detector from the primary source of current. The precaution applies to tests where you have a sensitive detector, which will pick up very small leakage currents.

The thought occurs to me that if we have leakage in testing where we are using a fairly low voltage for supplying the transformer under test, we must have some leakage when the transformer is installed on a very high-voltage line, say 50,000 volts. Is there any capacity current there which will affect the accuracy of the transformer, particularly at light loads?

I appreciate that the instruments used in service are far less sensitive than those used in testing, but I haven't seen any figures or heard of any results of measurements made to show the probable magnitude of the error.

I should like to add another precaution in dealing with heavy current and sensitive detectors—I refer to stray fields. I think that anyone who has worked with instruments of the kind mentioned, or circuits of the kind mentioned, knows that the effects of stray fields must be eliminated before accurate measurements can be made. In eliminating stray fields, I should like to put in a good word for the vibration galvanometer, when used with the circuit Dr. Silsbee has shown.

In Fig. 1, shown herewith, T is the current transformer being tested, R_1 the primary non-inductive resistance, R_2 is the secondary non-inductive resistance, and M is the mutual inductance. As R_1 and R_2 are made up, the terminals are very close together, and the leads all need to be twisted together to avoid picking up stray fields. The inductance is made astatic, but it may be somewhat affected by stray fields.

If the two leads at R_1 are put under the same binding post (Fig. 2) and the same thing is done at R_2, it involves only a very slight movement, because the binding posts are very close together. If now the mutual inductance is set to zero, then with the full primary current going through the circuit, there should be no vibration of the detector. The circuits must be so arranged to avoid any deflection of the galvanometer under these conditions before you can start to test.

The vibration galvanometer is an excellent detector for this work because as Dr. Silsbee has said, it responds to any current of the fundamental frequency regardless of the phase of that current. You can do a similar thing with a detector requiring shifting the phase of the field current, but that is not so easy, and the very motion of the phase shifter may influence the detector and cause trouble. The vibration galvanometer is an excellent exploring device for getting rid of stray-field errors before starting the measurements.

W. H. Pratt: There is just one word of caution that I think it is well to express; that is, that we should not in practical testing expect from the more convenient methods of relative testing an accuracy approaching the accuracy that can be obtained by the more exact methods. That is I think clearly pointed out in Dr. Silsbee's paper, but nevertheless the figures that sometimes appear as representing what can be obtained by the convenient methods, are a little bit dangerous; that is, they are a little bit better, perhaps considerably better, than are often obtained in the hands of many who may be expected to use these methods.

Frank V. Magalhaes: I would be glad to offer a constructive suggestion to the author of the paper. It would have been very desirable to have Dr. Silsbee add or consider the factor of time as well as the order of accuracy involved in the use of the various equipments and methods. For example, it might be understood that the methods which Dr. Silsbee calls the balanced absolute methods and which employ equipments more or less elaborate would also take considerable time to obtain the measurements. This is not so. With a properly designed primary equipment and a trained operator it is possible to obtain within a few minutes the precise readings of ratio and phase angle which Dr. Silsbee describes in detail.

Dr. Silsbee's paper is a very well prepared comparison of the accuracy of the results that may be obtained by the different equipments or the different methods. There are, however, other factors which would affect the decision of any individual or organization which might be considering the purchase of such a checking equipment for instrument transformers.

The public utilities are probably the largest class of users of instrument transformers in the country. These transformers are used either in connection with the watthour meters or with the power relays, both requiring accurate adjustment.

The various utilities operate under varying rules, depending on the locality. These rules may be the State Public Service orders or municipal regulations in connection with the accuracy and periodicity of check of watthour meters. Certain of these rules require periodic checks of the instrument transformers. These tests may be made on the transformers as received new and prior to installation or may be made in position and connected in service.

Careful consideration would need to be made of various factors, such as the number of transformers involved, the cost of removing them from service for possible check, the period of time between checks and the degree of accuracy desired on the check itself to enable decision to be made as to the type of equipment to be purchased and used.

If the measurements were to be made only on new transformers as received from the manufacturer and they were received in sufficient quantity, these conditions would justify the purchase of one of the more elaborate or expensive equipments, giving balanced absolute results which are of a high order of accuracy and can be very quickly obtained.

If, however, the equipment is required for a public utility of relatively small size with a limited number of instrument transformers all in use and these are by local rule subject to a short period between tests, it would probably be cheaper not to remove the transformer from service but to purchase and use one of the portable sets that do not give the precise results of the laboratory equipment, but provide sufficiently accurate results for the purpose and could be used to test the transformers in position.

One other point that I believe might have been discussed or emphasized by Dr. Silsbee and that is the number of operators necessary to use the various equipments.

It might be considered that the more elaborate equipments giving the precise readings would require several operators. This is not so as equipments of this character can, after they are set up and properly calibrated, be operated very satisfactorily and quickly by a single well trained operator.

J. R. Craighead: There is in Dr. Silsbee's paper. I think, a little tendency to confuse the sensitivity of a method with the accuracy obtainable from the method.

Without going into the details of the methods presented I wish to suggest that the reader keep in mind that the sensitivity which a method will produce is a distinct thing from the accuracy and that the sensitivity mentioned in certain of these cases should not be read as accuracy because the accuracy of the method is dependent upon the certainty of calibrations of the various parts of the apparatus, the accuracy of adjustments, the certainty of temperatures and many other things while the sensitivity is dependent only on the theory of the method, and the relation of the quantities selected for comparison to the sensitivity of the detector.

Perry A. Borden (by letter): The only one of the methods described by Mr. Silsbee for testing current transformers, with which I can claim to have had any great experience, is the Baker Test Ring; but since this combines the precision of an absolute method with the convenience and simplicity of a relative method, I trust I may be pardoned the seeming narrowness of my viewpoint. For fourteen years I have found this system most satisfactory for all classes of current transformers, whether in the laboratory, the workshop or the field. Even with the roughest readings an accuracy of 0.1 per cent is obtained; and with reasonable care ten times that degree of precision may be expected. An excellent dynamometer for use with the ring consists of a Weston Model 310 "low-power-factor" wattmeter, with its moving coil fed directly from the fine wire winding on the ring, and its field excited from normal load current, taken alternately from two phases of a three-phase system. (Higher precision could be obtained with an instrument of the zero-reading type, which would obviate mutual inductance between internal circuits).

In actual practise it is usual to take three or more readings at each value of current, when the system becomes self checking; for, if any source of error has intruded itself into the observations it is almost certain that the several points as plotted will depart from their ideal condition of even spacing along a straight line. For general work it has been found practicable to plot the readings on isometric paper, thus doing away with the need for a drawing board and special scales; and under these conditions the computation becomes very simple, and the possibility of error practically nil.

The true secondary burden on a current transformer interconnected with others on a polyphase metering system is almost impossible to duplicate in the laboratory; and the constants of transformers so installed will differ according to whether they be installed on the leading or the lagging phase of the system. It is highly desirable, therefore, that where the measurement of large blocks of power is concerned, the transformers be checked under actual operating conditions. The Baker method lends itself particularly to work of this class; for, while the outfit is easily portable, the possibility of completely insulating the primary from the secondary winding makes it possible to connect the apparatus directly into the feeder under test, and obtain an absolute determination of current-transformer constants with the circuit actually carrying its load. This, I believe to be regular practise in the plant of the Ontario Power Company at Niagara Falls.

F. B. Silsbee: Mr. Stein asked if this figure of 0.3 per cent possible variation in the pole-type transformer would be applicable to other than bad ones. I think the answer is that it is only in the poorer types of transformers that a variation of this magnitude can be expected to result from different locations of the primary cable. We have made tests at various times at the Bureau on pole-type transformers, trying to place the leads through the holes, in the most widely different positions. In the worst transformers we have come across, have had as much as a 0.5 per cent difference. In the better grades, where the winding is distributed, the error to be expected is decidedly less than the figure in the paper. I put this figure in merely as a caution.

In the matter of capacity currents in the transformer, that is a very interesting point, and I don't think any one knows the answer definitely. Of course, in testing the transformer, especially by the absolutely balance methods, instruments are used which are much more sensitive than the ammeter and wattmeter used in the transformer service. In the higher voltage ranges it is barely possible such a variation would come in.

Stray fields are one of the things always found around heavy current set-ups, and I thought that stray field precautions were so axiomatic they need not be mentioned. The way Mr. Stein outlined is the handiest way to test for stray fields, and is the way we have been doing it at the Bureau.

Mr. Magalhaes raises the question of time. One reason for not laying more stress on it in the paper is the difficulty of estimating the time it takes for a given job because this time depends so greatly on the skill of the operator. Another point is that in most cases a large fraction of the total time of the test is employed in making the connections and in adjusting the burden to properly duplicate the burden at which a test is to be made. All of this time is an overhead common to all methods. After this time is allowed for there is little difference between them as Mr. Magalhaes has pointed out for the balanced method. With the two watthourmeter methods you have to take time to let the meters grind out a fair number of revolutions and this

time is considerable, and is referred to in the paper. Practically all of the methods can be worked with one observer, although it is often convenient to have two men on the job.

Mr. Craighead's comments on the difference between sensitivity and accuracy are well taken. One of the fundamental things to care for in all of this work is to have the burden on the transformer correspond to that at which the standard transformer was tested, and to that at which the transformer under tests is to be used. Any departure from this introduces an error quite apart from the sensitivity of the method and must be guarded against.

Recent Developments in Kilovolt-Ampere Metering

BY B. H. SMITH
Associate, A. I. E. E.
Westinghouse Elec. & Mfg. Co.

and

A. R. RUTTER

Review of the Subject.—*The problem of measuring kilovolt-amperes power factor has received considerable attention from the rate maker and the electrical engineer during the last few years. This paper describes two late developments in kv-a. demand meters. One meter is of the indicating type and indicates total kw. hours, kw. demand and kv-a. demand. The other meter is of the recording type and gives a record of kw. demand kv-a. demand, kw. hours, and kv-a. hours.*

THE problem of measuring voltamperes presents difficulties to the electrical engineer which are not as readily solved as might first be suspected. The difficulties lie in the fact that to measure the product of volts and amperes through the complete range of lagging and leading power factors requires either a shifting of the phase relation between the voltage and current in order to measure the quantities by the wattmeter principle, or the measurement of the two components, reactive and power, of the voltamperes which then must be added vectorially to obtain the apparent power.

Assuming that there is a demand for voltampere measuring devices, without considering the scope or possibilities of such a demand, it is the purpose of this paper to discuss the design of two recent developments in kilovolt-ampere-demand meters. The meters described are of the type which combines the registration of two demand meters. While each kv-a. meter employs the same method of obtaining the energy and reactive components, different schemes are used to obtain the vector sum of the components, or in other words, different mechanical devices are used to obtain the "square root of the sum of the squares."

The methods of measuring watthours are widely known because of common application; the measurement of reactive voltampere hours is not so generally used, and hence data concerning the various methods are not available from as great a number of sources. A complete report on the subject will be found in the 1921 Report of the National Electrical Light Association Meter Committee.

Of the various possible methods of measuring the reactive component probably the most outstanding one is the "Compensator" or auto transformer method. This method facilitates the measurement because it uses a standard watthour meter which is calibrated as a watthour meter. Since this method is preferred in connection with the use of the new volt-ampere meters a brief analysis is given here.

To measure the reactive component with a watthour meter it is necessary to connect the meter so that the potential impressed on the voltage coil is in quadrature to the voltage used for the watthour measurement. The reactive component compensator gives the quadrature relation and proper magnitude of voltages for use with

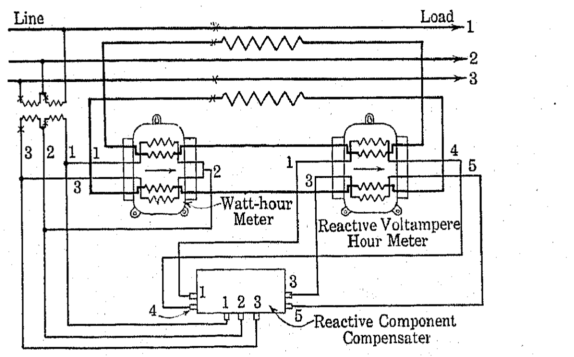

FIG. 1—CONNECTIONS FOR MEASURING VOLTAMPERE HOURS WITH A REACTIVE COMPONENT COMPENSATOR

commercial watthour meters by using two small auto-transformers with suitable taps and connections. In making the connections for reactive component measurement it is necessary to take into consideration the phase rotation since the direction of rotation of the meter changes with phase rotation as well as lagging and leading power factors.

The vector diagram for the connections which are shown in Fig. 1 are given in Fig. 2.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

It will be observed in the diagrams that the small auto-transformers have taps at 57.7 per cent and 115.5 per cent of the primary winding and that the voltages thus obtained are combined so that the resultant voltages are equal in magnitude to the impressed voltages but are in quadrature to the impressed voltages.

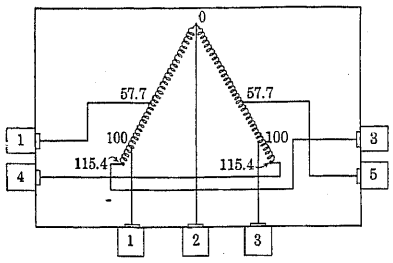

FIG. 2—INTERNAL CONNECTION OF REACTIVE COMPONENT COMPENSATOR

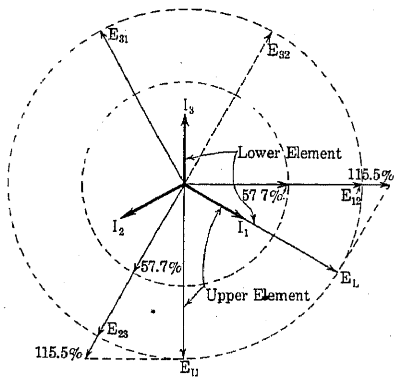

FIG. 3—VECTOR DIAGRAM OF REACTIVE COMPENSATOR VOLTAGES

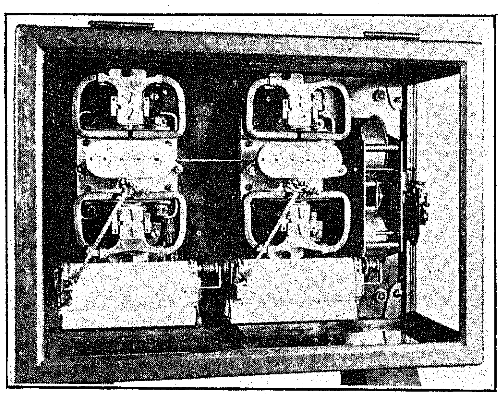

FIG. 4—DUPLEX *R A* DEMAND METER

The voltage used on the upper element of the R.Va.H meter is 57.7 per cent of *E*12 plus 115.5 per cent of *E*23, which is equal to the voltage *E*12 but is 90 deg. behind this voltage. Likewise the voltage on the lower element is equal to the voltage *E*32 but lags it by 90 deg.

It is manifest therefore from the brief description of the reactive voltampere hour meter that it is possible to measure the reactive component practically as easily as the energy component. However the obtaining of the apparent energy or the "square root of the sum of the squares" presents a more difficult problem for which a number of solutions have been offered. Two of the most recent developments are described below.

TYPE *RS* KV-A DEMAND METER (PANTAGRAPH TYPE)

It should be understood that watthour demand meters can be substituted for the two meters in Fig. 1.

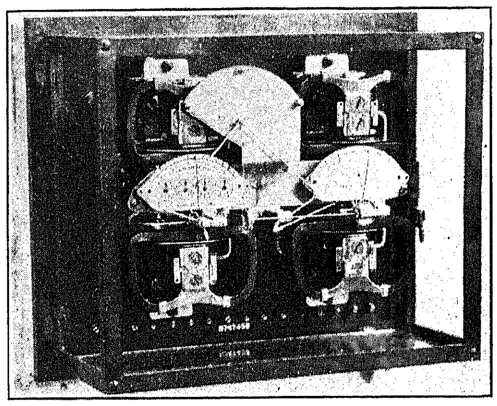

FIG. 5—TYPE *R S* KILOVOLT-AMPERE DEMAND METER

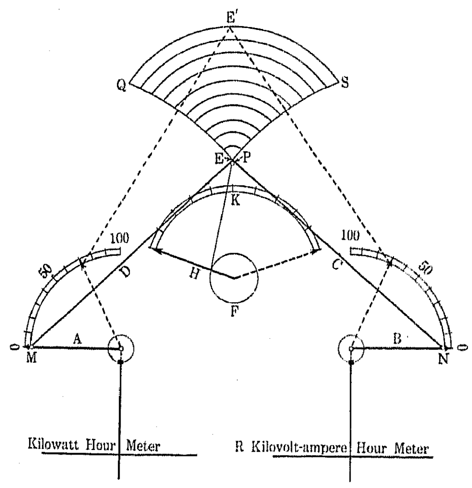

FIG. 6—SCHEMATIC PLAN OF INDICATING MECHANISM OF THE TYPE *R S* KV-A. METER

Fig. 4 shows the arrangement of two demand meters in one case and operated by one clock so as to obtain simultaneous records. When two demand meters are so used it is possible to obtain directly or by calculation the following data:

1. Kw. hours.
2. R kv-a. hours
3. Apparent power factor at which 1 and 2 were obtained.
4. Maximum kw. demand
5. Maximum *R* kv-a. demand.

6. Apparent power factor at which 4 and 5 were obtained.

7. Kw. demand during any time interval on chart.

8. *R* kv-a. demand during any time interval on chart.

9. Apparent power factor for 7 and 8.

While each of these items is valuable in studying the load history of an installation, all are not essential in billing for electric service. In most of the present rate

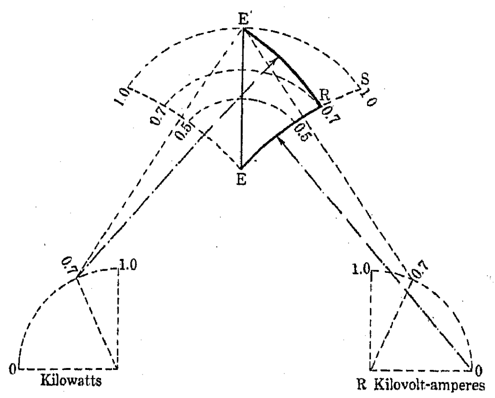

FIG. 7

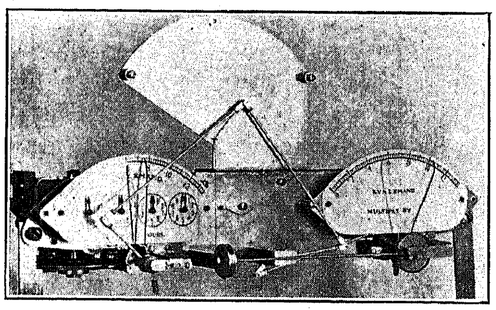

FIG. 8—FRONT VIEW OF REGISTER FROM TYPE *R S* METER

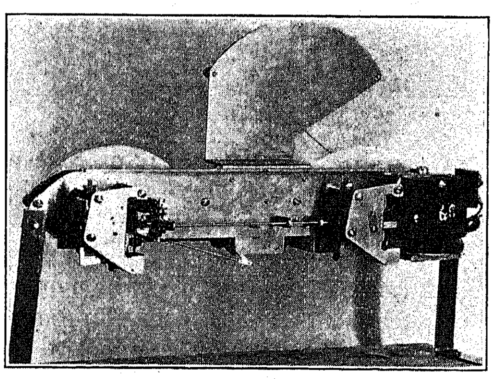

FIG. 9—REAR VIEW OF THE REGISTER FROM TYPE *R S* METER

schedules which take in consideration power factor and kv-a., the important items are kw. hours, maximum kw. demand, maximum kv-a. demand and power factor at time of maximum demand. The type *R S* meter shown in Fig. 5 indicates the kw. hours, the maximum kw. demand and the maximum kv-a. demand. Although the meter has been developed only in the indicating type the principle employed is equally applicable in a graphic type of meter similar to the type *R I* described later in this paper.

The principle employed in the type *R S* meter is a pantagraph arrangement of levers operated by the kw-h. meter and *R* kv-a. *H* meter. A schematic diagram of the operating principle of the meter is given in Fig. 6. *A* and *B* represent pointers for demand registers placed on the kw-h. meter and kv-a. *H* meter. These pointers are placed to the additional use of acting as levers in the pantagraph arrangement of levers *A*, *B*, *C*, and *D*, which are pivoted at *M*, *N* and *E*. During the operation of the meter the point *E* moves over the

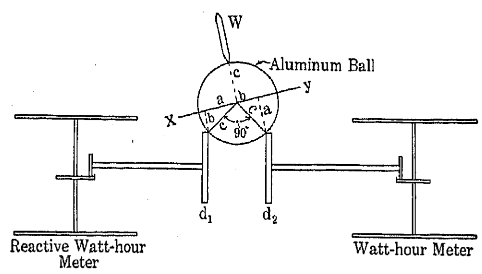

FIG. 10

Radii *a* and *b* to axis of rotation are proportional to respective speeds of wattmeters. Wheel *W* is therefore of a speed proportional to *c*, which is $\sqrt{a^2 + b^2}$ and is therefore proportional to kv-a. *W* is geared to the pointer in meter charts; it also drives dials which register kv-a. hours.

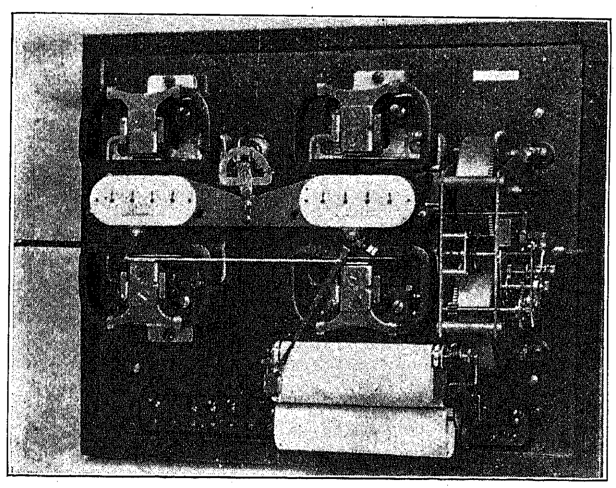

FIG. 11—TYPE *R I* KV-A. DEMAND METER

surface *E S E' Q*, the path of the point depending upon the relative movement of the levers *A* and *B*. A cord is attached to the point *E* and passed through a guide (*P*) to a pulley (*F*) on which the kv-a. pointer (*H*) is mounted. The movement of the point *E* to some point such as *E'* advances the kv-a. pointer (*H*) proportional to the length of cord *E E'*. Now the length of *E E'* is equivalent to the hypothenuse of a right triangle whose sides are equivalent to the indications of the kw-h. and *R* kv-a. *H* meters respectively.

This is more clearly illustrated in Fig. 7 where the point *E* in moving to *E'* may be considered as moving along the path *E* to *R* to *E'*. The base of the right

triangle (E-R) is proportional to the indication of the kw-h. meter while the altitude ($R\,E'$) is proportional to the indication of the R kv-a. H meter. If it is assumed that the reactive component is zero, the point E would move along the line $E\ R$ to the point R which would give a kv-a. indication equal to that of the kw. register, or in other words, a unity power factor indication. Each arc drawn on the surface $Q\ E\ S$ with E as center represents a given value of kv-a. The various radial

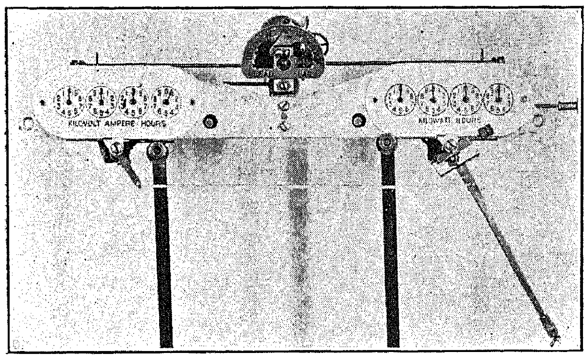

FIG. 12—TYPE *R I* DEMAND METER, FRONT VIEW OF REGISTER

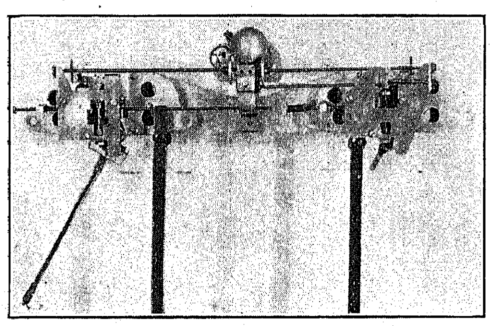

FIG. 13—TYPE *R I* DEMAND METER, REAR VIEW OF REGISTER

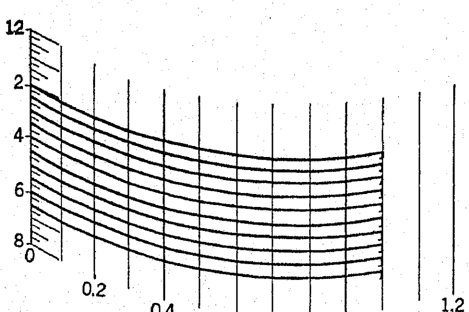

FIG. 14—UNITY POWER FACTOR RECORD

lines such as $E\ S$ - $E\ E$ and $E\ Q$ represent power factor. Hence, the apparent power factor for any kv-a. indication can be determined by observing the position of point E. The approximation of the true kv-a. by the pantagraph method used in the Type $R\ S$ meter depends upon the choice of the length and location of levers and the angles of deflection of the levers. In the design of the meter these variables have been selected so that the maximum difference between the true and the indicated kv-a. demand is well within the accepted limits of accuracy for watthour meters.

The construction of the $R\ S$ meter utilizes commercial polyphase watthour meters for the meter elements and parts of commercial demand registers in the construction of the register. The time interval is determined by the same type of small induction motor as in the commercial form of demand register and the gravity resetting of demand pointers is arranged similar to the same device. Figs. 8 and 9 show front and rear views of the kv-a. demand register.

TYPE *R I* KV-A. DEMAND METER (BALL TYPE)

Another method of combining reactive and power components of volt-amperes make use of a valuable

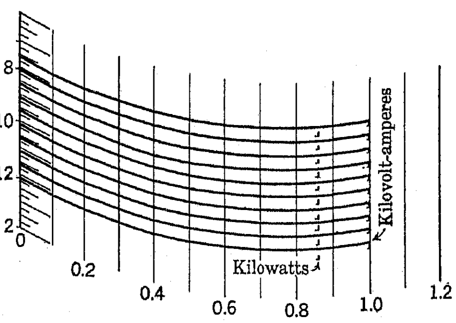

FIG. 15—85 PER CENT POWER FACTOR RECORD

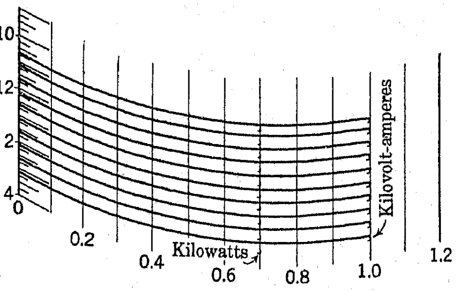

FIG. 16—70 PER CENT POWER FACTOR RECORD

property of a sphere driven by two disks and driving a third disk in which combination the angular motion of the third disk is the vector sum of the motion of the two disks. Referring to Fig. 10, the aluminum ball is supported by disks d-1 and d-2 running in the same direction at varying speeds. The ball assumes an axis of rotation $X\ Y$ such that perpendiculars a and b are proportional to the respective speeds of the disks. The disks are spaced 90 deg. apart so that the two triangles a-b-c are similar and equal. It is evident that in the right triangle a-b-c that c the radius of the sphere is the hypotenuse of the triangle and is therefore the vector sum of a and b. In the type $R\ I$ voltampere meter d-1 and d-2 are driven respectively by reactive and watthour meters and a wheel W is mounted in a movable frame so that it rolls on a great circle of the spher

whose plane is always perpendicular to the axis $X\ Y$ and the angular motion of W is then proportional to the radius C of the sphere.

The frame which carries W is arranged so that it can swing about an axis passing through the center of the ball perpendicular to the plane in which $X\ Y$ moves.

Through suitable gearing the integrated angular motion W is communicated to the pen and leaves a record on the paper chart. The pen is reset at regular intervals as in other recording demand meters. It is

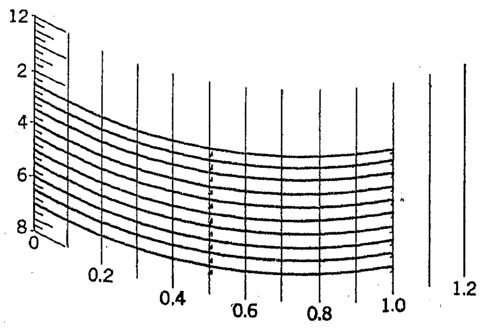

FIG. 17—50 PER CENT POWER FACTOR RECORD

obviously desirable to have both kw. and kv-a. demands readings on one chart, and this was accomplished by arranging a mechanism on the kw. element which causes the pen to hesitate a fraction of a section during the process of resetting and make a mark on the paper which indicates the kw. demand. Since kv-a. is always greater than kw. there is no possibility of this stop advancing ahead of the kv-a. mechanism.

Figs. 14 to 18 illustrate the records obtained under

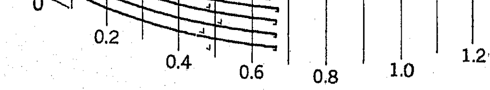

FIG. 18—CONSTANT POWER FACTOR AND VARIABLE LOAD

several conditions of power factor. In Fig. 14 with 100 per cent power factor the kv-a. and kw. indications are coincident and show a demand of 1000 watts for the time interval which was 15 minutes on the particular meter used on these tests. In Fig. 15 the kv-a. demand is still approximately 1000 watts but as the power factor is approximately 85 per cent the kw. record is reduced to about 850 watts. In Figs. 16 and 17 the kw. demand is still less with a corresponding power factor of 70 per cent and 50 per cent. Fig. 18 is a record of gradually decreasing demand with a constant power factor of about 70 per cent. The right hand dials are arranged to register kw. hours and the left hand dials kv-a. hours, hence the apparent power factor for the month can be obtained. Referring again to Fig. 10 a/c is the ratio of kw. to kv-a. and is the cosine of the angle through which moves the frame which carries the wheel W, therefore a pointer mounted on this frame will give an indication of the power factor at any time.

From the above it is manifest that the meter gives a direct reading of indicated power factor, total kw. hours, total kv-a. hours, and kw. and kv-a. demand for the time interval. The power factor for any time interval particularly at the time of maximum demand can be readily obtained by inspection of the chart.

Discussion

W. H. Pratt: Volt-ampere and volt-ampere-hour measurements seem to be occasioned almost wholly by the problem of making suitable rates for electrical energy when used at low power factor; that is of making rates that will stimulate the raising of the power factor in such cases. From this viewpoint devices of this kind should be in a measure self-eliminating, for once the power factor fairly approaches unity there is little or no excuse for the added complexity of apparatus above that of the watthour meter.

The practical problem does not involve the measurement of volt-ampere hours through a wide range of power factor, in fact almost all cases that arise can be met by a watt-hour meter construction excited at a displaced phase. It is often advisable to use a three-element watt-hour meter for the sake of symmetry of connections.

Since the cosine of small angles remains near unity, it is possible to cover a range of 23 deg. with a simple watt-hour meter excited at a suitably displaced phase with maximum errors of one per cent. This represents a range of power factor of from 92 to 70 per cent, or 80 to 50 per cent, ranges amply large for including possible maximum demand connections for a very large portion of practical cases. A simple duplication of parts with a selective register makes the double angle possible.

In the types of apparatus described in the paper it does not seem fair to expect that errors arising from mechanical causes can be less than one per cent and they are likely to be of an irregular character.

One condition which is quite common does not seem to be well met by the ball types of device. That is the regular or irregular pulsation of power factor arising from such loads as machine tools—for instance, wood-working machinery. The roller on the ball would never be where it should be. This criticism would vanish if the roller moved at a speed such as shown in the moving picture, where everything was going fast. But if the roller moves at a leisurely rate, as I understand it does, it seems that in a large number of cases the reading will not be sufficiently accurate.

A. E. Knowlton: Both the kilovolt-ampere metering devices presented in the paper represent commendable progress. It should be noticed, however, that as proposed in the paper, they rest upon a method of potential connections for obtaining the reactive component which is inherently inaccurate on unbalanced loads. An analysis and experimental study of these inherent errors of the "compensator" or "phasing-transformer" scheme of getting quadrature potentials (reported in *Electrical World*, Vol. 82, No. 26) shows the possibility of several per cent

of error in power factor, reactive component, and total kilovolt-amperes under certain conditions of unbalanced inductive load. If the loads, which are so important as to require the integration of kv-a. and indication of kv-a. demand, become materially unbalanced, then much of the value and precision of these new devices is lost through the inherent inaccuracy of the means of obtaining the potentials impressed on the reactive meter elements. The very necessity of observing phase sequence in making the connections to the reactive meter also underlies the fact that any unbalance of volt-amperes is registered in the wrong sense by the reactive meter.

The article does not refer to the type of adjustments provided for the purpose of correcting errors which arise in these two meters while in service. Much of their value to the industry depends on the simplicity and directness of those adjustments which must often be made by a meterman who is none too well qualified to deal with delicate and complex instruments. It would appear that the adjustments at the sphere and disks to compensate for dial friction, slippage, etc., would be materially different in nature from those made by the average meterman handling standardized watt-hour meters.

A. E. Kennelly (by letter): The two types of demand meters described, namely, the pantograph type and the ball type, are both ingenious and interesting. They serve to construct mechanically the magnitude of a hypothenuse from the two side components of a right-angle triangle.

As a matter if terminology, it is suggested that the three sides of the power triangle might logically be called: (1) the active power, or active watts, for the base, (2) the reactive power, or reactive watts, for the perpendicular, and (3) the vector or apparent power (vector watts or the volt-amperes) for the hypothenuse. The reactive power is just as truly power as the active power, except that it does not leave the circuit. The indicating instruments for measuring these three powers would logically be named (1) the active wattmeter (ordinarily, for brevity, the wattmeter), (2) the reactive wattmeter, and (3) the vector wattmeter or volt-ampere meter.

When the corresponding energy components are referred to, they might be called (1) the active energy, or active watt-hours, (2) the reactive energy, or reactive watt-hours (3) the vector energy, or vector watt-hours, or the volt-ampere hours. In this case, the reactive watt-hours would be fictitious, because their true summation value is zero. The corresponding instruments might be named (1) the active watt-hour meter (ordinarily abbreviated to watt-hour meter), (2) the reactive watt-hour meter, and (3) the vector watt-hour meter, or volt-ampere hour meter.

A. R. Rutter: Mr. Chairman and Gentlemen: In connection with the kv-a. paper, I believe the title of the paper points out that the purpose of the paper was to discuss two recent developments, and that the title indicates that there should be future developments in kv-a. metering.

Now, in considering either of the types mentioned in the paper, we should consider the commercial accuracy and the commercial demand of the device as well as the theoretical accuracy, somewhat in line with Mr. Pratt's remarks on testing of instrument transformers.

Now, it is one thing to speak of the theoretical accuracy, and another of the practical commercial accuracy. In regard to the measurement of reactive component it was the intention of the authors to point out that there are a number of schemes or methods of measuring the reactive component. A number of these methods are inaccurate with unbalanced currents, and unbalanced voltages. The particular scheme mentioned, that of the reactive component compensator is described as the outstanding method, and by that we meant the outstanding method at the present time. The method of measuring reactive component with the commercial watthour meter and the use of a reactive component compensator is probably the most widely used method at the present time.

Mr. Smith made some remarks indicating that the development of a true sine-meter is quite possible; in fact, sine-meters are being used I believe by the Philadelphia Electric Company. There are at least two different schemes that might be used to give a theoretical accuracy for a reactive meter.

In connection with the comparison of say, the type $R\,I$ meter with other commercial kv-a. meters, I believe that we should take into consideration the commercial accuracy; that is, that the meter employs standard watthour meter parts and standard apparatus in practically all details.

In regard to the adjustment of the meters, both the type $R\,S$ and the type $R\,I$ are adjusted as standard watthour meters. The adjustment of the pantagraph arrangement in the type $R\,S$ or the adjustment of the ball mechanism in the type $R\,I$ depends upon the workmanship in the construction of the register. In other words, these quantities are fixed.

In connection with Professor Knowlton's comment on reactive metering, I would like to call attention to Professor Knowlton's paper in the December, 1923, issue of the *Electrical World*. In an article entitled, "Tests on Accuracy of Reactive Metering," Professor Knowlton has given a very thorough discussion and summary of reactive metering, and in connection with the commercial application of reactive meters, I believe he has summed up the question of using sine-meters or reactive component meters, using the reactive component compensator, with the remark that of the cost of meter administration and the proficiency of meter men in installing, reading and testing meters are to be given due consideration along with the accuracy of registration, there is a question whether any, except method B, of the methods outlined can be wholly condemned as too inaccurate for use in the majority of loads.

In designing these meters the designer used the reactive scheme feeling that it was the most widely known method and except with extreme cases of unbalanced voltage no serious error would be introduced. Of course, as we have pointed out on a number of occasions if the demand presents itself, a true sine-meter can and will be developed to measure the reactive component.

Mr. J. M. Jones of Pittsburgh has presented written questions on the type $R\,S$ meter. Question No. 1: "Is the ball used only for indicating power factor?"

The ball is used in the type $R\,S$ meter to give the graphic indication, to indicate the power factors, and to integrate the kv-a. hours. In other words, the ball drives the kv-a. mechanism.

The next question has been answered by the first: "Does this ball have any effect on the graphic part of the meter?"

It drives the graphic part of the meter; that is, it drives the pen. Of course, the clock drives the chart.

"Are standard watthour parts used in this meter?"

Standard polyphase watthour meter parts are used. The comment was made that the meter must be such that the same meter man can maintain them that maintains the polyphase watthour meters.

In this connection, I might remark that the meter is a demand meter and the meters should be maintained by the men that maintain the watthour demand meters or other demand meters. In other words, demand meters require a higher maintenance than the ordinary watthour meters.

"With rapidly fluctuating loads and power factor can the ball meter indicate this rapidly changing load?" Mr. Smith will asnwer that question.

"What is the cost, with and without the graphic?"

In this connection I might say that the relative cost of the meter is approximately double that of the single watthour demand meter.

"Can a demand contact be added?"

Demand contacts could be added to the kv-a. register or to the watthour register.

B. H. Smith: Mr. Pratt, Mr. Hart and also Mr. Rutter mentioned Mr. Jones' question on the ball mechanism: "What is the effect of the ball shifting on the registration of the meter?" By actual test we have found in a given time interval, (in a fifteen-minute interval), if the power factor changes from one hundred to fifty per cent, the error at any load is about one-third of one per cent, so it is very small.

If the power factor comes back again to one hundred per cent in the same interval, the error is corrected, so that over all, there is no error due to the shifting of the ball mechanism. This is very readily checked by counting the revolutions of the watthour meter, and the reactive watthour meter, taking the square root of the sum of the squares and calculating what the kv-a. reading should be.

That ease of checking also lends itself to checking by metermen of the operation of the meter, and Mr. Knowlton's question read by Mr. Warner, referring to adjustments by meter men, the ball mechanism itself will not need any adjustments if it is running properly, and we can determine if it is running properly by counting the revolutions of the disk and reading the record on the chart.

Mr. Magalhaes can see the ball in this meter and we would like to have every one look it over.

The ball is one inch in diameter of solid pure aluminum and weighs about twenty grams, a little over half an ounce.

Later tests included in report to the A. I. E. E. Meter Committee give further information on some of the above points.

Automatic Transmission of Power Readings

BY B. H. SMITH

and

R. T. PIERCE
Associate A. I. E. E.
Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

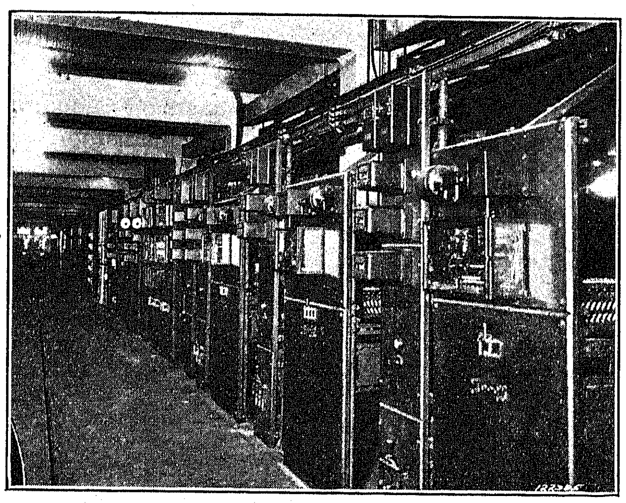
Review of the Subject.—*The need of information at one point as to power conditions in large systems for load dispatching, billing, or other purposes has led to the development of various methods of transmitting power readings over long distances. The development of superpower emphasizes this need and the perfection of means of communicating complete information as to power and load conditions will hasten the development of superpower.*

We wish to discuss various automatic methods which may be employed for remote metering. Our paper will describe the following methods:

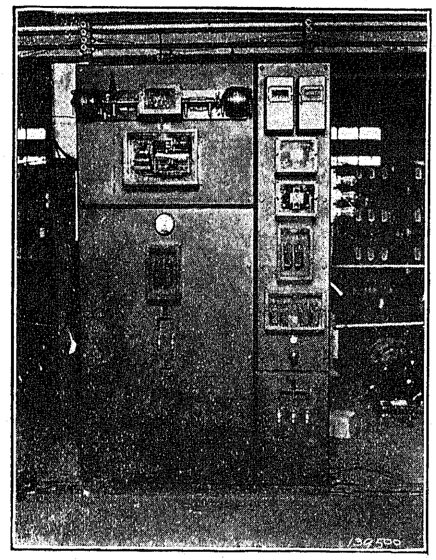
1. Frequency
2. Inverse Current
3. Potentiometer
4. Position
5. Voltage
6. Current
7. Impulse

Frequency Method

One of the earliest developments in the field of long distance metering has now been in operation on the Pacific Coast Electrified Section of the C. M. & St. P. R. R. for several years. Its purpose there is to register the total amount of power received at several substations from a hydroelectric company, to indicate and record this total at the dispatcher's office and then to send back controlling impulses over the line which regulate the trolley voltage and maintain as steady an electrical load as possible and prevent the occurrence of heavy peaks. A pair of No. 8 copper wires was installed over the whole length of the electrified section especially for the metering system, and over this line is transmitted at from 1000 to 2000 volts alternating current whose frequency varies anywhere from 20 to 60 cycles depending upon the load measured. If the load is heavy the wattmeters through suitable



Test Set Up—C. M. & St. P. R. R., Frequency Method



Apparatus of Intermediate Station—Frequency Method

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

speed regulating apparatus increase the speed of small a-c. generators until just the right frequency is sent out equivalent to the measured power. At each station the frequency of the metering circuit is regulated so as to be equivalent to the total power from all stations up to that point, and then at the dispatcher's office the frequency is translated back to watts in a local 60-cycle circuit. This is accomplished as follows: The incoming frequency operates a small synchronous motor whose speed is measured by a speedometer which in turn is balanced against a Kelvin balance wattmeter until the watts are made equivalent to the incoming frequency and thus the total power consumed by the railroad. The local circuit then leads to recording meters, watthour, recording demand, plain indicating wattmeters and a regulator. Thus the dispatcher has immediately available a complete and up-to-the-minute record of the power conditions of the road. This system has given exceptionally good service, but there are several factors involved which preclude universal adoption. First the amount of power required to actuate the metering apparatus and which must be transmitted over the lines is about 40 watts. This amount of power cannot be transmitted over existing telephone or signal lines and involves a special line costing several hundred dollars per mile for copper alone. In addition the sending and receiving apparatus is not suitable for installation on the premises of the average power consumer due to size, energy consumption, and attention required.

Inverse Current Method

Another early installation was on the Montana division of the C. M. & St. P. R. R. Here a current, inversely proportional to the load, is transmitted over a special metering circuit. The wattmeters in each substation measure the a-c. power and regulate an automatic rheostat until resistance is introduced in the metering circuit proportional to the load. All stations are connected in series and a constant voltage is maintained in the dispatcher's office at one end of the circuit. The total resistance in all the stations and the line resistance reduces the current in the circuit to a minimum for full scale readings of the meters in the dispatcher's office, of about 250 milliamperes. As the load decreases this current increases and the fluctuations are recorded in the dispatchers office on graphic milliammeters and various regulating instruments.

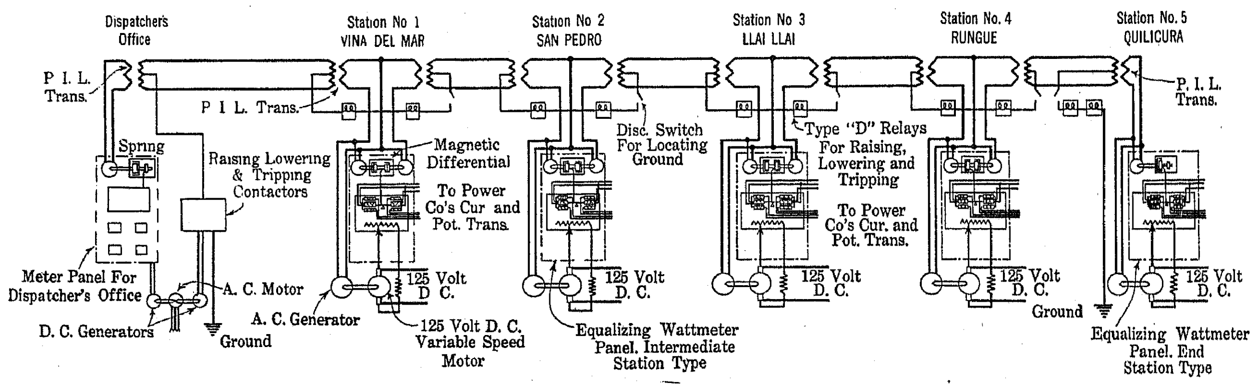


Fig. 1—Schematic Diagram of Indicating and Limiting Equipment

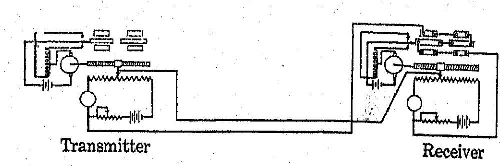

Fig. 2

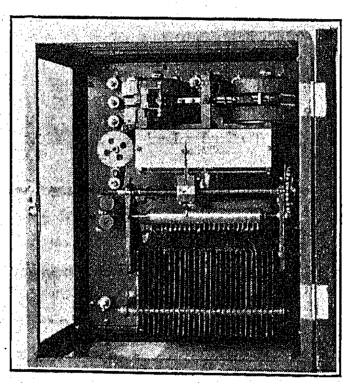
Potentiometer Method

A standard relay-type graphic wattmeter, either single-circuit or totalizing, is equipped with a slide resistance and a slider is fastened on the pen carriage. A voltage is applied to the slide and the voltage drop from one end of slide to slider is transmitted to the receiver.

The receiver consists of a contact-making galvanometer which operates a slider across a resistance. A voltage is applied to this resistance which opposes the voltage applied to the transmitter slide. Consequently

Totalizing Transmitter—Potentiometer Method



Receiver—Potentiometer Method

the slider on the receiver takes up a position where the receiver voltage is equal to the transmitter voltage and no current flows. If both resistances are in equal steps, the position of the receiver slide is the same as the position of the transmitter slide.

This method is very accurate as long as equal currents are maintained in the local slider circuit. It is a "Nul" method so that it is independent of transmission line resistance, the only effect of a high-resistance line being a lower accuracy in the receiving instrument.

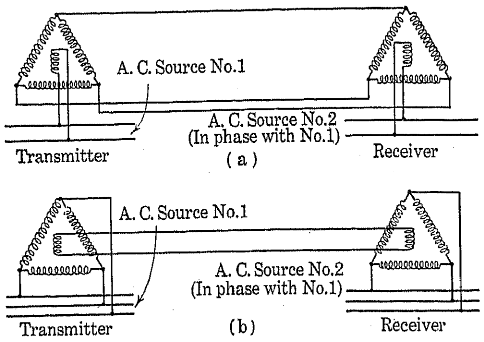


Fig. 3
a—Single-phase excitation.
b—Three-phase excitation.

The main objection to this method is the complicated connections required to give indications and totalization. A second slide and slider is placed on the receiver operating in parallel with the first slider. A constant voltage is applied to this second slide resistance. It requires a voltage regulator to keep this battery voltage constant. This voltage from one end of the slide to the slider is applied to a voltmeter whose scale is marked in kilowatts for indicating purposes and these voltages, as taken from several receivers, are connected in series for totalizing purposes.

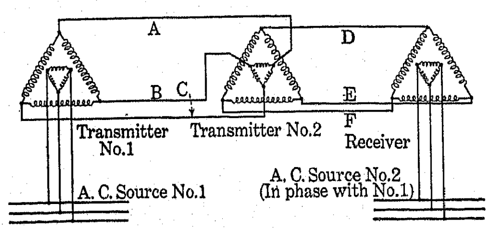

Fig. 4

This is the method employed at the Springdale station of the West Penn Power Co. Totalizing graphics are used for measuring purposes and there are several single-circuit receiving instruments in various parts of the power station. By gearing a long pointer on the worm which operates the receiving slider, a large diameter boiler room indicator is obtained. Alternating-current control is used on this installation.

Fig. 2 shows schematic diagram of this method.

Position Method

Fundamentally this method consists of the use of one of the various types of position transmitters, so connected as to take up positions corresponding to the power measured, and a proper receiver at the receiving end. The Kelvin balance relay type graphic meter may be used to measure the power and the position transmitter properly geared to the mechanism which drives the pen across the paper.

There are various types of position transmitters which would apply here but we believe the induction type has a wider application than most and will, therefore, discuss it in more detail.

If two induction motors are connected as shown in Fig. 3 any motion produced in one will be closely followed by the other. A vane type of synchronoscope may be substituted for the receiving motor and its pointer will follow the rotation of the transmitter rotor. Thus the dial may be marked in kilowatts if the transmitter is connected mechanically to the pen mechanism of the above mentioned graphic.

For totalization, a totalizing graphic could be used for making the measurements and the transmitter connected to it. Another method of totalizing would be to

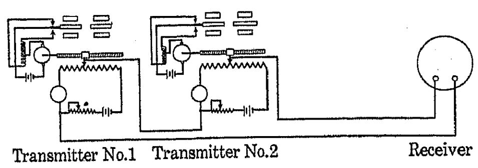

Fig. 5

connect the transmitters on several single-circuit graphics in concatenation so that the positions are additive. This requires the use of a three-phase supply as shown in Fig. 4.

If Transmitter No. 1 rotates, this causes a phase rotation in the rotor windings of Transmitter No. 2 which acts as a transformer so that the receiver is rotated through a corresponding angle. Now if Transmitter No. 2 is rotated this adds an angular displacement in wires D—E—F, so that its motion is added on to that of Transmitter No. 1 and the receiver shows the sum of the two.

Voltage Method

This method consists of mounting a slider on the pen carriage of a relay-type graphic wattmeter which will operate over a slide wire to which constant voltage is applied. The drop across the slide is transmitted to a voltmeter calibrated to read kilowatts. If it is desired to totalize several of these the voltages are connected in series so that the receiving voltmeter reads the sum. See Fig. 5.

Adjusting rheostats and a small ammeter are shown in the slide circuit so that adjustments may be made to take care of changes in battery voltage.

Current Method

This method is similar to the potentiometer method but is much simpler. The power to be transmitted is measured by a Kelvin-balance-wattmeter element with the control spring omitted. A d'Arsonval meter element has its moving element mechanically connected to the moving element on the Kelvin balance. The contacts on the Kelvin balance control a motor-operated rheostat which varies the current in the d'Arsonval meter element until its torque is equal and in opposition to the torque of the Kelvin balance. This current is therefore proportional to the power being measured.

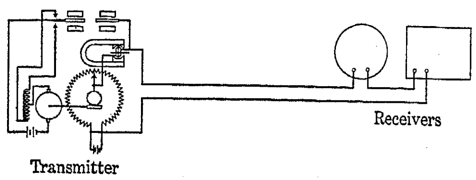

Fig. 6

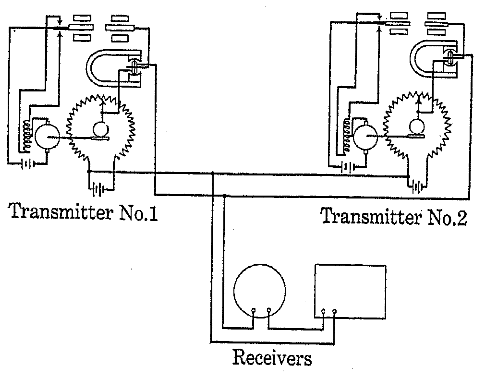

Fig. 7

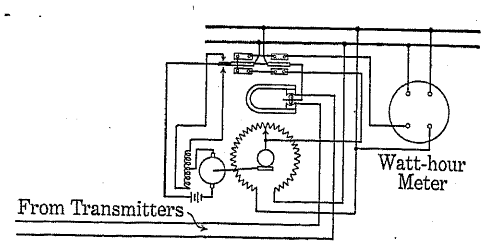

Fig. 8

A standard direct-current ammeter serves as a receiving instrument and may be indicating or graphic. Several instruments may be connected in series both in the generating station and at the remote point without changing the calibration of those already installed or destroying the accuracy of each individual receiving instrument. This is done in some cases to widely distribute the readings.

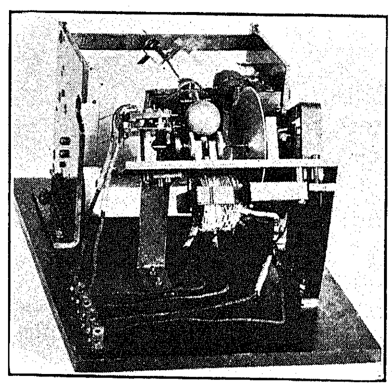
If it is desired to totalize the power from several generating stations, the direct-current control circuits from the various transmitters are connected in parallel so that the receiving instrument measures the sum of all currents.

Fig. 6 shows a simple transmitter and receiver outfit. The contact making Kelvin balance operates the motor which, in turn, operates the slide arm. Since the torque of the Kelvin balance increases in equal steps for equal increases in power, the counter torque produced by the d'Arsonval meter element must increase in uniform steps. Since the scale of a d'Arsonval meter is uniform the curve of transmitted current against power measured will be a straight line passing through zero.

It should also be noted that since the operation of the apparatus depends on current, it is independent of control voltage.

Fig. 7 shows connections for totalizing several transmitters.

In some cases it is desirable to obtain watthour meter readings at the receiving end. This is accomplished by using a transmitter at the receiving end connected in reversed. The direct current is brought into the



Graphic Receiver—Impulse Method (Rear View)

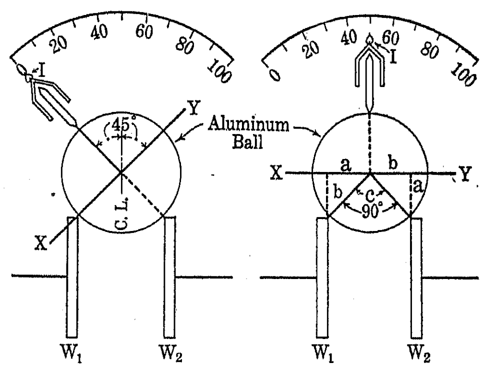
d'Arsonval meter element and the rheostat controls the alternating current from an auxiliary source which passes through the Kelvin balance and watthour meter in series. Fig. 8 shows this connection.

This method allows the transmitting of readings over telephone lines without interfering with conversation up to distances of twenty-five miles.

Direct-current Impulse Method

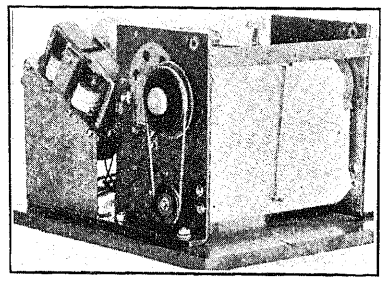
Another solution of long distance metering problems is found in the method of transmitting indications by means of a series of d-c. impulses the frequency of which is proportional to the sending meter speed. A system of this kind has now been operating for some months on a street railway system in connection with supervisory Control of automatic substations from a central load dispatcher's office. Power is measured on polyphase watthour meters in each substation. These meters are equipped with commutators on the main shaft, and with brushes and brush rigging similar to that on a d-c. watthour meter. Alternate opposite

pairs of segments are short-circuited so that for every revolution of the shaft a circuit is alternately made and broken four times. The circuit is completed through a telephone relay whose contacts are connected so as to transmit impulses of alternating polarity of not over 100 volts over standard telephone wires to the dispatcher's office. In the office the impulses are received and actuate a polarized excapement mechanism which allows a tooth of the escape wheel to go by for each complete cycle of impulses or four teeth for each revolution of the sender meter. Dials are geared to the escapement wheels and register the total watthour reading. Indicating readings are accomplished by a ball mechanism which compares the speed of the escapement wheel with a constant speed obtained from a small synchronous motor. Referring to Figs. 9 and 10, an aluminum ball is supported so as to be driven by wheels $W-1$ and $W-2$. If the speed of $W-1$ is zero, the ball will rotate about an axis $X-Y$ inclined 45 deg. from the horizontal. If the two wheels have equal speeds the axis will be horizontal and at any point between these limits the position of the axis is an indication of the ratio of speeds of $W-1$ and $W-2$. In order to determine the characteristics of this relation; it is necessary to consider the triangle $a-b-c$, and $a-1$, $b-1$ and $c-1$; a and b being radii drawn from the point of contact fo the wheels $W-1$ and $W-2$, to the axis of rotation and, therefore, proportional respectively to the speeds of the two wheels. Since the angle between c and $c-1$ has been fixed at 90 deg. the two triangles are similar and equal and the sides, a, b, and c are equal to $a-1$, $b-1$ and $c-1$ and c/a is tangent of the angle which measures the departure of the axis from the zero position. Therefore the receiver meter, the position of whose indicating pointer is determined by this axis has its scale divisions marked proportional to the tangents of angles from 0 to 45 deg. over which range the scale is near enough uniform for practical use.



FIGS. 9 AND 10—REMOTE METERING "RECEIVER" ANALYSIS OF BALL MECHANISM

The time required for the pen or pointer to travel from one point to another with change of load is about 8 seconds, but as with other meters the time has a logarithmic characteristic and tests show that with a peak load lasting five seconds approximately 90 deg. of the actual value will be indicated. A 3-second peak



GRAPHIC RECEIVER—IMPULSE METHOD (FRONT VIEW)

will register about 60 per cent but if the current holds up for about eight seconds the indication will be complete, thus we have an indicating wattmeter which quickly and accurately responds to change in speed of

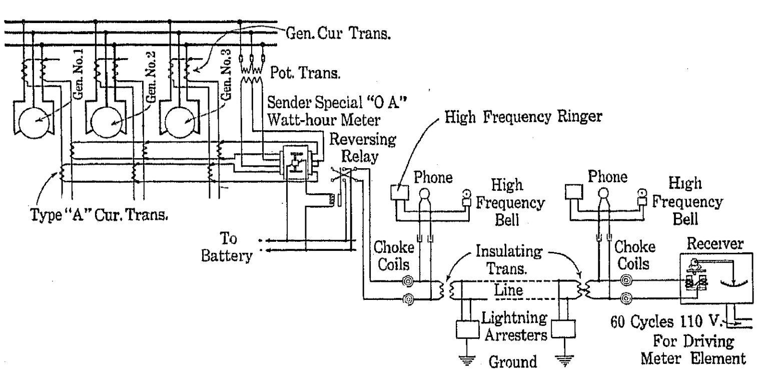


FIG. 11—IMPULSE METHOD. SCHEMATIC DIAGRAM

the sender meter at the distant station. If the distance is so great that not enough energy is received to actuate the receiver mechanism a sensitive telegraph

LARGE BOILER ROOM INDICATOR

relay is interposed which will operate on one or two milliamperes. Where the above system is operated over telephone lines, speech may be transmitted at the

same time. There is a faint noise from the meter impulses although with proper precaution this can be reduced so that it is not seriously objectionable. It is necessary to connect the telephone instruments to the line through condensers and use high-frequency calling apparatus which will also operate through the condensers as shown in the diagram, Fig. 11. This procedure is necessary, otherwise the meter impulses would be short-circuited by the telephone instruments. In order to prevent the telephone current from entering the metering apparatus, choke coils are interposed ahead of the latter which allow the low-frequency impulses to pass but keep out the relatively high voice frequencies.

As in the telegraph industry the need arises for transmitting several messages or indications at once over one pair of wires. This is accomplished by duplexing when one indication is required each way, or by quadruplexing where two indications are required each way. The principle involved with metering as in telegraphy involves polarized relays which respond to reversal of direction of current and marginal relays to increased quantity of current. The home relays do not respond to outgoing messages because the current divides in a differential winding between the line circuit and an artificial local circuit. In this class of service difficulty is encountered on outside lines, but with underground cables good results are obtained.

In general this method compares well in results obtained and in distances transmitted with the telegraph industry.

Discussion

H. P. Sparkes (Pittsburgh): In connection with remote load indication we have been watching several different systems. In the Pittsburgh territory, with regard to this movement, it means this: When several big power plants are tied together, the growth of that system will eventually develop into a miniature superpower system. This necessitates some method of the load dispatcher knowing the exact load on each station.

Now, if you will go into the matter you will find that it is necessary for the system load operator continually to call his power stations and find the load over the territory. In case of trouble, quite often they can't get the stations, due to line interference or some form of trouble out on the power line. Or they haven't time to get them. At a recent meeting this same point was brought up in the Ohio Electric Light Association. They wanted to know the possibilities of such a scheme on a large power system tied in together with several operating companies. In doing so, it will be necessary there to transmit these readings over several hundred miles. A telephone company, a company at least operating the master telephone system there, is at present installing super-telephone equipment to take care of this new development.

As a result, if the superpower program actually comes through, this remote load indicator problem will be solved by that time, and we shall have something by which the load operators can tell what is going on in various parts of the superpower system.

As to the actual operation of these outfits, I have been carefully watching one system in Pittsburgh to determine whether the thing was really successful by using the various schemes with reference to the Potentiometer system in Pittsburgh. I might say we have operating there one scheme which is very successful. It was used last year at the February meeting of the Institute to transmit the loads of the West Penn Power Company's plant from Springdale to the Chamber of Commerce.

A peculiar incident happened during that time. Everything was running, the meter was operating perfectly, and suddenly dropped to zero. I immediately thought something had happened on the local telephone wires as we were using local wires through the local telephone exchange. About ten minutes later the operator on the System whose load was being used for remote indication came in and asked how it was working.

I said, "We are having trouble."

He said, "No, we had it. We had an excellent load on the plant but lost everything. The telephone wires immediately dropped to zero and gave me that indication."

You can see how valuable the immediate notice of loss of power is to an operating company. That system has been operating satisfactorily. It was one of the first systems installed in this part of the country, and has auxiliary indicators operating in the boiler and turbine room, about 37 in. in diameter which may be seen from any part of the plant. One of these indicators is located in the boiler room where considerable dust is sifting through the air. The meter is enclosed in a steel case and is dust-proof.

P. MacGahan (by letter): The importance of the paper by Messrs. Smith and Pierce lies in the fact that the future superpower system will require the transmission of instrument readings to a remote point. Conversely, the development of such instruments will greatly facilitate and perhaps advance the day when the super-power system will be brought into use.

One of the earliest installations of the remote transmission of instrument readings was that at the Springdale Power Plant of the West Penn Power Company near Pittsburgh where the graphic recording wattmeter readings on a switchboard were transmitted to a load dispatcher's office and to a large boiler room indicator approximately 36 in. in diameter, of the illuminated-dial type. This installation works on the potentiometer principle described in the paper.

In later installations it was found desirable to provide for the totalization of readings in several circuits either in the same plant or in different powerhouse locations or in entirely separate plants. The current equipment described in the paper seems to facilitate obtaining this desired result. By adding the desired milliamperes a totalized indication or graphic record can be obtained, at any desired location.

When several circuits are in one location, the previous practise has been to construct a totalizing graphic wattmeter consisting of one meter element in each circuit, all tied together mechanically so as to add the resulting power. This system has the disadvantage that whenever an additional unit is to be installed all the previously equipped units have to be changed and the complete totalizing graphic instrument recalibrated. With the proposed electric totalization method, however, a separate measuring unit would be located at each circuit and a totalizing unit installed in such a way as to allow additional units to be installed at any future time without disturbing the original outfit.

The electric transmission of power readings is intimately associated with the subject of remote control on automatic stations, thus it would seem desirable to have a system for the remote transmission of power readings such as would function without interference with supervisory control over the same connecting wires.

Perry A. Borden (by letter): It is fitting that at this time, when transmission and distribution networks are daily becoming more intricate, there should have been placed before the Institute such a summary of the existing methods of remote indication and totalization of power loads as has been presented by Messrs. Smith and Pierce. By way of further broadening our horizon of such matters I should like to add a brief description of a system

which has recently been placed upon the market by a British manufacturer. This is known as the Fawcett Remote Power Indicator; and, while it might be said to fall within the fifth class enumerated, it possesses features which would almost justify its consideration under a separate class.

The Fawcett indicator makes use of a form of thermal wattmeter, similar to that employed in the Lincoln demand meter. In this meter the difference of temperature of two heating elements is proportional to the watts in the circuit being metered; and, it will be remembered, that in the Lincoln meter expanding elements are made use of to give an indication of this temperature difference. In the Fawcett indicator the temperature difference is made to actuate a pair of thermocouples, thus giving at the point of metering a direct electromotive force representative of the value of the power measured. While, in its present form, this device makes use of a direct deflecting galvanometer in its indicator, it would appear that such a method, if combined with a balancing recorder, would present great possibilities for American practise, particularly in large urban distribution systems.

B. M. Jones (by letter): This paper is on a subject which has in recent years become very important, both to the power companies and to the consumers. At the present time, our company is using a method of obtaining the power factor as outlined in Fig. 1 of Messrs. Smith and Rutter's paper. This gives us very good results, although not the most accurate possible. To put in service in consumers' stations equipment to record power factor (or its equivalent) in the most accurate way possible appears hardly worth while for several reasons; one of which is that the equipment would be special, complicated, elaborate and expensive. Another is that it would not be possible for the general run of meter testers who now work on standard watthour meters and a few other meters, to take over the adjustment of these meters without experiencing some trouble and difficulty. Another point against using the most accurate means of measuring power factor is the fact that the instruments for obtaining these measurements would more than likely have to be tested or recalibrated in the laboratory, which would mean that they would have to be taken off the job, transported to the laboratory, tested, retransported to the job and reinstalled; all of which takes time, costs money, and in addition leaves a loophole for disturbing the adjustment during transportation and reinstallation.

Professor A. E. Knowlton of Yale University, published an article in the December 29, 1923, issue of *Electrical World*, on the subject "Tests on Accuracy of Reactive Metering" which was of great interest. In this paper, Professor Knowlton goes into the question from two or three different angles, and two or three methods of obtaining the power factor are thoroughly covered. His conclusions are very interesting, especially the third conclusion, in which he states that, "If the cost of meters, the cost of maintenance of meters, and the proficiency of metermen in installing, reading and testing the meters are to be given due consideration along with the accuracy of registration, there is a question whether any of the methods except Method B (outlined in his paper) can be wholly condemned as too inaccurate for use with the majority of loads."

To the writer's mind, this is the most important conclusion of Professor Knowlton's paper, and is the one in which power companies are primarily interested just now. Most power companies have thousands of meters of very similar types and the metermen are very proficient in installing, maintaining and testing these meters. To run in a new instrument of complicated design, and call upon them to install, maintain and test it will doubtless bring on errors which may counteract the increase in accuracy. The scheme outlined in Fig. 1 of Messrs. Smith and Rutter's paper and also Fig. 3 of Professor Knowlton's paper is one which uses standard watthour meters with the phasing transformer, and will undoubtedly meet with the approval of the meter-maintenance crew who have to live with the equipment and make it operate with a fair degree of accuracy. This equipment is made by several manufacturers and can be obtained on very short delivery and at quite reasonable prices, and can be tested the same as standard watthour meters.

There are a few points and questions that the writer wishes to bring out regarding the "R. I." kv-a. demand meter which was discussed in detail in Messrs. Smith and Rutter's paper, a sample of which they exhibited.

1. Is the ball used only for indicating power factor?
2. Does this ball have any effect upon the graphic part of the meter?
3. Are standard watthour parts used with these meters?
4. Meters must be such that the same metermen will maintain them who now maintain polyphase watthour meters?
5. In very rapidly fluctuating loads and power factors, can the ball meters indicate the rapid changes accurately? This is very important to most companies on such loads as coal-mining hoist loads and similar loads where the hoist load is a great portion of the total load and is on for a few seconds, 15 or so, and off for 15 to 30 seconds.
6. What is the cost of this meter with and without the graphic parts?
7. Can a demand contact be added to this instrument to operate the usual demand meters?
8. What simple method can be used for testing this meter in the field so that the metermen will know that it is fairly accurate without having to take it to the laboratory for each test? The writer considers this very important, as the matter of taking this meter to the laboratory every time to make a test is objectionable and is to be avoided. If a simple test or check can be made on the meter regularly and it be taken to the laboratory periodically for a thorough test once a year or every six months or so, it is much to be desired.
9. How much does the ball slip and what method can the meter testers use to determine if the ball is slipping? This is especially important where there is a great amount of dust in the consumer's plant where these meters have to be installed.

The question of power-factor clauses in rates is a very important one and has come up in recent years, and is now written into quite a few new contracts that some power companies are making. The ability to obtain accurately and conveniently a record of the power factor for the joint benefit of the consumer and power company is greatly to be desired, and with the present equipment available, this can be done. This is largely due to the perseverance of the manufacturers' meter designers.

B. H. Smith: Referring to discussion by letter from B. M. Jones in answer to his questions 1 to 9, they may be answered as follows:

1. As mentioned in the text of the paper, the ball is used not only for operating the indicating power factor mechanism, but also combines the reactive component and power component meters so as to give a quantity which is proportional to kv-a. hours. This ball mechanism is the heart of the meter and is the mechanism which makes a kv-a. reading possible.
2. The ball drives the pen mechanism which registers kv-a. demand. The kw. indication on the pen is, however, obtained directly from the kw. element, as explained in the text of the paper.
3. The meter elements are standard polyphase watt-hour meter parts.
4. With proper instructions it is expected that this meter can be maintained by the same men who now maintain polyphase watt-hour meters.
5. In rapidly fluctuating loads there is no likelihood of errors in this meter, but with rapidly changing power factors the kv-a. element reads somewhat low, due to the motion required for the ball mechanism to adjust itself. It is found that with power factors changing once a minute from 100 to 0, the error is about

four per cent, and changing from 100 to 70 every minute, the error is about one per cent. If the power factor changes every few seconds, the error would be somewhat greater.

6. The cost of this meter is in the neighborhood of $300. It is not available without the graphic parts.

7. Since the meter gives complete demand readings, it is not necessary to add demand contacts.

8. A simple method of testing this meter in the field is to allow the kw. element to rotate a proper number of revolutions at unity power factor and see if the pen gives a correct reading. A similar test may be made at zero power factor, counting the revolutions of the reactive element.

9. Since, with the meter running properly, the pen furnishes practically no load upon the ball mechanism, there is no tendency for any slipping. but this point can readily be checked by the test given under 8. Complete instructions for the operation and maintenance of this meter are covered by the instruction book which is furnished with the apparatus.

R. F. Pierce: In regard to the Fawcett scheme, although I am not intimately familiar with all the details of it, yet it seems asif, using a thermocouple and small e. m. fs. that are generated thereby, a very delicate receiving instrument would have to be used and the line resistance for considerable distances would cut down the sensitiveness of the response. Of course, a potentiometer method of taking readings could be used, but that is not within the scope of this paper. We are covering automatic methods and to use a very sensitive hand-operated potentiometer method which might be necessary with long distances with this scheme would not give to the operator at all times a knowledge of the load conditions at various points.

The Quadrant Electrometer for the Measurement of Dielectric Loss

BY D. M. SIMONS and W. S. BROWN

Associates, A. I. E. E.

Both of the Standard Underground Cable Company, Pittsburgh, Pa.

Review of the Subject.—*Walker, Skinner, Addenbrooke, Rayner, Orlich, Schultze, Thielers and others* have given a great amount of useful information on electrometers for the measurement of dielectric loss. We have found instruments made somewhat after the design of Skinner and Rayner, so rugged, and so useful as laboratory instruments, even when the instrument is subjected to severe jars and mechanical vibration, and capable of such great accuracy that we have spent considerable time developing methods of use and investigating the sources of error. Our instruments are essentially high-voltage instruments as the needle may have impressed upon it voltages up to about 8500 volts. One of these instruments has been in use almost continuously since 1913, a period of ten years, and for the last seven years it has been continually in use without needing repairs of any sort, in spite of breakdowns of the load being measured, and no adjustments have been made except an occasional turning of the quadrant leveling screws.*

We have developed what we believe to be a new zero method of measuring power factor which has many advantages, and have also used the electrometer as a detector in a high-voltage bridge. We have also gone thoroughly into the errors of the electrometer, both for the deflection and zero methods, and have included these errors in our equations, so that we believe they may be taken care of practically.

Our excuse for publishing this information is that we believe it may be of use to others, and may lead to the more general recognition of the many advantages to be procured in using electrometers.

Part I—Theoretical

1. Symbols

The following symbols will be used:

E = the voltage on the load taken as numerically equal to the transformer voltage.
I = the load current or the charging current of specimen.
I_h = charging current flowing from the needle to the high quadrant.
I_l = charging current flowing from the needle to the low quadrant.
r_1 = resistance across the electrometer quadrants.
r_2 = resistance inserted in the needle circuit in the zero method, *i. e.*, the potential resistance.
C_1 = total capacity to ground of the high quadrant and all connected parts.
C_2 = capacity in the needle circuit.
$\cos \varphi$ = power factor of the load.
$\cos \psi$ = power factor of the circuit in which I_h flows.
$\sin A$ a term included to take care of phase shift in voltage of the point of the transformer winding to which the needle is connected.
d = deflection of the electrometer.
n = ratio of the transformer voltage to the needle voltage.
K = a constant.
f = frequency.
ω = $2\pi f$.

2. Deflection Method

The usual method of using an electrometer to measure power or power factor is shown in Fig. 1A (diagram of connections) and in Fig. 1B** (vector diagram). The usual equation is:

$$\frac{n\,K\,d}{r_1} = E\,I\cos\varphi - \frac{n-2}{2}\,I^2\,r_1 \qquad (1)$$

In this and all the following vector diagrams, the load current represented by $A\,X$ is taken as the vector of reference. The voltage impressed upon the load, $A\,N$, lags behind $A\,X$ by the angle $X\,A\,N$ or φ. $N\,B$ is the voltage across the quadrants, D is the mid-point of the quadrant resistance, and B is the grounded end. $A\,B$ is the transformer voltage. In Fig. 1B, the voltage across the quadrants being a pure resistance drop, is made parallel to $A\,X$. The needle is attached to the transformer (or potential divider) at the point O. $O\,B$ is equal to E/n and $O\,D$ is the effective voltage on the needle, *i. e.*, the voltage to which the deflection is proportional according to Maxwell's theory. The usual procedure is to ground one set of quadrants as shown in Fig. 1A. In what follows this set will be spoken of as the "low quadrant" and the other set the "high quadrant."

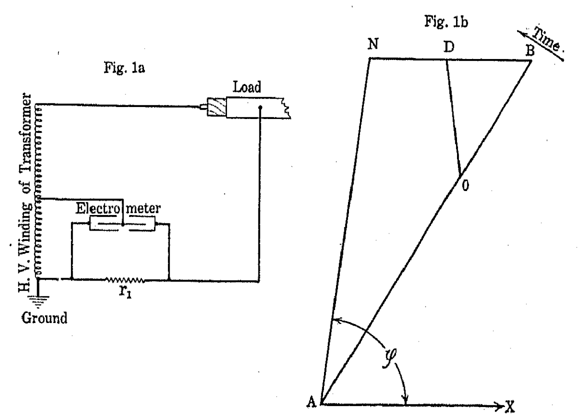

FIG. 1

In actual practise, the impedance across the quadrants is never a pure resistance, inasmuch as the capacity to ground of the high quadrant and all connected parts, the capacity to ground of the low-voltage electrode of the specimen and the distributed capacity of the resistance itself form a shunt across the quadrant resistance. If the load current is large or the sensitivity of the electrometer very high, a large deflection is obtained with a relatively small value of r_1, and it is often quite possible to neglect this capacity shunt; when, however, very small loads are to be measured

*Transactions of A. I. E. E. 1922, p. 601, Simons: "Bibliography of Dielectrics" for reference to articles by these authors and others.

**Note that time is shown revolving counter-clockwise, and thus direction of heating and lagging is reverse of usual.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

especially with very insensitive electrometers, this capacity shunt must be considered. In many of our measurements, the part of the deflection due to the capacity to ground was larger than that due to the power factor of the load. The rigid equation which takes into account the capacity to ground is as follows:

(See Part II, paragraph 18 for its derivation.)

$$\frac{n\,K\,d\,(1 + r_1^2\,C_1^2\,\omega^2)}{E\,I\,r_1} = \cos\varphi + r_1\,C_1\,\omega\,.\,\sin\varphi - \frac{n-2}{2}\cdot\frac{I\,r_1}{E} \quad (2)$$

The diagram of connections and the vector diagram are shown in Figs. 2A and 2B. In Fig. 2A the entire capacity to ground is shown shunting the resistance. The effect of this capacity on the vector diagram 2B, is to make the quadrant voltage, $N\,B$, lag by an angle α, such that $\tan\alpha = r_1\,C_1\,\omega$.

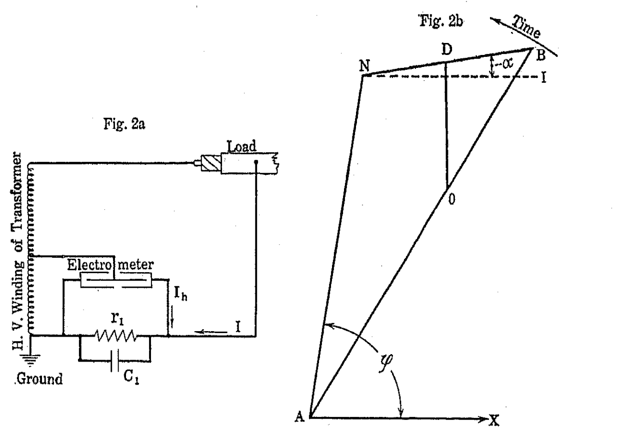

Fig. 2

For most practical cases, $r_1^2\,C_1^2\,\omega^2$ is negligible and $\sin\phi$ may be taken as unity. The equation then reduces to:

$$\frac{n\,K\,d}{E\,I\,r_1} = \cos\varphi + r_1\,C_1\,\omega - \frac{n-2}{2}\cdot\frac{I\,r_1}{E} \quad (3)$$

In the above equations, I_h the charging current flowing from the needle to the high quadrant, has been neglected. This current flows through the resistance and capacity across the quadrants and therefore produces a deflection. The relative importance of this deflection depends on the ratio of I to I_h, and in the case of extremely small specimens where I and I_h are more nearly equal it cannot be neglected.

In addition to the effect of I_h on certain terms of the equation, the energy loss between the needle and high quadrant, whether due to ionization, dielectric loss in the medium in which the electrometer is immersed (usually air but sometimes oil) or direct leakage is also measured.

Another error due to phase shift of the needle voltage is introduced by the use of a potential divider. The high-voltage winding of the transformer may be provided with taps at 1/2, 1/4 and 1/8 voltage or the potential divider of Orlich and Schultze[1] may be used. In either case a plus or minus phase shift of the needle voltage will take place and an error will be introduced which may be a function of the angle of shift, which error we have called $\sin A$. The phase shift due to resistance of the needle suspension might also be included in this term. This error may be calculated exactly and is equal to the resistance of the needle suspension multiplied by the susceptance of the circuit from the needle to the quadrants. In our electrometer this error is negligible and therefore will not be included in the term $\sin A$.

The following equation has been developed (see Part II, paragraph 20, for derivation) to include the errors mentioned above:

$$\frac{n\,K\,d}{E\,I\,r_1} = \cos\varphi + (I_h/I)\cos\psi + (1 + I_h/I)\,r_1\,C_1\,\omega + (1 + I_h/I)\,\frac{[n\,I_h - (n-2)\,I]\,r_1}{2\,E} + \sin A \quad (4)$$

In the above equation it is assumed that $\sin\varphi$ may be taken equal to unity and that $r_1^2\,C_1^2\,\omega^2$ is negligible. In order to apply this formula it is necessary to know the value of I_h for every deflection, as this value is a function of the position of the needle in the quadrants. The method of determining the various quantities appearing in the equation will be found under the zero method.

3. Zero Method for Measuring Power Factor

There are so many well known advantages in the use of a zero rather than a deflection method, that it is hardly worth while to mention them at this point. When applied to the electrometer the zero method obviates the necessity of designing an instrument with a "straight line" constant, eliminates the necessity of calibration, and gives readings almost independent of small voltage fluctuations. Another particular advantage of a zero method is that Maxwell's law for the deflection of an electrometer has been somewhat challenged, especially for large deflections. For a zero method using a reasonably symmetrical instrument Maxwell's law must hold very accurately. The method consists in *bringing the deflection back to zero by the insertion of a resistance in the lead to the electrometer needle*, the power factor being calculated from the value of resistance used. The diagram of connections and the vector diagram are shown in Figs. 3A and 3B respectively.

The effect of the resistance r_2 may be explained as follows. Referring to Fig. 3B the deflection of the electrometer is proportional to the scalar product of the voltage across the quadrants, $N\,B$, and the needle

1. Orlich and Shultze, *Archiv fur Elektrotechnik*, 1912., Vol. 1, page 1.

voltage $T D$. The greater the angle between these two vectors, the smaller will be the deflection and the deflection will be zero if they are perpendicular. If r_2 is inserted in the needle circuit a resistance drop is introduced in quadrature with the needle voltage, causing $T D$ to swing to the right with D as a center, increasing the angle between $N B$ and $T D$ and thereby decreasing the deflection. When r_2 has been increased to a sufficient value to bring the electrometer deflection back to zero, the needle voltage $R D$ becomes perpendicular to the quadrant voltage, $N B$, $T R$ being the voltage drop across r_2.

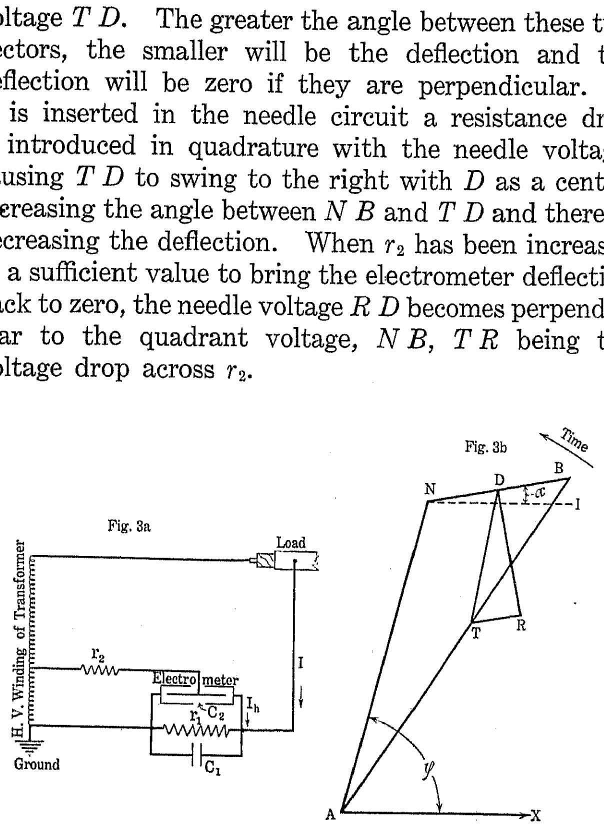

FIG. 3

If n is large and the needle voltage falls to the left of $R D$ (when $r_2 = O$) the deflection will be negative and the insertion of r_2 will merely shift the needle voltage further to the left and increase the negative deflection. Special methods as described in Section 15 must then be used.

The rigid equation applying to the method as outlined above is:

$$\cos \varphi\,(1 + r_1 C_1 \omega \,.\, r_2 C_2 \omega)$$

$$= \sin \varphi\,(r_2 C_2 \omega - r_1 C_1 \omega) + \frac{n-2}{2} \cdot \frac{I r_1}{E} \quad (5)$$

(See Section II, paragraph 19 for derivation).

For most practical cases $r_1 C_1 \omega .\, r_2 C_2 \omega$ is negligible and $\sin \varphi$ can be taken as unity, and we have the following working formula:

$$\cos \varphi + r_1 C_1 \omega - \frac{n-2}{2} \cdot \frac{I r_1}{E} = r_2 C_2 \omega \quad (6)$$

For a given set of conditions, a certain voltage drop across the potential resistance, r_2, is necessary in order to bring the deflection back to zero (See Fig. 3B). The small value of the charging current of the needle would necessitate the use of a very large potential resistance. To avoid this, a condenser, C_0, of 0.004 μf. capacity, was shunted between the needle and ground, which made it possible to bring the deflection back to zero, with a few thousand ohms. In Fig. 3B, one side of C_0 is shown connected to the mid-point of r_1. If this were actually done, the charging current of the auxiliary condenser would flow through one-half of the quadrant resistance introducing an important error. In all our measurements one side of C_0 was connected directly to ground as in Fig. 4. When this is done, it can be shown analytically by a method similar to that used in Part II, Paragraph 19, that the quantity $\dfrac{I r_1 \,.\, r_2^2 C_2^2 \omega^2}{E \sin \varphi}$ should be added to the right hand side of (**5**). The value of this term is so small as to be negligible in our case. If a resistance were inserted between C_0 and ground of such value that the voltage drop across it is equal to half the voltage drop across the quadrants, the above error is approximately compensated for. Experiment showed that this resistance was not necessary.

For very small loads the value of I_h may be comparable to I, so that the former can no longer be neglected. For this case the following formula (see Part II, paragraph 20) has been derived:

$$\cos \varphi + (I_h/I) \cos \psi + (1 + I_h/I)\, r_1 C_1 \omega$$

$$+ (1 + I_h/I)\, \frac{[n I_h - (n-2) I]\, r_1}{2 E}$$

$$+ \sin A = r_2 C_2 \omega \quad (7)$$

This equation is a general one which will be used in all that follows. For $n = 2$ and $n = 1$, equation (**7**) takes the forms:

½ voltage on needle:

$$\cos \varphi + (I_h/I) \cos \psi + (1 + I_h/I)\, r_1 C_1 \omega$$

$$+ (1 + I_h/I)\, \frac{I_h r_1}{E} + \sin A = r_2 C_2 \omega \quad (8)$$

Full voltage on needle:

$$\cos \varphi + (I_h/I) \cos \psi + (1 + I_h/I)\, r_1 C_1 \omega$$

$$+ (1 + I_h/I)\, \frac{(I + I_h)\, r_1}{2 E} = r_2 C_2 \omega \quad (9)$$

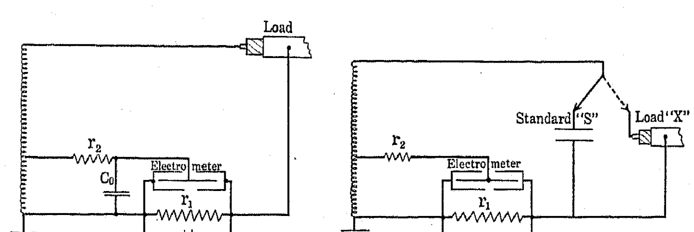

FIG. 4 AND 5

4. OPERATION AND SOLUTIONS OF THE ZERO METHOD WITH CIRCUIT CONSTANTS I_h, $\cos \psi$, $\sin A$ AND $r_1 C_1 \omega$ UNKNOWN

In the majority of practical cases of measuring dielectric losses of cables, the relatively simple conditions of equation (**6**) obtain. The power factor may be quite accurately determined by taking two balances one with a quadrant resistance r_1 and the other with a quadrant resistance $r_1/2$, after the manner of Ray-

ner's deflection method. That is, from these two readings it is possible immediately to eliminate the second and third terms of equation (**6**) and solve for $\cos \varphi$.

This method, however, would not work for very small specimens when the fuller equation (**7**) applies, as may be seen by inspection. Furthermore, it is assumed that C_1 is constant, while actually there may be a slight change between the two readings inasmuch as the distributed capacity to ground in the quadrant resistance is an element of C_1, and the method involves changing the resistance.

A method of overcoming these difficulties has been developed involving the use of a zero loss air condenser of about the same capacity as the specimens. A reading is first taken on the zero loss condenser, using quadrant resistance equal to r_1. Remembering that $\cos \varphi = O$, we may make the following equation:

$$(I_h/I) \cos \psi + (1 + I_h/I)\, r_1\, C_1\, \omega + (1 + I_h/I) \frac{[n\, I_h - (n-2)\, I]\, r_1}{2\, E} + \sin A = r_2\, C_2\, \omega \quad \mathbf{(10)}$$

If we now reduce r_1 to $r_1/2$, and balance with r_2' of potential resistance, there may be a slight change in capacity to ground, which will be called C_r. We then have:

$$(I_h/I) \cos \psi + 1/2\, (1 + I_h/I)\, r_1\, (C_1 + C_r)\, \omega + 1/2\, (1 + I_h/I) \frac{[n\, I_h - (n-2)\, I]\, r_1}{2\, B} + \sin A = r_1'\, C_2\, \omega \quad \mathbf{(11)}$$

Now assume that we increase the capacity to ground by means of an air condenser in such a way as to make $r_2'\, C_2\, \omega$ exactly half of $r_2\, C_2\, \omega$. Calling this added capacity C_x we have

$$(I_h/I) \cos \psi + 1/2\, (1 + I_h/I)\, r_1\, (C_1 + C_r + C_x)\, \omega + 1/2\, (1 + I_h/I) \frac{[n\, I_h - (n-2)\, I]\, r_1}{2\, E} + \sin A$$
$$= 1/2\, .\, (I_h/I) \cos \psi + 1/2\, (1 + I_h/I)\, r_1\, C_1\, \omega + 1/2 (1 + I_h/I) \frac{[n\, I_h - (n-2)\, I]\, r_1}{2\, E} + 1/2 \sin A \quad \mathbf{(12)}$$

and therefore,

$$(1 + I_h/I)\, r_1\, C_x\, \omega = \frac{-\, I_h}{I} - \cos \psi - (1 + I_h/I)\, r_1\, C_r\, \omega - \sin A \quad \mathbf{(13)}$$

Now balance without C_x in circuit on a load whose capacity to ground is C_1', whose power factor is $\cos \varphi$, and whose load current is closely equal to I using a quadrant resistance r_1, and we have

$$\cos \varphi + (I_h/I) \cos \psi + (1 + I_h/I)\, r_1\, C_1'\, \omega + (1 + I_h/I) \frac{[n\, I_h - (n-2)\, I]\, r_1}{2\, E} + \sin A = r_2''\, C_2\, \omega \quad \mathbf{(14)}$$

Now add to the high quadrant, a capacity to ground equal to C_x and change r_1 to $r_1/2$. Then we have

$$\cos \varphi + (I_h/I) \cos \psi + 1/2\, (1 + I_h/I)\, r\, (C_1' + C_r + C_x)\, \omega + 1/2\, (1 + I_h/I) \frac{[n\, I_h - (n-2)\, I]\, r_1}{2\, E} + \sin A = r'''\, C_2\, \omega \quad \mathbf{(15)}$$

Substituting from (**13**) for the term involving C_x, we get

$$\cos \varphi + 1/2\, (I_h/I) \cos \psi + 1/2\, (1 + I_h/I)\, r_1\, C_1'\, \omega + 1/2\, (1 + I_h/I) \frac{[n\, I_h - (n-2)\, I]\, r_1}{2\, B} + 1/2 \sin A = r_2'''\, C_2\, \omega \quad \mathbf{(16)}$$

Doubling (**16**) and subtracting (**14**) from it we obtain the final equation.

$$\cos \varphi = (2\, r_2''' - r_2'')\, C_2\, \omega \quad \mathbf{(17)}$$

Inasmuch as I_h, $\cos \psi$, $\sin A$, $r_1\, C_1\, \omega$, and C_r do not appear in equation (**17**), it may be used to solve for the power factor when the circuit constants are unknown.

5. Operation and Solution of the Zero Method by Comparison with a Standard

The diagram of connections for this method as developed by us is given in Fig. 5. The low-voltage electrodes of the load and of the zero loss condenser used as a standard are permanently connected to the high quadrant maintaining constant capacity to ground except as noted hereafter. (See Section 6). Two balances are taken one with high voltage on the standard and the other with high voltage on the load of unknown power factor. If the charging currents of the standard and the load are approximately the same, equation (**7**) will apply to both readings, $\cos \varphi$ being equal to zero for the first balance. Subtracting equation (**7**) as applied to the first reading from the same equation applying to the second reading will therefore give the unknown power factor. If I is very large compared to I_h the charging currents of the standard and the load need not be equal if $n = 2$.

If the auxiliary condenser C_0 used in the needle circuit is of such capacity that $C_2\, \omega = 1$ or 1×10^N where N is any whole number, and two resistance boxes are used for the potential resistance, the application of this method is simple, convenient, and quick. A balance is first obtained on the zero loss condenser, with one of the potential resistance boxes, the voltage is shifted to the load and another balance obtained using the other resistance box. The unknown power factor can then be read directly from the resistance setting on the second box without calculation.

6. The Error Due to Shunting Capacity

The above method of measurement is based on the assumption that the total capacity to ground of the high quadrant and all connected parts is held constant by permanently connecting the low-voltage electrodes of both the standard condenser S and the unknown load X to the high quadrant. This is not usually the

case, however, as may be seen from what follows. Both S and X are in reality made of three condensers shown diagrammatically in Fig. 6.

Let C_a = capacity between high and low-voltage electrodes.

C_b = capacity between high-voltage electrode and ground (including the guards which are also grounded).

C_c = capacity between low-voltage electrode and ground (including the guards which are also grounded).

With high voltage on S, the total capacity to ground is

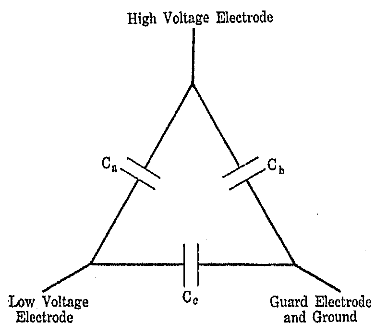

FIG. 6—DIAGRAM OF THE THREE CONDENSERS OF WHICH A CONDENSER IS COMPOSED

made up of the capacity to ground of the high quadrant and all connecting parts, the distributed capacity to ground of the quadrant resistance, the C_c capacities of S and X and in addition, since the high-voltage lead of X is disconnected, a capacity which we shall call C_{ab} made up of the C_a and C_b capacities of X in series and therefore equal to:

$$\frac{C_a \times C_b}{C_a + C_b}$$

In the same way when voltage is on X, there is an additional capacity to ground made up of the C_a and C_b capacities of S in series. Only in case these two additional capacities are equal is the capacity to ground of the system a constant.

In our measurements the above condition does not hold. It was perfectly possible, however, to measure the a, b and c capacities of both S and X, as shown in Sec. 8, to permit of the necessary corrections by substitution of the values so obtained in the equations. If S is a guarded condenser only one set of measurements is necessary unless the temperature varies within indefinite limits. Then as C_a of X must be measured anyway to obtain the load current, only two extra measurements must be made, the C_b and C_c capacities of X. The necessity of making these measurements is eliminated however, if S is of variable capacity. The C_a capacity of the standard can then be made exactly equal to that of the unknown, and if the C_b capacity of the condenser which is not connected to the high voltage is short-circuited by connecting its high-voltage electrode to ground, the additional capacity to ground is always C_a, a constant. The construction of a variable standard air condenser to be operated at high voltage is a somewhat formidable proposition, but it is believed by us by no means impossible of achievement. The relatively small maximum capacity required would greatly lessen the difficulties in construction.

In many cases it may be inconvenient to use any of the methods outlined above. The power factor of a given load can be determined by one reading if I_h, I, $\cos \psi$, $\sin A$ and C_1 are known. The methods used in obtaining these quantities will now be outlined.

7. DETERMINATION OF I_h

Two methods were available for the measurement of this current. In the first, a non-inductive resistance of 1,000,000 ohms was placed between the high quadrant and ground. The voltage drop across this resistance with 7000 volts impressed on the needle was then read on a low-voltage electrostatic voltmeter, from which the current was readily calculated. I_h varies with the position of the needle in the quadrants and the value when the deflection is zero should be used in the equations. It was therefore necessary to put another resistance of 1,000,000 ohms in series with the low quadrant to maintain zero deflection of the instrument. The use of a three-electrode vacuum tube as an amplifier greatly reduced the amount of resistance required in the first method. With two stages, amplification of over 700 times was obtained, thereby reducing the resistances in series with the quadrants to about 1400 ohms. If a condenser of known capacity is shunted across the quadrants and the procedure of Section 13 carried out, the value of I_h can be obtained

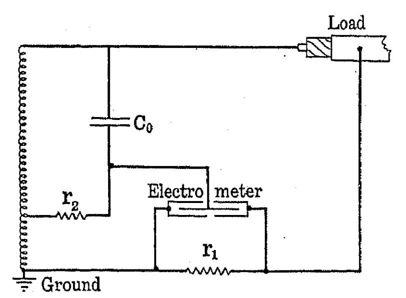

FIG. 7—DIAGRAM OF CONNECTIONS SHOWING LOCATION OF THE AUXILIARY CONDENSER C_0 IF THE INITIAL DEFLECTION IS NEGATIVE

by solving equation (**19**). The value thus obtained was used to check the first method.

8. DETERMINATION OF $r_1 C_1 \omega$

Assuming that the capacity to ground of the quadrant resistance does not change appreciably between r_1 and $r_1/2$, $r_1 C_1 \omega$ can be measured by taking two balances with $n = 2$ on a given load, the first with r_1 and the second with $r_1/2$. Applying equation (**8**) to both readings, subtracting the second equation thus

obtained from the first and dividing by $(1 + I_h/I)$, we obtain an equation which can be directly solved for $r_1 C_1 \omega$.

9. Determination of sin A

If we make the same assumption regarding the capacity to ground of the quadrant resistance as in the last paragraph, sin A may be easily obtained. First determine the value of $r_1 C_1 \omega$ by the method of the last paragraph using a zero-loss condenser as the load. Then take two balances on the same load, one with $n = 1$, and voltage on the needle and load equal to E, and the other with $n = 2$, voltage on the needle of E and voltage on the load of $2E$ this keeping I_h constant. Two equations can now be written and solved for sin A.

10. Determination of cos ψ

If $r_1 C_1 \omega$ and I_h are known, the value of this quantity at any voltage E can be obtained from equation (**9**) by taking a reading on a zero-loss air condenser with $n = 1$. The equation can then be solved for cos ψ.

11. Determination of cos ψ and $r_1 C_1 \omega$

Cos ψ may be determined in one way absolutely independently of our ability to calculate exactly $r_1 C_1 \omega$ as described in paragraph 8, if only the constant, K, of the instrument be known, as of course it would have to be known if used for the deflection method. Incidentally $r_1 C_1 \omega$ becomes accurately known.

Load the instrument with a zero-loss condenser. Make n equal 1 and take a reading at voltage E by the deflection or zero method, preferably the latter. Calling the reading A, then

$$A = (I_h/I) \cos \psi + (1 + I_h/I)\, r_1 C_1 \omega + (1 + I_h/I) \frac{(I + I_h)\, r_1}{2E}$$

Remove the voltage from the zero-loss condenser by disconnecting its high lead but not its low lead. Then keeping everything else the same as before, put the voltage E on the instrument and take deflection, d, and we then have:

$$\frac{K d}{r E I_h} = \cos \psi + 1/2 \frac{I_h r}{E} + r_1 C_1 \omega + r_1 C_{ab} \omega \quad \textbf{(18)}$$

C_{ab} being the shunting capacity of the zero-loss condenser which is now added since the voltage is removed from the high-voltage electrode (see paragraph 6). But C_{ab} is known or can be measured as explained in paragraph 8, and therefore from the above two equations, cos ψ and $r_1 C_1 \omega$ may be calculated, as they are the only unknowns.

12. Determination of $r_1 C_1 \omega$, cos ψ and sin A

We have found it most convenient to determine the capacity to ground as well as cos ψ once for all by means of measurements with two zero-loss condensers of different capacities. Our main purpose in this was to check the general equation for the electrometer, but it also gave a very convenient method of calculating these quantities. One actual set of readings is given in the experimental section under Part III paragraph 23, and will therefore not be described in detail here.

13. Measurement of Capacity by the Electrometer

Capacities may be very conveniently measured by the electrometer used as a zero instrument by merely balancing the deflection of the electrometer with voltage connected to a condenser of zero or constant power factor, and then connecting the condenser of unknown capacity between the high quadrant and ground and obtaining another balance. An examination of equation (**7**) will show that the only change introduced by the insertion of additional capacity to ground is in the term containing C_1, and therefore we may write immediately

$$(1 + I_h/I)\, r_1 C_x \omega = (r_2' - r_2)\, C_2 \omega \quad \textbf{(19)}$$

in which C_x is the unknown capacity, r_2 is the potential resistance which was used to balance before C_x was inserted, and is r_2' is the potential resistance after the insertion of C_x.

This method of measuring capacity has been used in general and in particular for the measurements of C_a, C_b and C_c of our condensers, which is described in detail in Part III, paragraph 22.

14. Effect of Ratio of Potential Division

Most of our measurements have been made with either full voltage or half voltage on the needle. The advantage of using full voltage on the needle is that the phase shift of the needle voltage is eliminated but the disadvantage is that, speaking in terms of power rather than of power factor, one-half the loss in the quadrant resistance is also measured. In general, as pointed out many times before there are distinct advantages in working with half voltage on the needle, because the loss in the quadrant resistance disappears entirely (except in so far as due to I_h) as may be seen from equation (**7**), and this is often of considerable importance, especially in those cases where the simpler equations (**3**) and (**6**) can be applied.

If n equals 2, *i. e.*, half voltage on the needle, the instrument will always deflect (neglecting sin A) unless cos φ, cos ψ, and C_1 are all zero. The direction of this deflection will be defined as the positive direction. If n is very large and the loss small, the instrument may give a negative deflection, as may be seen from equation (**7**). In this case, the insertion of resistance r_2, instead of bringing the negative deflection back to zero will merely increase it in a negative direction.

15. Negative Deflections

If the initial deflection is negative, the zero method must be modified, and several alternatives are available.

(A) The deflection may be brought back to zero by adding capacity between the high quadrant and ground, or preferably, the deflection may be made positive by

this means, and then brought back to zero by the potential resistance r_2, making the above described zero method available. This may become objectionable, however, when it makes the value of $r_1 C_1 \omega$ very large, inasmuch as the part of $r_2 C_2 \omega$ due to load power factor may be very small, and slight errors in $r_2 C_2 \omega$ might make a large error in the power factor.

(B) Another method of accomplishing the result is to change the position of the auxiliary condenser in the zero power factor method from that shown in Fig. 4 to its position in Fig. 7. Speaking in terms of instantaneous values, it will be seen that the direction of current in resistance r_2 would be reversed by this method, and that therefore the needle voltage would be shifted in the opposite direction.

(C) A method based on Miles Walker's suggestion of adding resistance in the high-voltage lead of the specimen is also available. Connect the low-voltage electrodes of S and X together and to the high quadrant, exactly as explained in Section 5. Put voltage on S which must have the same load current I as the unknown X, and add resistance in the high lead until a zero deflection or a slightly positive deflection is obtained, which can be brought back to zero by the usual potential resistance r_2. Now shift the voltage to X, keeping the same resistance in the high lead and again bring the deflection back to zero by increasing r_2. Then, for the simplest case the following equation will apply.

$$\cos \phi = (r_2' - r_2)\, C_2\, \omega$$

Unfortunately the equation above will not apply unless not only the load currents of S and X are the same but also the currents from the high-voltage electrodes to the guards and ground, *i. e.*, C_b must be the same. A correction must also be made due to the fact that the total capacity to ground is not constant, as explained in Section 6.

(D) Another method due to Russell[2] might be used. In this method the deflection is brought back to zero by varying n. It may be seen from equation (4) that the deflection will be zero if:

$$n = \frac{2\,E\,(I \cos \varphi + I_h \cos \psi)}{r_1\,(I^2 - I_h^2)} + \frac{2\,(E\,.\,r_1 C_1\,\omega + E \sin A + I\,r_1)}{r_1\,(I - I_h)} \qquad (20)$$

Assuming that all the circuit constants were known and that this value of n had been determined, it would be possible to solve at once for $\cos \varphi$ in the above equation.

Incidently we have here a check on the derivation of the main formulas presented in this paper. Equations (4) and (7) for the deflection and zero method were derived independently but it will be noted that one side of each is the same. This must necessarily be the case since the two methods coincide for the value of n giving zero deflection as both d and r_2 are then equal to zero.

There are great difficulties in applying this method as varying n with a given value of E means varying the needle voltage, and to accomplish continuous variation of n means a transformer with an infinite number of taps on the high-voltage winding, or difficulties with a high-voltage potential-divider.

(E) When the initial deflection is negative due to a large value of n, probably the best method is to use the connections due to Petersen[3] although this method has not been tried out practically. Quite constant results have however, been obtained with the deflection method and Petersen condensers, with $E = 40{,}000$ volts and the needle voltage of only 1000. Petersen obtained the needle voltage by means of a potential divider composed of two condensers in series, with the needle connected to the mid-point as shown in the diagram of connections, Fig. 8A. The method as suggested by us would consist in placing these two condensers between the *midpoint* of the transformer and ground. With this arrangement the great advantage of using $n = 2$ would be obtained regardless of the ratio of potential division and the initial deflection will always be positive. A resistance inserted between the mid-point of the transformer and the first of the potential condensers shown in Fig. 8A would serve for r_2.

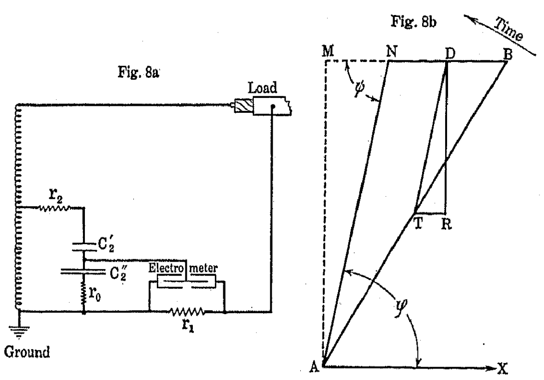

Fig. 8—Petersen Series Condensers Used as Potential Divider

One end of the potential condenser system used in the Petersen method is connected to the mid-point of the quadrant resistance, the center of symmetry. The charging current of these condensers will therefore flow through one half of the quadrant resistance to ground, causing an appreciable error for which correction must be made. This difficulty could be largely avoided if the condenser system was only virtually connected to the mid-point of the quadrant resistance, that is, if a resistance, r_0, was inserted between the low-voltage condenser and ground of such value that the voltage drop across this resistance would be equal to one-half

2. A. Russell, Alternating Currents, 1914. Vol. 1, page 320.
3. Petersen, *Archiv fur Elektrotechnik*, 1912, Vol. 1, page 95.

of the voltage drop across the quadrant resistance. Dielectric losses in the potential condensers and the capacity to ground of the various parts would cause a slight residual error.

The method outlined in this section presents one great advantage in that it can be applied for very high values of n, or what is the same thing, dielectric loss measurements at high voltage could be made with a very sensitive low-voltage electrometer. In such an instrument, I_h would be negligible and due to the high sensitivity, the value of r_1 required for an accurate balance would be so small that the term $r_1 C_1 \omega$ would become negligible. The simple conditions shown in vector diagram 8B would then exist, the voltage drop across the quadrants $N B$, being parallel to the vector of reference $A X$ the load current, angle α vanishing. All the correction terms would disappear and $\cos \varphi$ would equal $r_2 C_2 \omega$ where C_2 equals the capacity of C_2' and C_2'' in series. In practise C_2'' would be variable and adjusted to give the proper needle voltage. It is important to mention that this method is based on the assumption that it is possible accurately to make the virtual connection of the potential condenser system to the mid-point of the quadrant resistance. The simplicity of the solution is due to the fact that angle $T D R = 90 - \varphi$, in Fig. 8B. If the virtual connection is not exact, the vertex of this angle will not fall at D thus introducing an error. The small values of resistance, however, required with a sensitive low-voltage electrometer would probably make this error negligible.

Instead of connecting r_2 between the transformer and the condenser C'_2, it might be connected between the condenser C'_2 and the point where the electrometer needle is connected, in other words r_2 would then be at a relatively low potential. The solution would be the same, and the advantage of having r_2 at a lower potential would be obtained.

(*F*) Another way of handling a negative deflection is to diminish r_1 until the deflection becomes positive, then balance as usual with r_2. As recently pointed out by Addenbrooke if n is greater than 2, a zero method is available by merely varying r_1. In the very simple case when C_1 is negligible, this would give excellent results. It would be very difficult to apply, however, to a comparative method where two balances are made one on a standard zero-loss air condenser and one on the load, as the change in r_1 would change the value of the term $r_1 C_1 \omega$. Furthermore C_1 which includes the distributed capacity of r_1 would vary with r_1.

16. Bridge Method of Electrometer

The electrometer may be used in a zero method according to the connections shown in Fig. 9, in which it will be seen that high voltage is placed upon both S and X, each connected to ground through a resistance, the upper end of each resistance being connected to one set of quadrants of the instrument. A resistance is inserted in the high lead of S. The procedure is the following. First connect both specimens to high voltage, and ground the needle of the instrument. Adjust r_1' and r_1'' until the electrometer reads zero. Secondly, connect the needle to the desired potential point and cut in resistance r_2 in series with S until the electrometer again reads zero. In the simplest case, the usual equations of an a-c. bridge will apply. It will be noted that this is in effect merely the two balances, first capacity and second power factor, in a power factor bridge, the electrometer being used as the detector. This method will not be developed further, although it is obvious that the same difficulties will be presented due to the capacity to ground and the needle charging current, if the specimens are so small that these are effective.

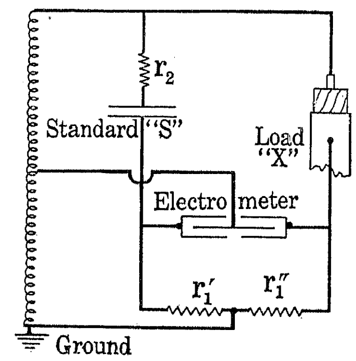

Fig. 9—Diagram of Bridge Method

17. Conclusions

In concluding, we hope that the complexity of some of our general equations and of some of the methods of measurement described will not create an impression that the quadrant electrometer is necessarily a very complicated instrument for the measurement of power factor. In attempting to obtain expressions for some of the smaller errors, we have possibly not emphasized sufficiently the great simplicity of the instrument for most practical cases. In the majority of practical measurements, we have no doubt that the method outlined in the first paragraph in Part I, section 4, will be amply sufficient. In fact, with rather large samples of cable, measuring with half voltage on the needle, the power factor may often be obtained directly from the setting of the potential resistance, r_2, according to equation (6), since the third term will vanish and the second term will probably be negligible.

Any conclusion would be incomplete without a word of appreciation of the late Charles W. Davis, who actually initiated the present work on the quadrant electrometer, practically designed the instrument, and suggested the possibility of developing the zero method just described. His continued interest and enthusiasm were of the utmost assistance in carrying this work to its conclusion.

The theoretical and mathematical sections of the

paper are the work of D. M. Simons, and the experimental section, of W. S. Brown.

Part II—Mathematical

(18) Derivation of Equation of Deflection of Electrometer Neglecting Needle Charging Current

The diagram of Fig. 2 B shows the vector diagram. $A X$, the load current is the vector of reference. $A N$ is the voltage on the specimen, lagging by angle φ, $\cos \varphi$ being the power factor of the load. This voltage will be represented by E. Let the voltage across the quadrants $= E_q = N B$. Let the transformer voltage be $E_0 = A B$. Let the needle voltage be $E_n = O D$.

Maxwell shows that the deflection of the electrometer is proportional to the scalar product of the voltage across the quadrants by the voltage from the needle to the mid-point of the quadrants, or in our case, we may say that the deflection is proportional to $E_q \times E_n$. The method of solution will therefore consist in finding the symbolic expressions for these two vectors and taking their product, which will be done as follows:

$$\dot{E}_0 = \dot{E} + \dot{E}_q \tag{1}$$

$$\dot{E} = E \cos \varphi + j\, E \sin \varphi \tag{2}$$

where I is the vector of reference.

The load current I flows through the resistance r_1 and capacity C_1 which are in parallel across the quadrants of the electrometer. The admittance of this circuit is therefore equal to

$$1/r_1 + \frac{1}{j\,.\,1/C_1\,\omega} = 1/r_1 - j\, C_1\, \omega$$

Therefore $\dot{E}_q = \dfrac{I}{1/r_1 - j\, C_1\, \omega}$

$$= \frac{r_1 I\,(1 + j\, r_1\, C_1\, \omega)}{1 + r_1^2\, C_1^2\, \omega^2} \tag{3}$$

Now $\dot{E}_n = \dot{E}_0/n - \dot{E}_q/2$, and from (1) therefore

$$\dot{E}_n = \dot{E}/n - \frac{n-2}{2}\, \dot{E}_q \tag{4}$$

Substituting (2) and (3) in (4), we obtain:

$$\dot{E}_n = 1/n \left[\left(E \cos \varphi - \frac{n-2}{2} \cdot \frac{r_1 I}{1 + r_1^2\, C_1^2\, \omega^2} \right) + j \left(E \sin \varphi - \frac{n-2}{2} \cdot \frac{r_1 I\,.\,r_1\, C_1\, \omega}{1 + r_1^2\, C_1^2\, \omega^2} \right) \right] \tag{5}$$

If d is the deflection of the electrometer and K is a constant, according to the Maxwell theory $K\, d = \dot{E}_n \times \dot{E}_q$. We may therefore substitute the values of these two vectors from (3) and (5), and after taking the "power product" and simplifying, we obtain:

$$\frac{n\, K\, d\,(1 + r_1^2\, C_1^2\, \omega^2)}{E\, I\, r_1} = \cos \varphi + r_1\, C_1\, \omega\,.\, \sin \varphi - \frac{n-2}{2} \cdot \frac{r_1 I}{E} \tag{6}$$

Equation (6) has also been derived geometrically, directly from the vector diagram.

19. Derivation of Equation for Zero Method with Electrometer, Neglecting Charging Current of Needle

As in section 18, E, E_0 and E_q, represent the load, transformer, and quadrant voltages respectively, represented by the vectors $A\,N$, $A\,B$ and $N\,B$ in Fig. 3B. Let E_p be the voltage on the potential elements, namely the resistance r_2 and capacity C_2 in series, shown by the vector $T\,D$. Let I_p be the current flowing in this circuit. Let E_n be the needle voltage, represented by $R\,D$, $T\,R$ being the voltage drop across r_2.

From the diagram, it will be seen that

$$\dot{E}_0 = \dot{E} + \dot{E}_q \tag{1}$$

$$\dot{E}_p = \dot{E}_0/n - \dot{E}_q/2 = \dot{E}/n - \frac{n-2}{2}\,.\,\dot{E}_q \tag{2}$$

$$\dot{E}_q = \frac{r_1 I\,(1 + j\, r_1\, C_1\, \omega)}{1 + r_1^2\, C_1^2\, \omega}$$

From equation (3) section 18 (3)

$$\dot{E} = E \cos \varphi + j\, E \sin \varphi \tag{4}$$

Substituting (3) and (4) in (2), we get

$$\dot{E}_p = 1/n \left[\left(E \cos \varphi - \frac{n-2}{\cdot 2} \cdot \frac{r_1 I}{1 + r_1^2\, C_1^2\, \omega^2} \right) + j \left(E \sin \varphi - \frac{n-2}{2} \cdot \frac{r_1 I\,.\,r_1\, C_1\, \omega}{1 + r_1^2\, C_1^2\, \omega^2} \right) \right] \tag{5}$$

For simplicity, let $M_1 = 1 + r_1^2\, C_1^2\, \omega^2$ and $M_2 = 1 + r_2^2\, C_2^2\, \omega^2$.

r_2 and C_2 being in series, the impedance of the potential circuit is $r_2 + j \dfrac{1}{C_2\, \omega}$, and therefore

$$\dot{I}_p = \frac{\dot{E}_p\,.\, C_2\, \omega\,(r_2\, C_2\, \omega - j\, 1)}{M_2} \tag{6}$$

and $$\dot{E}_n = j\, \frac{1}{C_2\, \omega} \times \dot{I}_p = \frac{\dot{E}_p\,.\,(1 + j\, r_2\, C_2\, \omega)}{M_2} \tag{7}$$

The symbolic representation of $\dot{E}_n$ may therefore be obtained by substituting the value of E_p from (5) in (7). Due to its length, this will not be done here.

If the electrometer is to read zero, E_n must be perpendicular to E_q. If two vectors are perpendicular, the slope (imaginary coefficient divided by real coefficient) of one must equal the negative reciprocal of that of the other. Setting up this condition and simplifying algebraically, we obtain finally

$$\cos \varphi\,(1 + r_1\, C_1\, \omega\,.\, r_2\, C_2\, \omega) = \sin \varphi\,(r_2\, C_2\, \omega - r_1\, C_1\, \omega) + \frac{n-2}{2} \cdot \frac{r_1 I}{E} \tag{8}$$

In most practical cases, $r_1\, C_1\, \omega\,.\, r_2\, C_2\, \omega$ is negligible, and if $\cos \varphi$ is small, $\sin \varphi$ may be taken as unity, and

we obtain an approximate equation similar to that of the deflection method:

$$\cos \varphi + r_1 C_1 \omega - \frac{n-2}{2} \cdot \frac{r_1 I}{E} = r_2 C_2 \omega \quad (9)$$

Equation (8) may also be obtained easily geometrically.

20. Derivation of General Equation for Zero Method of Electrometer

This derivation is so excessively long algebraically that certain portions will be merely outlined. One equation for instance contained 48 terms, each composed of a product of from 3 to 6 factors of the form $\cos \varphi$, $r\,C\,\omega$, etc. It is believed therefore that an outline will be sufficient.

In the vector diagram of Fig. 10, I the load current is the vector of reference, namely $A\,X$. $A\,B$ or E_0 is the transformer voltage. $A\,N$ or E is the load voltage, $\cos \varphi$ being the power factor, φ being the angle $N\,A\,X$. E_q or $N\,B$ is the voltage across the quadrants of which more will be said later.

The voltage on the potential circuit, r_2 and C_2 in series, is $T\,D$ or E_p, and I_p is the current in this circuit. The effective voltage on the needle to which a deflection would be due is $R\,D$ or E_n.

Let I_h be the current from the needle to the high quadrant, due to the voltage $R\,N$ or E_h. If there is any loss in this circuit, I_h will not be perpendicular to E_h, but will lead it by an angle ψ shown as angle $H\,N\,R$. I_h will therefore be in the direction $H\,N\,L$. If there were only resistance across the quadrants, the voltage drop across the quadrants due to I_h would be in the direction $N\,L$. Inasmuch as the capacity across the quadrants C_1 also exists, the drop due to I_h will lag behind $N\,L$ by some angle α and will be represented by $N\,E$. The drop across the quadrants due to the load current I would be in the direction $N\,I$ (parallel to the load current $A\,X$) if C_1 were not present. Due to C_1 it also lags behind $N\,I$ by the same angle α and may be represented by $N\,J$. The total drop across the quadrants mentioned above, $N\,B$, is therefore the vector sum of $N\,J + N\,E$.

The equation will now be developed. By inspection,

$$\dot{E}_0 = \dot{E} + \dot{E}_q \quad (1)$$

$$\dot{E}_p = \dot{E}_0/n - \dot{E}_q/2 = \dot{E}/n - \frac{n-2}{2} \cdot \dot{E}_q \quad (2)$$

$$\dot{E} = E \cos \varphi + j\,E \sin \varphi \quad (3)$$

$$\dot{E}_n = \dot{I}_p \times j \frac{1}{C_2\,\omega} \quad (4)$$

Since I is the vector of reference, $\dot{I} = I + j\,O$. Let the angle between I and I_h be β, namely the angle $I\,N\,L$, which angle must later be eliminated. Then $\dot{I}_h = I_h \cos \beta + j\,I_h \sin \beta$, and the total current through the quadrant resistance and capacity will be $\dot{I}_0 = I + I_h \cos \beta + j\,I_h \sin \beta$.

Now $$\dot{E}_q = \frac{\dot{I}_0}{1/r_1 + \dfrac{C_1\,\omega}{j}}$$

Let $M_1 = 1 + r_1^2\,C_1^2\,\omega^2$
and $M_2 = 1 + r_2^2\,C_2^2\,\omega^2$ for simplicity (5)

Then substituting $\dot{I}_0$ in (5) and simplifying, we obtain:

$$\dot{E}_q = 1/M_1 [\,(I\,r_1 + I_h\,r_1 \cos \beta - I_h\,r_1 \,.\, r_1\,C_1\,\omega \,.\, \sin \beta) + j\,(I\,r_1 \,.\, r_1\,C_1\,\omega + I_h\,r_1 \,.\, r_1\,C_1\,\omega \cos \beta + I_h\,r_1 \sin \beta)] \quad (6)$$

Now $$\dot{I}_p = \frac{\dot{E}_p}{r_2 + j\dfrac{1}{C_2\,\omega}} \quad (7)$$

Therefore $$\dot{E}_n = \frac{\dot{E}_p \,.\, (1 + j\,r_2\,C_2\,\omega)}{M_2} \text{ from (4)} \quad (8)$$

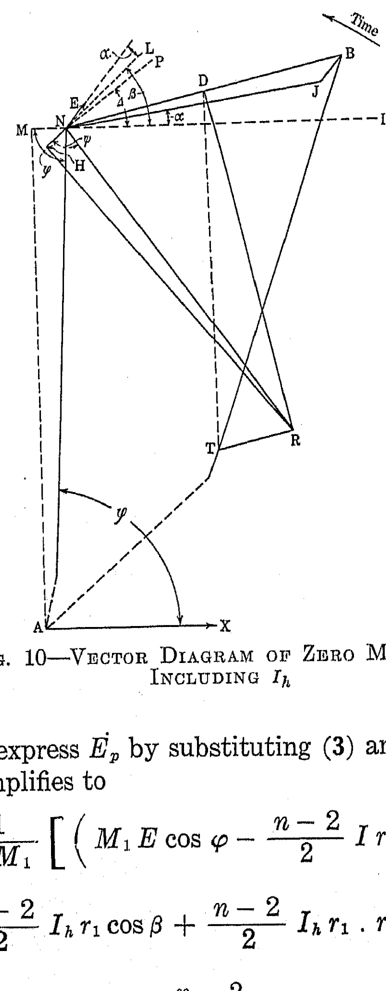

Fig. 10—Vector Diagram of Zero Method Including I_h

We may express $\dot{E}_p$ by substituting (3) and (6) in (2), which simplifies to

$$\dot{E}_p = \frac{1}{n\,M_1}\Bigg[\Bigg(M_1\,E \cos \varphi - \frac{n-2}{2}\,I\,r_1 - \frac{n-2}{2}\,I_h\,r_1 \cos \beta + \frac{n-2}{2}\,I_h\,r_1 \,.\, r_1\,C_1\,\omega \sin \beta\Bigg) + j\Bigg(M_1\,E \sin \varphi - \frac{n-2}{2}\,I\,r_1 \,.\, r_1\,C_1\,\omega - \frac{n-2}{2} \,.\, I_h\,r_1 \,.\, r_1\,C_1\,\omega \cos \beta - \frac{n-2}{2}\,I_h\,r_1 \sin \beta\Bigg)\Bigg] \quad (9)$$

The value of $\dot{E}_p$ from (9) is now substituted in (8) and the expression for $\dot{E}_n$ obtained. This will not be done here due to its length, but it will be called equation (10).

The condition that the deflection of the electrometer shall be zero is that E_n and E_q are perpendicular, or analytically that the slope of one vector is equal to the negative reciprocal of that of the other. We have the expressions for these two vectors in (6) and (10). If the above equation is set up and simplified algebraically (this is the long equation mentioned in the beginning) we obtain the following:

$$[I \cos \varphi + I_h \cos (\varphi - \beta)] (1 + r_1 C_1 \omega \,.\, r_2 C_2 \omega) = [I \sin \varphi + I_h \sin (\varphi - \beta)] (r_2 C_2 \omega - r_1 C_1 \omega) + \frac{n-2}{2} \cdot \frac{r_1 (I^2 + 2 I I_h \cos \beta + I_h^2)}{E} \quad (11)$$

The above equation (11) will of course reduce to equation (8) of Section 19, if $I_h = O$. This equation is rigid, and no simplifications have so far been made. It can not, however, be used in its present form due to the presence of the unknown angle β, which must now be eliminated.

To get rid of β, draw the line $N P$ perpendicular to $N R$. By inspection, angle $L N P = 90° - \psi$. Let angle $P N I = \Delta$. Then $\beta = \Delta + (90 - \psi)$.

$$\text{Therefore} \quad \tan \beta = \frac{\tan \Delta + \cot \psi}{1 - \tan \Delta \cot \psi} \quad (12)$$

This equation gives β in terms of the constant of our circuit, ψ, and the unknown angle Δ, which will now be evaluated. Tan Δ is the slope of the line $N P$, which is by hypothesis perpendicular to $N R$, or E_h. The solution will therefore consist in finding the expression for E_h and tan Δ will be the negative reciprocal of its slope.

From the figure, it will be seen that

$$\dot{E}_0/n = \dot{E}_{r2} + \dot{E}_h + \dot{E}_q \quad (13)$$

where $\dot{E}_{r2}$ is the voltage across r_2, or $T R$. Therefore

$$\dot{E}_h = \dot{E}_0 - \dot{E}_q - \dot{E}_{r2} = \dot{E}/n - \frac{n-1}{n} \dot{E}_q - \dot{E}_{r2} \quad (14)$$

$$\dot{E}_{r2} = r_2 \dot{I}_p = \frac{r_2 C_2 \omega (r_2 C_2 \omega - j\, 1) \,.\, \dot{E}_p}{M_2} \quad \text{See (7)} \quad (15)$$

$\dot{E}_{r2}$ may therefore be obtained by substituting $\dot{E}_p$'s value from (9) in (15). $\dot{E}_h$ may then be obtained by substitution of (3), (6) and (15) in (14).

As stated above, tan Δ is the negative reciprocal of the slope of E_h, and if the above process be carried out, it will be found that:

$$\tan \Delta = - \frac{\begin{gathered}2 M_1 E \cos \varphi - (2n - 2 + n r_2^2 C_2^2 \omega^2)(I r_1 \ldots \\ \ldots + I_h r_1 \cos \beta - I_h r_1 \,.\, r_1 C_1 \omega \sin \beta) \ldots \\ \ldots - 2 M_1 E r_2 C_2 \omega \sin \varphi + \ldots \\ \ldots + (n-2) I r_1 \,.\, r_1 C_1 \omega \,.\, r_2 C_2 \omega \ldots \\ \ldots + (n-2) I_h r_1 \,.\, r_1 C_1 \omega \,.\, r_2 C_2 \omega \cos \beta \ldots \\ \ldots + (n-2) I_h r_1 \,.\, r_2 C_2 \omega \sin \beta\end{gathered}}{\begin{gathered}2 M_1 E \sin \varphi - (2n - 2 + n r_2^2 C_2^2 \omega^2) \ldots \\ \ldots (I r_1 \,.\, r_1 C_1 \omega + I_h r_1 \,.\, r_1 C_1 \omega \cos \beta + I_h r_1 \sin \beta) \ldots \\ \ldots + 2 M_1 E r_2 C_2 \omega \cos \beta \ldots \\ \ldots - (n-2) I r_1 \,.\, r_2 C_2 \omega \ldots \\ \ldots - (n-2) I_h r_1 \,.\, r_2 C_2 \omega \cos \beta \ldots \\ \ldots + (n-2) I_h r_1 \,.\, r_1 C_1 \omega \,.\, r_2 C_2 \omega \sin \beta\end{gathered}} \quad (16)$$

If the value of tan Δ from (16) is substituted in (12), and the resultant value of β is substituted in (11), a rigid equation of the power factor as measured by this zero method will be obtained, as no approximations have been introduced so far. Unfortunately, the complicated expression for tan Δ does not collapse if this is done, and therefore the rigid solution if obtainable would have no practical value due to its complexity. It will therefore be necessary to introduce approximations at this point. The method of solution will therefore be to simplify the expression for tan Δ. This will in most cases introduce no appreciable error, for β itself is not a very important part of equation (11).

Examination of the various terms of (16) shows that it is made up of quantities of very disproportionate magnitudes. E is very large, while I_h, $r_1 C_1 \omega$, $r_2 C_2 \omega$, cos φ, and sin β are very small. Sin φ, cos β and M_1 are close to unity. The first term in the denominator of tan Δ reduces to $2 E$, which is very large, while all the other terms contain at least one of the very small quantities. The entire denominator may therefore be taken as $2 E$. The first term in the numerator is $2 E \cos \varphi$, which contains one of the small quantities. All terms containing two or more of the small quantities may therefore be dropped. We may therefore state that:

$$\tan \Delta = - \cos \varphi + \frac{(n-1)(I + I_h) r_1}{E} + r_2 C_2 \omega \quad (17)$$

Some of the terms dropped may however become significant if n is very large. Inspection of the figure, especially when it is elongated to its practical proportions shows that β must be a very small angle. We may therefore substitute (17) in (12) as follows: Since tan Δ cot ψ is negligible:

$$\tan \beta = \sin \beta = - \cos \varphi + \frac{(n-1)(I + I_h) r_1}{E} + r_2 C_2 \omega + \cos \psi \quad (18)$$

and $\cos \beta = 1$.

The substitution of these values in (11) will give a complicated but very accurate equation for cos φ. For all practical purposes however, the equation may be still simplified by taking sin φ as unity and dropping the term $r_1 C_1 \omega \,.\, r_2 C_2 \omega$ and thereby obtain the following final equation:

$$\cos \varphi + (I_h/I) \cos \psi + (1 + I_h/I) r_1 C_1 \omega + (1 + I_h/I) \frac{[n I_h - (n-2) I] r_1}{2 E} = r_2 C_2 \omega \quad (19)$$

Before applying this formula to the measurement of extremely small samples, consideration should be given to whether or not $\sin \varphi$ may be taken as unity and $r_1 C_1 \omega \cdot r_2 C_2 \omega$ may be dropped. If this is not justifiable, the procedure outlined in the paragraph should be adopted. Large values of n may also introduce errors in $\sin \beta$ in its approximate form.

Equation (**19**) has been also independently derived by an entirely geometric method directly from the vector diagram, on the assumption that the angles are so nearly zero (or 90 deg. as the case may be) that the sines of large angles and cosines of small angles may be taken as unity.

A similar method of procedure for the case of measurement in parallel of two specimens of different power factors, $\cos \varphi_1$ and $\cos \varphi_2$, and different charging currents, I_1 and I_2, gives the following equation which is sometimes of value.

$$\frac{I_1 \cos \varphi_1}{I_1 + I_2} + \frac{I_2 \cos \varphi_2}{I_1 + I_2} + \frac{I_h}{I_1 + I_2} \cos \psi$$

$$+ \left(1 + \frac{I_h}{I_1 + I_2}\right) r_1 C_1 \omega + \left(1 + \frac{I_h}{I_1 + I_2}\right)$$

$$\frac{[n I_h - (n-2)(I_1 + I_2)]\, r_1}{2E} = r_2 C_2 \omega \quad \mathbf{(20)}$$

The derivation of the general equation for the electrometer used as a deflecting instrument, given in (**4**) of Part I of this paper, will not be developed due to similarity to the above derivation. The method used was to find E_q which is exactly the same as (**6**) of the zero method in this section, and finding the effective needle voltage E_n which is the same as E_p given in equation (**9**) of the zero method. $K d$ then equals the scalar product of these two complex quantities and an equation is obtained which contains the unknown angle β. β is then eliminated by a method similar to that used above, though somewhat simpler, and equation (**4**) of Part I of this paper is obtained.

Part III—Experimental

21. DESCRIPTION OF APPARATUS, SOURCE OF POWER

The variations in frequency and voltage on the lines of the local Central Station were too great to permit of the accurate electrical measurements required. These variations especially when combined with the effect of factory vibration on the instruments made rapid observations impossible. The wave form also departed from that of the sine wave.

In view of this condition, a complete outfit was installed for the production of high-voltage alternating-current of constant voltage, constant frequency, and good wave-shape. Two motor generator sets were used. The first of these consisted of a 10-h. p., 2-phase, 440-volt, 60-cycle, squirrel-cage induction motor, direct-connected to a 5.5-kw., 125-volt, direct-current compound-wound generator. In the second set, a -h.p., 1700-rev. per min., 110-volt direct-current shunt-wound motor was direct connected to a 5.0/2. kw., 3-phase 220/110-volt, 60/25-cycles, 1800/750-rev. per min. special sine-wave generator. Central station service was used to supply the alternating-current induction motor of the first set through a starting compensator, fuses, relays, etc. The direct current obtained from the generator of this set was used to supply the direct-current motor of the second set and the alternating current obtained from one phase of the sine-wave generator was used to feed the primary of a 5-kv-a., 110/220-50,000-volt, 60-cycle single-phase testing transformer of special design. This transformer was provided with taps at ½, ¼ and ⅛ voltage.

In order to obtain greater constancy of voltage and frequency of the sine-wave alternating current, a Tirrell voltage regulator was connected to the d-c. generator and a small speed regulator was mounted on the shaft of the d-c. motor. By this means the variations were reduced to a very small amount. Table I gives a comparison of the wave shape of the sine-wave generator at no load and at full load and zero power factor, as compared with a sine-wave.

TABLE I

	No Load Ordinates		Full Load Unity Power Factor Ordinates		Full Load Zero Power Factor Ordinates	
Degrees	Voltage Wave	Equivalent Sine-wave	Voltage Wave	Equivalent Sine-wave	Voltage Wave	Equivalent Sine-wave
0	0.00	0.00	0.00	0.00	0.00	0.00
15	2.50	2.58	2.57	2.58	2.50	2.58
30	5.02	5.00	5.03	5.00	5.00	5.00
45	7.12	7.07	7.08	7.07	7.18	7.07
60	8.70	8.66	8.62	8.66	8.72	8.66
75	9.66	9.66	9.65	9.66	9.75	9.66
90	9.85	10.00	10.05	10.00	9.90	10.00

The maximum deviation of the voltage wave from the equivalent sine-wave is only about 3 per cent.

QUADRANT ELECTROMETER

The design of the instrument as constructed in the laboratory of the Standard Underground Cable Company is of marked simplicity. The base which consists of a large iron casting 20 inches in diameter is supported on three legs which serve for leveling screws. This base in turn supports another casting, or sub-base on ball bearings. This sub-base which carries the entire instrument is centered and free to turn, thus providing adjustment of the instrument with respect tothe scale. On a glass plate 18 inches in diameter, ¼-inch thick supported on three steel rods ¾ inches in diameter, screwed into the sub-base, rests the upper portion of the instrument from which the moving system is suspended. Lateral and vertical motion of this upper portion on the glass plate permits of centering of the needle in the quadrants. The needle can also be made to take up any desired position in the quadrants

by revolving this portion of this instrument on its axis. The needle is constructed in the shape of a figure eight, the major axis being 6⅝ inches and the maximum width 3⅜ inches. It is made of thin sheet aluminum with an edge formed of ¼-inch aluminum tubing. The suspension is a phosphor bronze strip 12 inches long and about 20 by 2 mils in cross-section. A small frame soldered to the lower end of the suspension carries a mirror with one meter radius of curvature, used to reflect a beam of light on a 50-centimeter glass scale. The quadrants are of cast aluminum. They were made by putting a 2-inch hole in the center of two aluminum disks 14¼ inches in diameter, and then cutting each of them into four equal sectors. The quadrants are supported on glass, the nearest points of support being 3 inches apart. The spacing between the upper and lower quadrant is 2 inches and between adjacent quadrants 1/16 inches. Damping is accomplished by means of a light aluminum vane moving in a cup containing a mixture of glycerin and water. The damping cup is supported on a glass plate which is provided with leveling screws resting on the sub-base.

The sensitivity of the instrument may be defined by stating that the constant of the instrument, K, is about 3500.

The Quadrant Resistances, r_1

These resistances aggregating 210,000 ohms were all Curtis wound non-inductive units. Two boxes containing 100,000 ohms each in 10,000 ohm steps and a third box, containing 10,000 ohms in 9 steps of 1000 ohms, 9 of 100 ohms and 10 of 10 ohms were used. This arrangement permitted a very fine adjustment. These boxes were mounted on a table at the right of the electrometer scale and were completely surounded by a grounded metallic shield, through which protruded long, hard rubber tubes fastened to the dials and provided with pointers running over numbered scales to permit of reading the resistance setting from the outside of the shield. A positive "click" on all boxes prevented possibility of error.

The Potential Resistances, r_2

A three-dial decade box with 9 steps of 1000 ohms, 9 steps of 100 ohms, 10 steps of 10 ohms and a 50,000 ohm box containing 10 steps of 5000 ohms were used for the potential resistance. These resistances were also Curtis wound non-inductive and were surrounded with a metallic shield connected to the transformer terminal supplying the needle voltage. They were suspended upside down over the observer's head and were provided with long handles, scales and pointers, similar to those on the quadrant resistances.

The Potential Condenser, C_2

A 12,000-volt Dubilier condenser with a capacity of about 40×10^{-10} farads was used for C_0. The capacity of this condenser, was not, however, taken as C_2 in the equations as C_2 must be the capacity which determines the entire current through r_2. This capacity includes the Dubilier condenser, the capacity to ground of the guarded lead from the resistance box to the needle and the capacity from the needle to the quadrants and the electrometer housing, which when determined by measurement of the current at 7000 volts came out 42.13×10^{-10} farads. Before the sine-wave generator was installed, the value of C_2 varied considerably depending upon the amount of potential resistance r_2 in the circuit. This variation was probably due to the damping out of some of the harmonics by resistance. It was therefore necessary to plot a curve showing the value of C_2 as a function of the value of r_2. With the sine wave generator, however, the value of C_2 as calculated from the total impedance of this circuit, the voltage and the charging current, came out practically a constant independent of the value of r_2.

The ratio of transformation of the transformer as furnished by the manufacturer was exactly 110/50,000 and this ratio was used to determine the secondary voltage. The primary voltage was read on standardized electrodynamometer voltmeters and was controlled by a resistance in the field of the sine wave generator. Frequency was read on a carefully calibrated Frahm vibrating reed instrument with 1/2 cycle reeds.

Three methods of measuring current were used. In the first method the voltage drop across the quadrant resistances was measured by a Kelvin 0-110 volt multicellular electrostatic voltmeter, connected through a mercury switch. A double-pole single-throw switch in the quadrant leads served to disconnect the quadrants, thus avoiding the small error due to the charging current between the high and low quadrants; and a double-pole, double-throw highly-insulated switch served to connect the electrostatic voltmeter either across the resistance or across a standardized electrodynamometer voltmeter supplied with current from the sine wave generator. Rapid and accurate calibration of the electrostatic voltmeter was thus obtained. Two highly sensitive vacuum thermocouples and a Paul microammeter and a specially constructed milliampere current transformer with a very sensitive ammeter were used in the second and third methods. These served principally as a means of checking the value of current as determined by the first method.

Air Condensers

Two air condensers of practically zero loss were available. Air condenser No. 1 was composed of 4 parallel galvanized iron plates about 3 feet square and separated by about 2 inches. The two inner plates were connected together forming the high-voltage electrode and the outer two plates also connected together formed the low-voltage electrode. The low-voltage plates were in two sections, the central ones of about 4 square feet in area forming the low-voltage

plates proper, and the outer ones the guards. Hard rubber strips securely fastened to both sections served as a means of support for the inner sections. The entire condenser with the exception of three small holes, one for the high-voltage lead, one for the low-voltage lead and one for connection to the guard electrode, was surrounded by a grounded metallic screen in order to shield the low-voltage electrode and to make its capacity to ground definite and constant. Voltages up to 20,000 were applied to the condenser without flashover and no ionization could be detected as high as 17,000 or 18,000 volts. These facts in connection with the careful guarding led us to believe that the losses in the condenser at 7000 and 14,000 volts were extremely small.

The other condenser, No. 2, of later and better design, was cylindrical in form. Two concentric copper tubes formed the electrodes. The inner one or high-voltage electrode was three inches in diameter. The outer tube was in three sections, the central one being the low-voltage electrode and the outer two the guard rings. The separation used was 1/8 inches. The entire condenser was surrounded by a heavy copper tube with steel caps at both ends and suitable high and low-voltage terminals. This condenser was always operated under 100 pounds pressure of CO_2 in order to cut down any loss due to ionization. Due to the general design, the presence of CO_2 and the absence of solid dielectric between the high and low-voltage plates, both being supported by the guards we believe the losses in the condenser to be practically zero at 14,000 volts.

22. Experimental Check of the Measurement of Capacity

In Section 13 a description was given of a method of measuring capacity by shunting the unknown condenser between the high quadrant and ground. This method was used to measure C_a, C_b and C_c of air condensers Nos. 1 and 2.

In the case of A C No. 1 (A C will be used for air condenser), the procedure was as follows: 14,000 volts was impressed on A C No. 2 alone, using one half voltage on needle, r_1 = 100,000 ohms, $f = 60$, and the resultant deflection was brought to zero by a value of r_2 = 18,600 ohms, $r_2 C_2 \omega$ was equal therefore to 0.02955. With the high voltage impressed on A C No. 2, the various electrodes of A C No. 1 were then connected between the high quadrant and ground as indicated in Table II, which gives the connections, the value of potential resistance required in each case to bring the deflection back to zero, and further calculations shown in columns 3 and 4. Column 4 refers specifically to the right hand side of equation (19), Section 13.

It will be noted by comparison with Fig. 6, that the readings shown in the above table measure in each case the sum of two capacities, which are: $C_a + C_b$, $C_b + C_c$, and $C_c + C_a$ respectively for the three readings.

TABLE II

Connections of A C No. 1 (1)				
To High Quadrant	To Ground	r_2' (2)	$r_2' C_2 \omega$ (3)	$(r_2' - r_2)x$ $C_2 \omega$ (4)
h-v electrode	l-v electrode and guards	31,600	0.05019	0.02064
h-v and l-v electrodes	guards	33,630	0.05342	0.02387
l-v electrode	h-v electrode and guards	31,100	0.04940	0.01985

Now $I_h = 30 \times 10^{-6}$ amperes, $I = 0.565 \times 10^{-3}$ amperes (A C No. 2 being the load in this case), and therefore $1 + I_h/I = 1.053$. Substituting all these values in equation (19), we find that:

$$C_a + C_b = 5.197 \times 10^{-10} \text{ farads}$$
$$C_b + C_c = 6.008 \times 10^{-10} \text{ farads}$$
$$C_c + C_a = 4.997 \times 10^{-10} \text{ farads}$$

We have therefore that $C_a = 2.11$, $C_b = 3.10$ and $C_c = 2.90$, all in 10^{-10} farads.

The charging currents corresponding to the C_a and C_b capacities of A C No. 1 were also measured by means of a non-inductive resistance shunted by a low-voltage electrometer, from which we obtain by calculation that $C_a = 2.1$ and $C_b = 3.0 \times 10^{-10}$ farads, giving a close check. The value of C_c could not be measured by this means as the air condenser would not stand a high enough voltage between the low-voltage plates and the guards.

A C No. 2, the voltage being impressed on A C No. 1, gave the following values of capacity:

$$C_a = 1.07 \times 10^{-10} \text{ farads}$$
$$C_b = 0.35 \times 10^{-10} \text{ farads}$$
$$C_c = 5.2 \times 10^{-10} \text{ farads}$$

These values are the results of numerous measurements and are checked by charging current readings, minor variations of as much as 2 per cent being averaged out in the values given above, which will be used in the following sections.

23. Check of General Equation (7) by Six Readings

Equation (7) of Section 3 is of course the fundamental and basic equation of this paper. The main distinction between it and the old equations which neglect the needle charging current, is a series of terms containing the ratio of needle charging current to load current. In order to check equation (7), therefore, it is necessary to have two condensers with as small a capacity as is practicable with the sensitivity of our instrument, in order to make I_h/I as large as possible, and the two should have different capacities in order to have a sufficient number of equations.

We therefore performed a series of measurements on our two air condensers in various connections and at different voltages. In all the following cases the low-voltage electrodes of both condensers were permanently

connected to the high quadrant. $r_1 = 100{,}000$ ohms and $f = 60$. Table III shows the connections and voltages of the two readings.

TABLE III

Reading Number (1)	Connections: High Voltage on (2)	Voltage (kv.) on Load (3)	Voltage (kv.) on Needle (4)	C_1 (5)	$1 + I_h/I$ (6)
1	A C No. 1 & A C No. 2	7	7	$8.10 + C_x$	1.0357
2	A C No. 1	7	7	$8.364 + C_x$	1.0539
3	A C No. 2	7	7	$9.355 + C_x$	1.0626
4	A C No. 1 & A C No. 2	14	7	$8.10 + C_x$	1.0179
5	A C No. 1	14	7	$8.364 + C_x$	1.0269
6	A C No. 2	14	7	$9.355 + C_x$	1.0531

It will be noted that $n = 1$ for the first three readings and $n = 2$ for the last three. We know I_h, and the charging currents of the condensers, and can therefore obtain the term $1 + I_h/I$ as shown in column 6, remembering that for readings 1 and 4 the charging current is the sum of the charging currents of the two condensers. We know the capacity to ground, C_1, except for the instrumental capacity to ground. In readings 1 and 4 the capacity to ground in addition to the instrumental capacity is the sum of the C_c capacities of A C No. 1 and A C No. 2. In readings Nos. 2 and 5 it is the same only increased by the C_{ab} of A C No. 2, while in readings 3 and 6 the capacity is the same as in readings 1 and 4 except that it is increased by the C_{ab} capacity of A C No. 1.

Referring first to readings 1, 2 and 3, the general equation in the form of equation (**9**) of Section 3 applies directly to readings 2 and 3, while equation (**20**) of Section 20 applies to reading 1 where the load is composed of two condensers. We may safely assume that the power factor of A C No. 2 is zero. There are therefore three unknowns in the equations namely $\cos\phi$ of A C No. 1, $\cos\psi$, and that part of the total capacity to ground which is due to the instrument, quadrant resistance, and leads, which will be called C_x. We have three equations and three unknowns and can therefore solve. The three equations are very closely satisfied by $\cos\varphi = O$, $\cos\psi = 0.00484$, and $C_x = 2.513 \times 10^{-10}$ farads.

Referring now to readings 4, 5 and 6, equation (**20**) of Section 20 applies to 4, while equation 8 of Section 3 applies to readings 5 and 6. There is an additional unknown, $\sin A$, introduced here, but we may substitute the values of $\cos\varphi$, $\cos\psi$ and C_x in three equations, and obtain three solutions for $\sin A$, which give as an average $\sin A = -0.0008$.

The easiest method of demonstrating the accuracy of this determination is to substitute all these values in equation (**7**) of Section 3 and calculate r_2. A comparison of these calculated values of r_2 with the actual values of potential resistance used will show the accuracy of the equations, according to Table IV:

TABLE IV

Reading	Potential Resistance r_2: Actual Value used	Potential Resistance r_2: Value Calculated from Equation (7)	Error: Ohms	Error: Per cent
No. 1	30,200 ohms	30,252	+ 52	+ 0.17%
" 2	30,080 "	30,191	+ 111	+ 0.36
" 3	33,040 "	33,046	+ 6	+ 0.02
" 4	25,350 "	25,324	− 26	− 0.10
" 5	26,260 "	26,262	+ 2	+ 0.01
" 6	29,290 "	29,472	+ 182	+ 0.62

The maximum error is 0.6 per cent. This is really quite accurate if the sensitivity of our electrometer is considered.

24. Check of Actual Power Factor Measurements

The ability of the instrument to measure power factor by the zero method was investigated by measurements on an artificial load whose power factor could be readily calculated. This load consisted of an air condenser in series with a variable non-inductive low-capacity resistance placed in the high-voltage lead of the condenser in order not to change the capacity to ground for the various readings. This resistance was completely shielded thereby introducing a small shunting capacity around the resistance which both calculation and test showed to be negligible. Five power factor readings were made with air condenser No. 1 and five with No. 2, each reading requiring two balances, one with the resistance short-circuited and one with the desired amount of resistance cut in. As equation

TABLE V
ARTIFICIAL LOAD OF AIR CONDENSER NO. 2 IN SERIES WITH RESISTANCE

Impressed Voltage = 14,000 r_1 = 100,000 ohms
Needle Voltage = 7,000 f = 60 cycles

(8) of paragraph 3 applies to these readings, the power factor for each reading can be obtained by subtracting the $r_2 C_2 \omega$ with short-circuited resistance from the $r_2 C_2 \omega$ with resistance cut in. The actual watt loss measured is equal to the square of the current through the resistance in the high lead times the value of that resistance. The current flowing through the resistance in the high lead is made up of two parts, one due to the C_a capacity of the condenser, the other to the C_b capacity, since the guards were grounded. The calculated power factor of the artificial load is therefore $r\ (C_a + C_b)\ \omega$, where r is the resistance in the high lead.

The foregoing two tables give the results of the power factor measurements, the resistance in the high lead being shown under the load.

Discussion

S. J. Rosch: I would like to ask the authors concerning the limitations of the apparatus and the measurements. For example, can we use it on 22,000 or 33,000 volt cable?

If I remember correctly, Mr. Brown referred to a limitation of 0.3 watt, in other words he claimed to have measured as high as 0.3 watt. If we take the care of a 33,000 volt cable and measure its dielectric loss at say 80° or 90° centigrade, the power factor of a good cable at that voltage and temperature would run about 3 to 4 per cent and the corresponding loss would amount to approximately one watt per foot.

I am also under the impression that the value of this paper would have been enhanced considerably, had the authors given some relative data on measurements obtained with both the quadrant electrometer and the dynamometer wattmeter methods. Curves of this nature would in my estimation, have given a better conception of the value of the method advocated.

D. M. Simons: Mr. Doyle and Mr. Rosch both bring up the question of our not having shown any actual measurements of losses in cables. We did not believe that the present paper was an appropriate place for showing data of this kind, since this is an article on an instrument rather than on cables, and our only interest was in losses which we could measure and which we could also calculate, and thereby check the accuracy of our equations.

The method Mr. Doyle shows is very interesting. The more methods we have the better off we are, in measuring the extremely low losses which are difficult measurements at best. I might add that in our company we have two separate methods: in our Perth Amboy laboratory we have a special bridge for measuring losses, and in Pittsburgh we use the quadrant electrometer. It is very convenient to be able to check measurements made by two such different methods.

In reply to Mr. Doyle's question, we have used the electrometer practically entirely for research work, and not for routine measurements; we have used it almost entirely on single-phase work. Seven or eight years ago, however, we made three-phase measurements with the electrometer, using the deflection method. It of course might be used equally advantageously with the zero method.

Mr. Rosch asked whether the electrometer may be used for measuring losses in reels of 22,000-volt and 33,000-volt cables, especially at the high temperatures. This question was apparently asked particularly because we showed in our tables the results of measuring extremely small losses. The electrometer can, of course, be used very conveniently for the measurement of larger losses and higher power factors, and, in fact, in these cases some of the difficulties mentioned in our paper practically disappear, the effect of the shunting capacity and needle current being negligible, and the measurements can usually be made with extreme ease and rapidity. In other words, the same instrument used to measure a 10th or 100th of a watt at low power factor can easily measure kilowatts, the only requirement being that considerably lower values of quadrant resistance will be required.

Recent Advances in the Design, Manufacturing and Testing of Static Condensers in Power Sizes

BY R. E. MARBURY
Asscoiate, A. I. E. E.
Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Review of the Subject.—*The static condenser is particularly desirable as a power factor corrective device since it requires no attention. To fully capitalize this advantage static condensers must be reliable.*

The reliability of insulation subjected to a constant potential stress, depends on the ratio between the working stress and the disruptive stress.

This ratio has been kept large in all electrical apparatus and years of successful use have followed.

Static condensers are described, which have been designed with insulation factors of safety such as have proved dependable in other apparatus for years.

These ratios have been maintained and the product still kept on a reasonable commercial basis by increased economy in construction and use of material and by accurate check of insulation quality in every unit.

* * * * *

A STATIC condenser is a device for storing electrostatic energy. It is similar in characteristics to an inductance, which stores electromagnetic energy, except that the energy stored and returned to the line is 180 deg. out of phase with the energy stored and returned by an inductance.

The static condenser is an ideal device for compensating for the lagging power factor of inductive loads since the energy for the magnetic field is stored locally as it is released, and is returned at the proper time to rebuild the magnetic field. The line is thus relieved of the need for handling anything but power current.

Wherever insulation is subjected to a potential stress

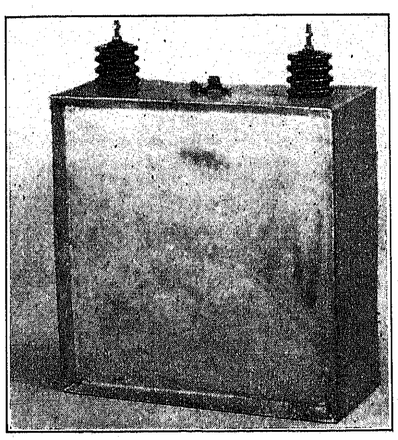

FIG. 1—2 KV-A., 2300 VOLT, 60-CYCLE CONDENSER UNIT TYPE "L. D."

Case dimension 6" x 13½" x 13½". Working stress 145 volts per thousandth of an inch.

as is the case with all electrical apparatus, a static field is established therein. If this potential stress is alternating, electrostatic energy is stored and returned to the source every half cycle. Insulation has been used for years to space electrically current carrying parts. In most cases its function is not only an electrical separator, but also a mechanical separator. Often times the mechanical stresses control the design of insulation, especially where large bodies of metal come in contact with it while expanding and contracting, or when it is subjected to bending or vibration. In addition to the mechanical and electrical stresses placed upon it, it is usually called upon to operate at relatively high temperature. Because in most apparatus, such as transformers, motors and generators, the insulation cost is relatively low as compared with that of other materials, and because the cost of assembly is great, high working stress for the insulation results in little saving in unit cost, while the occasional failure introduced causes a considerable contingent loss. The condition for greatest manufacturing economy for such apparatus is thus the use of low working stress for the insulation.

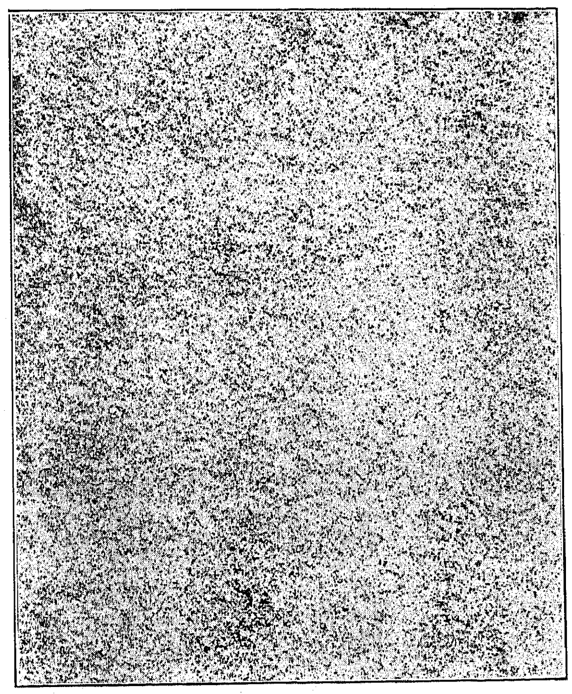

FIG. 2

electrostatic energy as in the case with a condenser, the whole situation changes. Here the only active material is the insulation. All accessories such as bushings, case, packing, etc., contribute nothing toward the storing of energy. The insulation, therefore, must for best economy, be worked at or near the maximum safe stress over the entire area.

Early in the development of condensers it was recognized that the conditions under which insulation is used in condensers are more favorable than in other electrical apparatus. The condenser units for power factor correction consist of four stacked sections connected in parallel and assembled in a vacuum tight sheet steel case having one opening for impregnation.

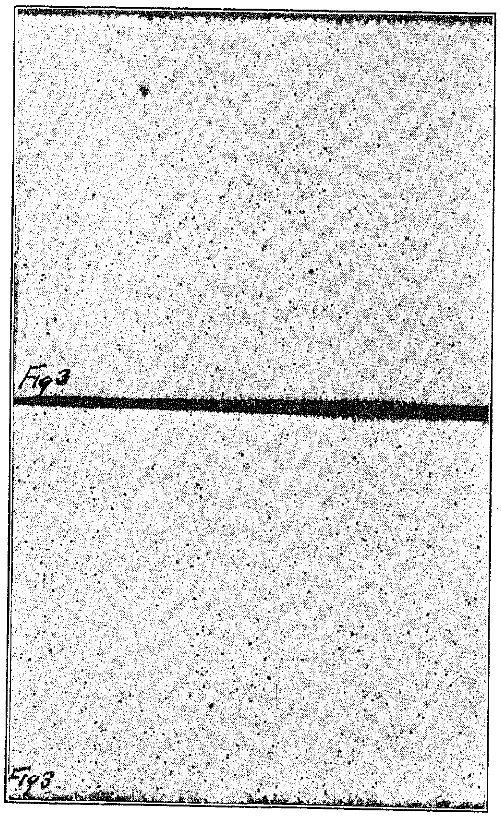

Fig. 3

Samples showing holes in the average thin paper manufactured carefully to be as free of holes as possible.

The sections are made by the inter-leaving paper and metal sheets, alternate sheets of metal extending in opposite directions and soldered to form opposite polarity terminals. Conductors are smooth plates, with no mechanical vibration or bending. Moisture can be more easily removed, thorough impregnation effected and low losses obtained. The operating temperature of the material is very low since the only losses are dielectric losses. The units are entirely filled with oil and sealed, this preventing air or water from entering the insulation during shipment. Early attempts to capitalize on these more favorable conditions led to the construction of condensers designed to work at voltage stresses many many times greater than those used in other apparatus. Laboratory samples have been made to operate thousands of hours at 1100 volts per thousandth of an inch, while commercial units designed with stresses of 400 volts per thousandth of an inch have operated over long periods of time.

When such high dielectric stresses are used, a number of manufacturing difficulties arise. For

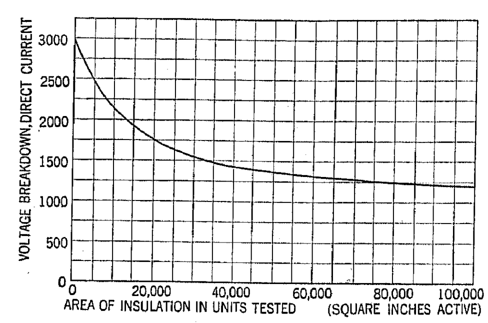

Fig. 4

relatively low voltages such as 2300 high stresses mean thin dielectrics between plates. Thin dielectrics with high stresses necessitate utilizing the barrier action of the paper to increase the ultimate strength far beyond that of the oil alone. In order to make use of the barrier action of the paper over large areas of insulation

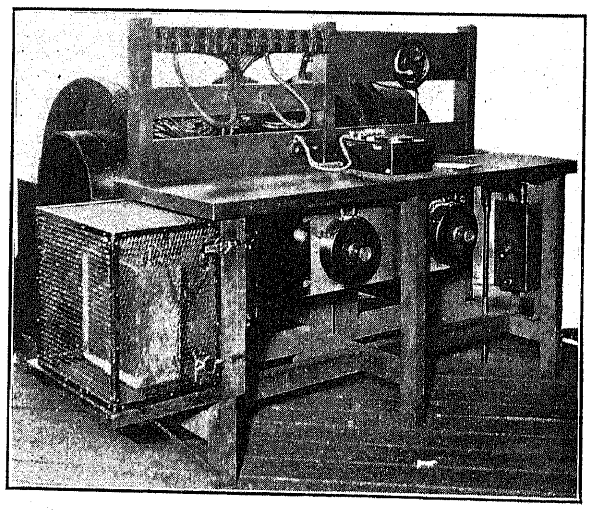

Fig. 5

practically perfect paper is required. The quality is, therefore, largely dependent on porosity in this case.

In addition to the structural requirements the paper must be practically free from metal particles since with very thin dielectric material the size of the conducting

particles is quite comparable to the dielectric thickness and the percentage increase in stress on the insulation where they occur is very great. The difficulties encountered due to metal particles lining up and reducing the breakdown or due to porous paper, increase with the size of the units due to a law of averages and the size of units that can be manufactured on the high stress basis is very limited.

The net result of the early development work using very high stresses showed that it is possible to over capitalize on the more favorable conditions and that we should not lose sight of the practical conditions that have caused us to choose the conservative insulation stresses used in other apparatus. Certain tests have been established which are conceded to insure a sufficient factor of safety for insulation in ordinary apparatus. These tests are based not only on the operating voltage, but also take account of abnormal overvoltage and surge conditions which occur in service. Since the condensers are to operate under conditions very similar to those on which the established tests are based, it is clear that condensers which pass these tests will have the same factor of safety as other apparatus so tested.

It has been found that, due to the high quality of insulation that can be put into condensers less insulations can be used to meet these established test requirements, than in the case of other apparatus. The standard test applied to all static condensers of our present design is 2¼ times normal operating voltage plus 2000 volts for one minute. Advantage has been taken of the more favorable conditions under which condenser insulation is worked, only to the extent that, while the standard test requirements have been met, it has been done by using less insulation and working with higher dielectric stresses than would

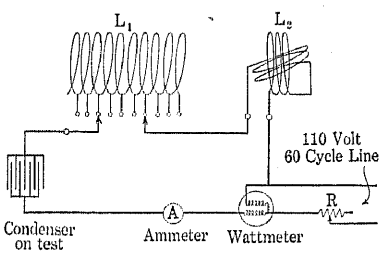

FIG. 6
Diagrams of connections of dielectric loss measuring equipment.

be desirable under the conditions with ordinary power apparatus. Moreover a much greater factor of safety is obtained due to the high quality of material as will be seen from the fact that the average 2300-volt condenser breaks down at 12,000 to 18,000 volts.

The use of large amounts of working material necessary to these low stresses has been made economically feasible by refinements in design which eliminate all unnecessary material and accessory parts as well as the reduction of cost of the paper itself. Since condensers are practically all insulation their cost is directly proportional to the insulation cost and a minimum can only be obtained by using material that gives maximum dielectric strength per dollar invested in insulating material. This does not necessarily mean that the most expensive material is the most economical as the electrical quality of the paper does not increase as rapidly as its cost when attempts are made to produce ideal material. When the cost of the material is plotted against electrical insulation value it is found that the

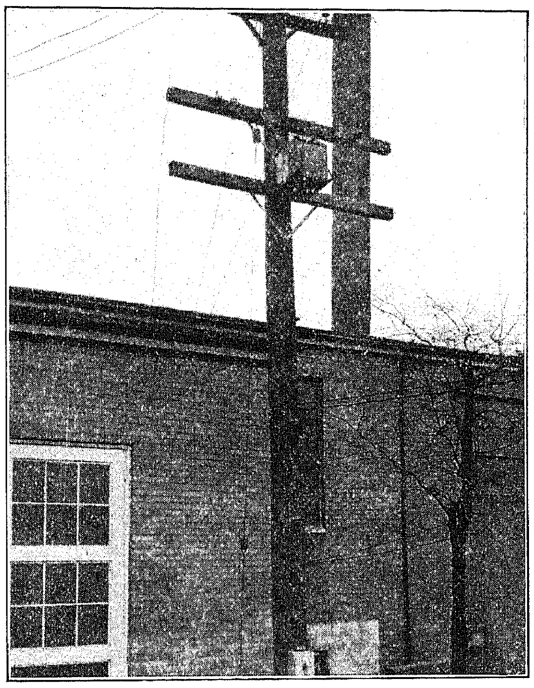

FIG. 7

highly refined materials are not commercially justified and in condensers just as in cable, transformers other apparatus the quality of the material is not so important as the relation between quality and cost. The selection of material is, therefore, an economic study.

An investigation was made as to the exact characteristics required in the paper with the object of reducing the cost due to unnecessary and expensive refinements. This, together with experience over a considerable period has resulted in the use of a very pure wood pulp paper that can be carefully controlled commercially, in so far as foreign materials and quality are concerned.

In carrying out the impregnation of the units, they are assembled along a pipe manifold by means of the pipe thread connection in the center and placed into an oven at 125 deg. cent. Moisture is removed by vacuum and oil is put in while vacuum is maintained. The entire process requires 100 hours. During the treatment over one pound of water is removed from 22 pounds of paper in each 2-kv-a. unit. The process cannot be completed on units having leaks which insure

electrostatic energy as in the case with a condenser, the whole situation changes. Here the only active material is the insulation. All accessories such as bushings, case, packing, etc., contribute nothing toward the storing of energy. The insulation, therefore, must for best economy, be worked at or near the maximum safe stress over the entire area.

Early in the development of condensers it was recognized that the conditions under which insulation is used in condensers are more favorable than in other electrical apparatus. highly refined materials are not commercially justified and in condensers just as in cable, transformers other apparatus the quality of the material is not so important as the relation between quality and cost. The selection of material is, therefore, an economic study.

An investigation was made as to the exact characteristics required in the paper with the object of reducing the cost due to unnecessary and expensive refinements. This, together with experience over a considerable period has resulted in the use of a very pure wood pulp paper that can be carefully controlled commercially, in so far as foreign materials and quality are concerned.

In carrying out the impregnation of the units, they are assembled along a pipe manifold by means of the pipe thread connection in the center and placed into an oven at 125 deg. cent. Moisture is removed by vacuum and oil is put in while vacuum is maintained. The entire process requires 100 hours. During the treatment over one pound of water is removed from 22 pounds of paper in each 2-kv-a. unit. The process cannot be completed on units having leaks which insure

oil tight units when completed. In order to check the degree of moisture removal before running the oil in a test is made for rate of water omission by means of a liquid air trap.

After the units come from the impregnating ovens they are measured for capacity, the exact values being stamped on the nameplates. They are then tested for dielectric losses first to insure that the impregnating process has been carried out properly and second to maintain the quality from the standpoint of power loss in service. After the losses are measured and it is established that the units are of proper quality each is given an over potential test of 2¼ times rated voltage plus 2000 for one minute. This is r. m. s. voltage and the tests are made on 25 cycles to reduce the loss in the metal parts in the condenser.

The average dielectric loss is ½ of 1 per cent of the kilovolt-ampere. There are many ways of measuring

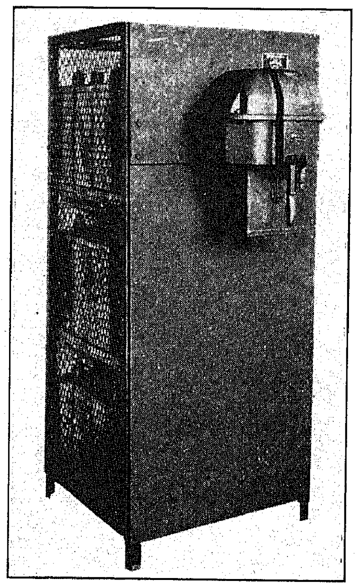

FIG. 8—36-KV-A., THREE-PHASE, 60-CYCLE, 2200-VOLT EQUIPMENT

losses on high voltages at practically zero power factor, but most of them require the use of delicate instruments and extreme care in the handling. For commercial use a method is needed by which every unit can be quickly and accurately measured so that the quality of the product can be closely controlled. The development of such a measuring device has contributed greatly toward the solution of the problem of condenser manufacture.

At the present time such an equipment is in use. The loss is measured under operating conditions with an error of not more than 3 per cent, and less than one minute per condenser is required for the measurement. An inductance of approximately 6 henrys for 2300 volts 60 cycles and having only about twice the loss as the condenser, is connected in series with the condenser to be tested. A 60-cycle voltage is applied and a portion of the inductance which is constructed as a variometer is adjusted so that the whole circuit has roughly unity power factor. The current is adjusted so that the condenser operates at its rated kilovolt-ampere and the loss measured by means of an ordinary wattmeter. By reference to the calibration curve of the inductance, the inductance losses are determined

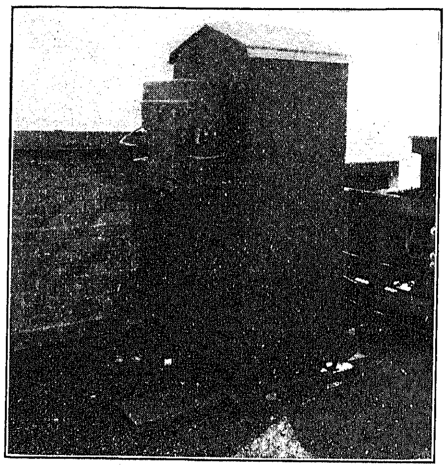

FIG. 9—36-KV-A., THREE-PHASE, 60-CYCLE, 2200-VOLT OUTDOOR INSTALLATION

for the particular current used, and these are subtracted from the total leaving the loss in the condenser.

The inductance was calibrated by means of a pyro-electric wattmeter. This calibration was double-checked by measuring the losses of the inductance and a condenser separately at the low power factors, and then connecting them in series and measuring the

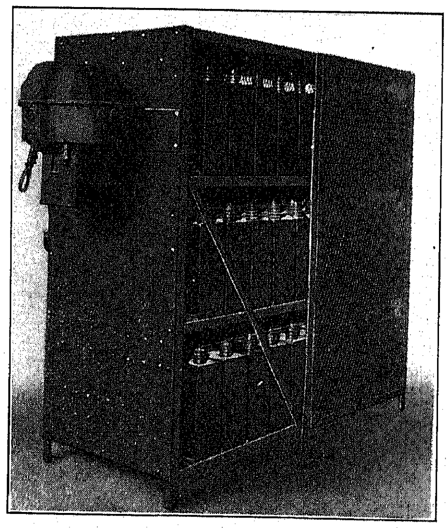

FIG. 10—120-KV-A., THREE-PHASE, 60-CYCLE, 2200-VOLT EQUIPMENT

losses at unity power factor. Extremely accurate tests were made and the sum of the first two checked the third. Such checks were made over the whole working range of the equipment. This establishes the accuracy of the method of measurement.

To meet the various application requirements

assemblies are made of units mounted in structural steel frames and enclosed by expanded metal screens. On the front panel of each is mounted a standard circuit breaker the leads of which connect to vertical bus bars behind the panel. Connections are made between these vertical bus bars and the units with small copper straps to form star, delta or two-phase circuits. The units in the frames are connected to one another by short copper links which may be removed to cut out any desired number of units when seasonal changes of load demand less corrective kilovolt-ampere.

Four standard frame sizes are available for maximum capacities of 36, 60, 96 and 120 kv-a. respectively. These frames are identical except for the depth which varies to accommodate different numbers of units. Larger installations are made up of combination of these standard frames arranged as desired and connected in parallel. This provides great flexibility in application and also permits change of correcting kilovolt-ampere by simply operating the breakers on the individual frames. With large outfits such as 600 and 1000 kv-a. this is very desirable.

Although the obviously large and growing field of application for dependable static condenser equipments has been at times a temptation to begin commercial manufacture prematurely it is now felt that it has been best to delay for complete assurance of quality backed by close control of materials and process with reliable and accurate checks at all stages of manufacture and with test standards for factor of safety of insulation strength which are in general use and which have been proved to insure good service.

Discussion

J. R. Craighead: In any engineering development which leads to the construction of devices of broadly new characteristics, there are usually two stages. The first stage consists in using available materials to produce the device. These materials are rarely exactly adapted to the purpose which they are to serve. The result of this step is usually a costly, heavy, and sometimes unsatisfactory device.

The second stage then must automatically follow. This stage includes the examination of the materials individually, to determine their characteristics, and frequently the development of a better grade of materials to serve the specific purpose more fully. The result of this stage is a device which eventually meets good engineering practise, suitable in cost and in service as related to cost.

In the development of the static condenser for power factor correction, we have completed the first stage and are now reasonably well along in the second stage. Condensers with commercial papers of various thicknesses, various impregnating materials, and various structures (paraffin being at least typical of the general nature of the impregnating materials used) constituted the result of the first stage. These condensers stood up satisfactorily in service under some conditions, but in order to get general satisfactory service from them, it was necessary to reduce the stress per mil in the insulation to the general order of the stress per mil in cables, otherwise they were not permanently satisfactory. The result was that size and cost made the commercial prospect of a condenser that would stand up rather uninviting. Consequently, it became necessary to begin on the second stage.

The second stage consisted of examination of the materials and development of the most suitable. Oil has been very largely substituted for other impregnating materials. We have subjected the type of oil selected to new methods of treatment in order to secure better conditions regarding dryness, purity, and dielectric strength.

Some study has been given to substitutes for paper, of which there is a number available, but the general results indicate the superiority of paper when properly made and applied. We have investigated the manufacture of paper, with a view to perfecting the quality, as to chemical purity, absence of conducting particles, and absence of holes, which tend to cause breakdown.

We have investigated the oil in bulk, as to dielectric strength and considerable improvement has been secured in the quality. We have also investigated this in comparison with the same oil when partially immobilized by the presence of dividing material such as paper.

The result has shown the immense advantage attainable by the use of a number of thin sheets immobilizing the oil very perfectly as compared with a much smaller number of heavier sheets.

The mechanical arrangement of the active parts of the condenser and their relation to electrostatic troubles have also been studied. The results of these studies are embodied in the present condensers which we manufacture.

Regarding Mr. Marbury's paper in detail, it appears to be chiefly a plea for the construction of condensers with a liberal thickness of insulation, as opposed to a construction with insulation of less thickness, but more carefully selected. This is actually a purely commercial question. The factor of safety in the condenser can be made equally great by either means. Consequently, it is not a question of which condenser will break down if the engineering is equally correct in both cases, but it is a question of which condenser will cost the more in the long run, considering first cost, failure or destruction, size of space occupied, and necessary conditions of handling.

Our own experience has indicated the superiority of condensers using a better grade of insulation, when backed up by careful engineering and extremely careful factory practise. We have made considerable investigations along the line of cheaper and more abundant insulation and the results obtainable have not appeared superior to our present method.

Eventual design in condenser practise will be determined by experience in the field rather than by the results of any shop tests that are now available. Meanwhile, the subject is of great interest for discussion before the Institute.

In the last column of page 3, in Mr. Marbury's paper, his language implies the possession of a large amount of interesting data. These data apply to subjects which are not yet by any means fully settled, and it would be of great value if he could contribute some of that to the files of the Institute.

E. K. Shelton: Mr. Marbury's paper calls attention to a development which has become of vast importance in the last few years, due to the intensive consideration given to the problem of low power factor loads. The possibilities in the power factor correction field put the static condenser in a position of importance in the industrial application of electric power.

The development problem involved in the design of static condensers upon analysis is found to be concentrated in the dielectric, its characteristics, treatment, and use. Several references are made in the paper to the advantages of a high working stress, but we are informed that a final selection was made of conservative stresses as used in other apparatus. A working stress of 145 volts per mil is given for the condenser construction as described. As a point of fact, working stresses in other electrical apparatus reach a maximum of 60 volts per

mil so that it is evident a value of 145 volts per mil is already two to three times conservative stresses used in other electrical apparatus. It is further indicated that a wood pulp paper is used. This is a type of paper commonly used in cable and transformer work. Let us see what this question of the selection of the working stress means.

We must keep in mind that the application of static condensers to power factor correction work is largely an economic problem involving reliability, a reasonable initial cost, and the question of size or weight. Reliability obviously must be obtained in any case. The initial cost must be reasonable to permit of a satisfactory return on the investment, else other means of correction will be used or the penalty accepted. Size or weight are factors of importance as this is a device that is added to an existing industrial establishment and must, in the majority of cases, be installed in an already rather completely utilized space. It is quite evident that by mere bulk application of the usual quality of insulating materials as commonly used in other types of electrical apparatus, and with operation at stresses equivalent to those uti ized in such aparatus, condensers can be built that may have reliability but at the expense of size and cost. In considering the advantage gained from the use of a higher stress, it is only necessary to remember that the corrective capacity obtained from a given unit area and thickness of condenser dielectric varies directly with the ratio of the squares of the applied voltages. Thus, an increase of 100 per cent in the working stress on the same dielectric means four times the corrective capacity obtained. If, by the use of a higher quality material, one-half the thickness of dielectric can be used for a given voltage, the same ratio holds, since twice the active area can be obtained in a given volume. This means one-fourth the bulk and weight for a given rating of equipment. Assuming any given economic limitation in size or weight, such an increase in working stress extends the range of application to four times the original limit. Certainly this is argument enough for a real engineering development that such advantages may be realized.

I have been intimately connected with a very extensive development on this same problem. Early work showed that ordinary grades of thin paper were entirely unsuited to this work as they would not give satisfactory results at the higher operating stresses. Such limitation, however, is no argument for retarding real engineering advance on a development of this nature. Paper, while suited for insulation work, was not originally developed with such application in view. Intensive co-operation with the paper manufacturers has already resulted in the production of papers of a quality never before obtained, and this on a basis that makes them entirely available commercially for this work. Conducting particles have been reduced to a very low value. By the selection of the proper materials, a dense paper has been produced that shows a remarkable comparison from the porosity standpoint with the best grades of wood pulp or Kraft papers. Experimental data between 2½ mil wood pulp paper and ½ mil paper of the type developed shows $^1/_3$ to ¼ the porosity for the ½ mil paper. A comparison of five sheets of this ½ mil paper with one sheet of 2½ mil wood pulp paper so that equal thickness is obtained shows approximately 1/15 the porosity for the 5-sheet construction. The advantage gained from the use of such high quality papers is evident. The use of a large number of these thin sheets for a given thickness of dielectric actually decreases the possibility of difficulties due to line-up of conducting particles or holes. A given corrective capacity of condenser with a few sheets of comparatively thick papers means a much larger active area over which this lining up may occur, combined with the greater percentage effect of partial lining up on two or three sheets.

Equally important advances have been made in the treatment of these materials. Methods that are entirely satisfactory when the ordinary stresses in other electrical apparatus are considered, prove utterly inadequate at these higher values, but engineering advances in any line necessarily involve changes and improvement. Advances already made along these lines have shown their value not only to the condenser problem but to the whole art of insulations in general.

Following out this line of development, condensers have been manufactured on a commercial scale that have been in successful operation for periods considerably over a year. 2300-volt units of this type have a breakdown voltage averaging 15,000 so that a factor of safety of approximately 6 is obtained. The normal working stress is 350 volts per mil. In comparison with the 11 pounds of paper per kv-a. required with the 145 volts per mil stress, only one and one-half pounds are used per kv-a. The development work that has already attained such remarkable results has directly benefited the whole electrical art. A definite advance has been made in the direction of more efficient utilization of insulations and in our understanding of dielectric phenomena. The future promises further progress along these lines.

J. E. Shrader: It was my privilege to have done some of the research work along the lines of the development of static condensers when the Westinghouse Company took up this problem, and since I have been called upon, probably something regarding the early work which was done might not be out of place.

It has been realized, not only in the manufacture of condensers, but in all lines of insulation, that the amount of moisture in the dielectric is a factor of very great importance, and also, that to get out the very smallest fraction of the moisture, the dielectric properties are increasingly proportionate.

The early practise was to boil the stacked condenser in oil at atmospheric pressure. This did not appear to me, when I took hold of the problem, to be a very satisfactory method. We first dried the stacked paper condenser in a vacuum at about 125 deg. cent., at which temperature no chemical breakdown of the paper occurred. After prolonged treatment, the oil was admitted into a vacuum space where it was heated before coming into contact with the condenser. This is what we call the spray process. In this process the oil was drawn under vacuum, heated, and allowed to spread through an open space in the vacuum, where it was released in the form of spray. Tests upon this method have shown that not more than a few ten thousandths per cent of moisture was still present. The oil was now introduced into the dried paper and there was no chance of moisture being absorbed in the process.

Any one who has studied the subject knows that by exposure to moist atmosphere, paper or oil will absorb a considerable amount of moisture. For this reason, the condenser was packed inside a vacuum tight vessel and after impregnation it was not again exposed to atmospheric moisture.

C. N. Johnson: The design of the static condenser has been well covered in Mr. Marbury's paper. The problem of the application of the condensers would seem to present a topic for an interesting paper at some future Meeting.

The need of a device for correcting power factor on lines supplying industrial load, is becoming more evident each year. With a reliable corrective device now available, which requires very little energy for its operation, its general use may be expected where a study of conditions shows that the installation cost is justified by the reduction in power losses and improved line condition.

Advances in meter design are keeping pace with the development of corrective devices. At this Meeting a paper is being presented showing some remarkably new developments in metering on a-c. lines. This metering device meets a general demand for a means of indicating the actual kv-a. load, and should bring about a more general use of power factor corrective devices.

Everett S. Lee: In the second column on page 2 of Mr. Marbury's paper we find him making reference to the increased dielectric strength which may be obtained over that of the oil itself by making use of the barrier action, wherein the oil is held

immobile to eliminate that motion which we find in oil in bulk when it is subjected to an electric field.

I think you are probably all familiar with the fact that if you have a bulk of oil and electrodes immersed in the oil, and subject that bulk to an electric field, there will be a motion of the oil; and any imperfections which may be in the oil are brought in the vicinity of the electrodes, with consequent breakdown at a low value.

Now, if we can utilize the principle whereby, if we put barriers in between those electrodes (and in a condenser those barriers are in the form of a number of very thin sheets of material which in turn have been well impregnated with good oil) we get thin films of oil separated by thin sheets of impregnated material, which means that the entire mass is held stationary, as it were, with very small liability of this movement which we find in bulk oil. Of course, we derive greater benefit from that consideration if we use a relatively large number of thin sheets, rather than a relatively small number of thicker materials. Consequently, that is one of the reasons why it seems quite desirable to, as far as possible, make use of that characteristic which we know is true and certain. At the same time, using the larger number of sheets, we decrease the liability of imperfections in the individual sheets lining up in such a way as to cause a path where the dielectric strength may be low.

In speaking of oil, I would call your attention to the fact that care is needed in its use as has been brought out by Dr. Shrader, just as care is needed in the selection of the paper which we employ. During the handling of the oil we must be very careful that it is not brought in contact with the air at such temperatures and in such a way that air may be absorbed by the oil, otherwise, although we so arrange the condenser cases that air may not come in, we still may have some air therein. Also, we must be sure that moisture is not contained in the cases, and that in the treating of the oil at such temperatures as we may use, no deteriorating effects are brought about.

Cooperation between the condenser manufacturer and the manufacturer of the oil has brought about a much better product, just as cooperation between the condenser manufacturer and the manufacturer of paper has brought about a much better product, and this cooperation we feel has been well worth while to the art and to the industry.

I dwell on these points particularly, one reason being the statement made in Mr. Marbury's paper that the loss in condensers, of a manufacture with which he is familiar, is about one-half of one per cent, whereas it is quite easy to obtain losses in the neighborhood of two-tenths of one per cent in condenser units where some of these other factors are not only taken into account, but are actually employed in the design and in the manufacture of the units.

The method of test which Mr. Marbury has outlined seems to have very desirable features, and if the accuracy which he has suggested can be obtained as easily as he has said, it is a method which probably will come into use. I would not, however, have you feel that the use of an electro-dynamometer wattmeter need require a whole laboratory force to take measurements therewith, as we find that it is just as easily possible to use such a wattmeter, following methods which have been outlined for years, I believe first perhaps by the late Dr. Rosa, of the Bureau of Standards. Those methods, together with the use of the dynamometer wattmeter, can be used by factory men in measuring losses in condensers in from one-half to one minute per unit.

I note in connection with the tests, that the test voltages used seem to be those as used in connection with electrical machinery; that is, about two times normal plus a thousand, whereas you may recall that in cables the values are two and one-half times normal for five minutes, rather than for one minute, as in the case of electrical machinery. In other words, there may be variations in the kinds of tests that are applied to different kinds of apparatus, and I believe there is a tendency on the part of many people who are studying these problems at the present time to say: "Perhaps we can get a more suitable test by using the lower values of potential applied for a longer time, rather than the higher values of potential applied for a shorter time;" that is, when the frequencies are at the value for which the apparatus is designed.

It seems that in the art today there is such a need for better insulation that if we can obtain better materials and if we can better the performance of insulating materials through these more refined manufacturing methods, it is much better that we try and do it, rather than to bring the condenser art down to the same level as we find in other types of apparatus. We feel that at the present time there is much more need for more serviceable insulation in other branches of the art than there is in the condenser game, and if, in studying these questions through the manufacture of condensers, we can better the insulation that may be available for other branches of the art, we certainly have gone a step in the right direction, rather than to allow ourselves to use what we may now have and just continue as we are, without having at least put our minds and abilities and resources to work to discover something better.

J. D. Stacy: The paper presented by Mr. Marbury gives a very comprehensive description of the problems of manufacture of condenser units in power sizes, and touches briefly on the question of application of these units to power circuits. It is in connection with the application problem that I wish to point out that since a condenser draws a current proportional to the frequency of the applied voltage, any harmonics present in the voltage wave will produce harmonic currents which, under certain conditions, may predominate, and the corrective effect of a leading current may be destroyed totally or in part by the introduction into the system of these harmonic currents which are just as detrimental in the loading of lines, cables, transformers, and generating equipment as the lagging current for which we attempt to correct.

Referring to Fig. 1, it is apparent that resonant conditions for any odd harmonic above the third may occur with series reactance of 5 per cent or less. These values of reactance lie within the range of line reactances encountered in distribution circuits and the chances are excellent that in applying condensers without reactance, many specific cases will be found where resonant or nearly resonant conditions with harmonics are present.

Experience has shown that line reactance does affect the operation of a condenser equipment. I know of two systems on which condenser equipments installed on very short feeders did not operate satisfactorily, but these same equipments, when moved to the ends of long feeders connected to the same bus as before, gave excellent satisfaction.

Fig. 2 shows a voltage wave form of a 2300-volt distributing bus of a large operating company on which it was desired to install a static condenser, together with condenser current wave forms with several values of series reactance. Calculations of the combined harmonic currents based on readings taken with a hot-wire ammeter, indicate that the combined harmonic currents with no series reactor were 73 per cent of the fundamental current, and with 3.5 per cent series reactor, 214 per cent of the fundamental.

Contrasting with these very poor wave forms, it is evident that when a 20 per cent reactor was used, the current wave form was quite comparable with the voltage wave form.

The effect of harmonic currents on the line current of a circuit which has had sufficient leading current of fundamental frequency added to correct the power factor from 70 per cent to 90 per cent is shown in the diagram Fig. 3. With combined harmonic currents equal to 50 per cent of the fundamental frequency leading current represented by $R\ A$ in quadrature with $O\ R$, the resulting line current is given by $O\ A$ and the equivalent power factor is 87.5. With 100 per cent harmonic

current, the line current is given by $O\ B$ and the equivalent power factor is 81.5 per cent. With 214 per cent harmonic current, which is the value just mentioned as applying for the wave form with 3.5 per cent reactance in Fig. 2, but which is by no means the maximum value obtained in tests on other systems, the line current is represented by $O\ D$ and the equivalent power factor is 59.8 per cent. In other words, by the installation of a static condenser under such a condition, we have increased the line current and lowered the power factor.

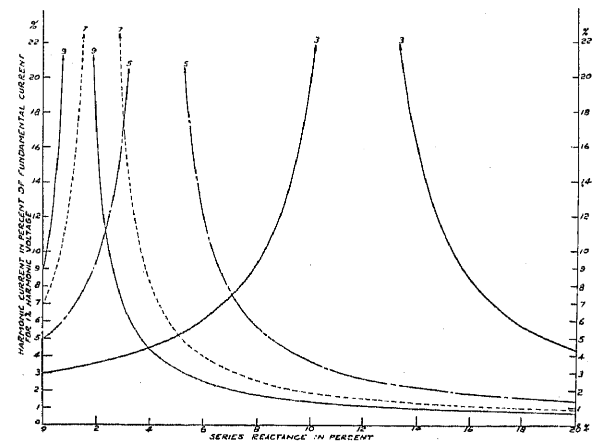

Fig. 1

The only practical method of being certain that a condenser can be furnished to perform its duty under all ordinary system voltage conditions is to furnish with it reactance sufficient to reduce all harmonic currents to a small percentage of the fundamental.

E. F. Northrup: Mr. Marbury's paper is a forceful, and concise statement of facts and information gained from wide experience and based on sound knowledge.

The power static condenser is almost universally thought of in connection with power factor correction on light and power circuits. There is however a development in the industry—

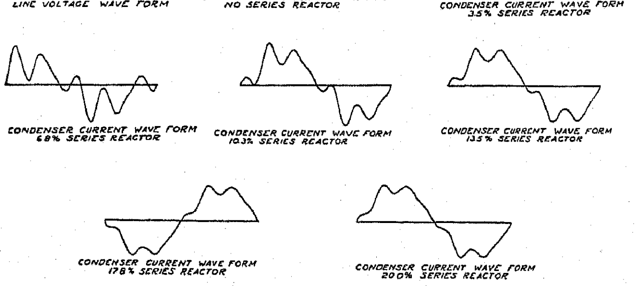

Fig. 2

that of ironless inductive heating-in which the static condenser plays a primary role.

All heating by high frequency currents—10,000 cycles or thereabouts—is only made possible through the employment of the static condenser. Ironless inductive heating using current of such moderate frequency as can be obtained from turbo or motor generator sets gives promise of being widely used, and here also static condensers find important application for power factor correction to secure economy.

It has been completely established that using ironless induction the rate of heating is satisfactory even when using currents of a frequency which can be readily obtained from alternators of substantially standard design.

The sole unfavorable feature of ironless inductive heaters is connected with the low power factor which is more or less inherent in the method. Heaters employing currents of medium frequency when applied to the heating of non-magnetic material have ordinarily a power factor of about 40 per cent. From a cost standpoint we must consider the equipment furnishing the power as made up of two units;

One to supply the in-phase component of the volt-amperes and one to supply the wattless component.

Or one may, of course, use a single unit, the generator, which is made large enough to supply both the in-phase and out-of-phase components. For a 40 per cent power factor uncorrected a single generator to take care of both components would need to be two and one-half times the size of a generator required to supply the same power at unity power factor.

In estimating the cost of an installation for ironless inductive heating it must always be inquired whether in a particular case

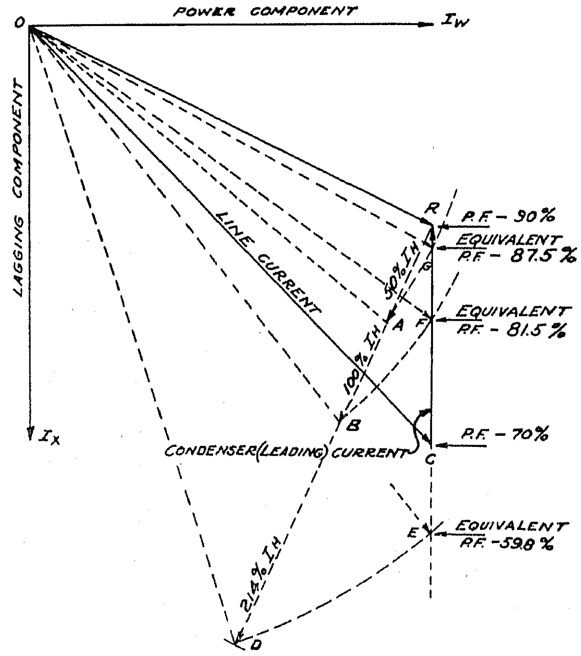

Fig. 3

it is more economical to use a single unit to take care of both components, that is, a unit having the kv-a. rating of the heater; or to supply two units,—a generator to develop the in-phase component of the power, and a static condenser to supply the out-of-phase component.

Any progress made on lowering the cost and in increasing the reliability of static condensers for supplying the out-of-phase component of the kv-a. supplied to ironless inductive heating devices has a directly favorable bearing on the economic feasibility of this highly important branch of the industrial use of electric power.

These remarks apply whatever frequency of current may be used for the ironless inductive heating. While the capacity of the condensers shunting the line to bring the power factor to unity decreases as the frequency chosen increases, the kv-a. of condenser required is independent of frequency used. Hence, whether one uses high, medium, or low frequency for inductive heating, it is of prime importance to so design the inductor that the wattless component shall be as small as possible, but when this has been done, it becomes of great importance to secure the needed kv-a. of condenser at the lowest cost possible.

If such cost becomes sufficiently reduced it will prove economical in all cases to use 2 units;—1 to supply the power and 1 to supply the wattless component of the kv-a. rather than make use of a single generator of capacity sufficient to furnish the entire kv-a. needed.

Mr. Marbury may well include, therefore, as a most important use for the static condenser its adaptation to the art of ironless inductive heating—now in steady progress toward extenive use.

G. D. Robinson: I am sure that there are some who are interested in the use of these condensers with d-c. circuits. If to be used with direct current apparently a condenser should be given a d-c. test.

A breakdown test performed on one of these units has led me to believe that the d-c. voltage which we may use with one of these condensers falls far short of the a-c. voltage.

I would like to ask Mr. Marbury what ratio exists between the a-c. and d-c. ratings of these units. Also, what is the ratio between the voltage to be applied on a-c. test and the voltage which may be applied on d-c. test

H. L. Curtis: The method which is outlined here indicates that Mr. Marbury makes a check by measuring both inductance and capacitance together and then each independently. I wish to call attention to the fact that that may not be a check at all. I have been working on methods of measuring condensers of this value for two or three years, and I have tried absolutley independent methods for making the measurements, and it is not easy to get those which will check. I merely wish to call attention to the fact that in order to get satisfactory checks it is necessary to use methods which are quite independent one of another.

Ralph E. Marbury: Mr. Craighead has given a brief history of the development of a static condenser with which he is familiar. While such a resumé is largely historical, there are certain points on which opinions differ.

The art of condenser manufacture is new. In all radically new apparatus questions arise which cannot be quickly answered. With static condensers the most important problem is the selection of insulating material and safe working stresses. The safe working stress varies with the quality and quantity of material used, operating temperature and character of service. The cost of the condenser depends largely on the cost of insulation. The quantity of insulation required depends on the working stress.

As Mr. Craighead points out in the early development of static condensers, wax impregnated insulation was soon found to be uneconomical, on account of the very low safe working stress.

The outstanding advantage of oil impregnated paper insulation was that the safe working stress was higher than that for solid insulation. The safe working stress for wax impregnated material was not definitely known, and while laboratory tests demonstrated instantly the superiority of oil and paper, time alone could establish the limits.

The first outstanding application of static condensers was for the correction of power factor. While the low power losses give condensers an advantage over other forms of corrective equipment, probably the most important feature is that of small maintenance and no attendance. To fully capitalize this chief advantage the device must be reliable.

For a given material the life of the condenser is indefinitely long below a certain critical working stress. When this stress is exceeded the life of the device becomes shorter, and the performance variable. This critical stress may differ in individual condensers manufactured under identical conditions, due to variations in the material itself or to other factors. This same characteristic would be noticed in most any material worked near the limit or where the limit varied with operating conditions.

Even if all the factors establishing this critical stress were definitely known and perfectly controlled, it would be unwise to work too near this maximum safe stress. Since, however, this is not the case we can only be governed by experience, and in choosing a stress we should introduce a sufficient margin to take care of all conditions that may arise.

We have available much data on insulation stress in similar apparatus extending over many years. These data cover working stresses from 20 to 100 volts per mil. During the development of static condensers thousands of laboratory hours were obtained of insulation as used in condensers, with stresses up to 1100 volts per mil, or over twice the average breakdown of the average insulation used in other apparatus.

If we should combine this laboratory experience with other insulation history we might select as a normal stress for static condensers 400 to 500 volts per mil. This would be expecially true if our choice were influenced by the fact that the size varies inversely as the square of the ratio of stresses. If the working stress is divided by 2 the size will be multiplied by 4.

The problem may be handled commercially in one of two ways. First:—A high stress may be adopted based on laboratory experience alone, and gradually reduced over a long period of manufacture until an entirely reliable device is provided. Second:—A stress definitely well below the safe stress may be adopted, and gradually increased over a long period, until the maximum of perfection is obtained.

In either case the final result would probably be the same, but years of experience in other apparatus has demonstrated the advantages of the second plan.

At first it appeared impossible to proceed along the second plan without excessive costs, and that it would be necessary to start at a comparaitvely high stress such as 300 volts per mil. In order to entirely follow the plan outlined, however, a stress of 145 volts per mil was chosen without regard to cost, and from this point the development became an economic study.

It is the object of this paper to briefly describe the work done which made possible a complete line of static condenser worked at stresses of 145 volts per mil, and at costs no greater than originally expected for 400 volts per mil, designs even though about seven times as much material was required.

A study of materials was made covering the entire range of cost and quality. Some paper cost as much as twelve times that of another. On examining the cost curves it was found that cost depends more on thickness than stock used. This is tied up with the tonnage that can be produced with a given outlay of paper making machinery. The electrical quality is about the same for either linen, wood or cotton fiber. The cost increases as the thickness is reduced, due to the reduction in tonnage, at the mil, to the necessity for using more costly stock, and to the increase in waste. The dielectric losses are hardly effected by the thickness or kind of stock, so long as impregnation and chemical purity remain constant.

For a given dielectric thickness the breakdown is increased by reduction of porosity of the paper or by greater subdivision of the oil by thinner and thinner sheets. If the breakdown is plotted against cost of a given area of material, the thicker more porous and less expensive materials prove far better.

The net result of this economic study of materials, together with improvements in mechanical construction method of impregnating and testing was the two-kv-a. 2300-volt 60-cycle unit, designed with a working stress of 145 volts per mil, and with a cost of no greater than originally expected for a 400-volt per mil design. Many thousands of these units have been manufactured and some have operated nearly three years, and not a single insulation failure has occured. The fact that 145 volts per mil was well within the safe limits has been fully established in service.

With the complete elimination of insulation failure and the ability of the condenser to withstand all line surges and periods of over voltages, individual fuses were no longer necessary. The increased surface of the units for radiation and the elimination of individual fuses made possible a very compact frame assembly, the overall dimensions of which were not a great deal more than those of the early experimental 400 volts per mil type.

In the early stages, dielectric loss measurement was a laboratory process, and it was unsafe to make loss measurements until

The weight of the units per kv-a. was reduced by the elimination of all metal with the exception of the containers and metal conductors.

after over-potential tests had been made, due to the possibility of damaging very delicate low power-factor wattmeters in the event of failure of the unit. Such improperly impregnated units were therefore found and destroyed on the voltgae test. A very reliable and fool-proof means was developed for making loss measurements, where an improperly impregnated condenser could not damage the equipment if failure occurred. This made it possible to select and return for retreatment such units without damaging them, except in rare cases where manufacturing errors were made in putting in the insulation.

This loss measuring equipment reduced factory scrap to a very low figure.

Other methods were developed for controlling the quality of the condensers throughout the entire manufacture.

All units are given a one-minute overpotential test of 2¼ times rating plus 2000 volts for one minute. This test is made generally on 25 cycles.

I do not wish to leave the impression that research ceased when it became possible to work at low stresses economically. Units have operated in the laboratory where their daily performance could be observed and a continuous study of materials is carried on.

One point that has been fairly well established is that a material which breaks down at 400 volts per mil. and is operated at 100 volts per mil. gives more dependable service than one which breaks down at 1600 and is operated at 400, even though the ratio between working stress and operating voltage is the same in each case initially.

Mr. Shelton emphasizes the importance of the porosity of paper. Low porosity is a desirable characteristic, except in cases where the cost of obtaining it overbalances its value. The writer has never seen ordinary paper manufactured here or abroad which was entirely free of holes. This can only be accomplished by subjecting the paper to chemical treatment which lowers its electrical quality. When thousands of square inches of material are used in a single condenser, holes may line up somewhere with even the best paper yet produced. When low stresses are used, and low porosity not depended upon, such a line up has little effect on the condenser, neither does the line up of a few metal particules.

I wish to agree with Mr. Lee that the dielectric losses can be reduced to 0.2 per cent by very careful treatment. This is desirable when very high stresses are used since the stored energy per unit volume of material is great. We work toward an average of ½ per cent on complete equipments. Even with this average many units run even lower than 0.2 of 1 per cent losses.

Since entirely satisfactory performance has been obtained with loss average of 5 watts per kv-a., the only other reason for holding it lower is power cost. The difference in power loss even at three cents per kw-hr. would not justify the special care required, to bring losses down to even 0.3 per cent.

I do not mean to create the impression that the electro-dynamometer is an impractical device. This instrument has been found to be most satisfactory for low power-factor measurements. Any one familiar with this device knows, however, that as the voltages at which tests are made is increased, the resistance of the potential circuit must be increased, and that this resistance, which sometimes must be as large as one megohm, must be free from distributed capacity and inductance, as a slight amount of either will cause large errors. In addition, the arrangement of the resistances with respect to other parts of the circuit is of great importance. In measuring condensers varying in capacity from ½ to 150 microfarads, and at voltages from 20 to 5000, considerable manipulation is needed, requiring a technical knowledge of the principles of the instrument. In addition should an accident occur, such as attempting to test a short-circuited or defective condenser, the meter will be seriously damaged.

The scheme of operation of the inductance test equipment has been fully covered in the paper. However, I might add that should a defective condenser be connected to the test no harm can come to the meters, as the voltage will not build up. If the condenser breaks down on test, the voltage drops to a low value, since the device operates on the principle of series resonance.

In reply to Mr. Curtis, I wish to point out that the calibration of the inductance was a laboratory operation which extended over two months and every precaution was taken to obtain a very accurate calibration. It is true that a measure of condenser losses and inductance losses separately and combined will not always show up a phase angle error in the potential circuit. However, this check was not solely relied on as evidence of correct measurements, but merely made as a final check to note any inconsistency. Once a complete calibration was made on the coil, the special wattmeter is no longer required. A condenser is simply connected into the circuit as shown in Fig. 5 of the paper. The screened enclosure is swung over the unit operating as it latches the safety switch. The current is set at the correct value for the unit on test and the watts loss read on the meter, a standard Westinghouse wattmeter. Assume a typical case of a total of 32 watts. By reference to a calibration curve, the loss in the inductance is determined which is of the order of 20 watts. To this is added the meter losses which in this case would be 3 watts. The loss in the condenser then is $32-(20+3)=9$ watts or 0.45 per cent, since the unit is measured at two kv-a. It might be of interest to note that several thousand pounds of copper were required to build a two kv-a. 2300-volt inductance with a loss of only 20 to 25 watts. This, of course, was an air core construction.

I would like to ask Mr. Stacy why the condenser did not operate without reactors on a short feeder. I am wondering if the difficulty was that of not obtaining the power factor expected, or failure of the insulation in the condenser due to heating of harmonic currents.

In applying reactors with static condensers it should be noted that a given reactor is suitable for only one value of condenser and that either the condenser capacity cannot be changed freely or the reactor must be changed by means of taps every time the kv-a. of the condenser is changed.

The writer has observed the performance of many condensers where no reactors were used and in no case has the use of a reactor been found necessary or even desirable. In all cases the power factor was that to be expected, as well as the currents in the condenser leads. It is quite possible that under certain conditions reactors may be indispensible. It does not seem necessary to make a general use of them. In fact their use should be avoided wherever possible. We are adding condenser capacity to correct for electromagnetic fields. If we add reactors we must add still more condenser kv-a. The type of condensers described above would not be damaged under the worst conditions by harmonic current. They have been used to pass a high 500-cycle superimposed current when operating at rated 60-cycle voltage, in special applications.

In reply to Mr. Robinson's question regarding d-c. application, I wish to say that we have found it desirable to work at higher stresses on d-c. than on a-c. Condensers for a-c. service are rated for commercial lines. The voltage may go up to fairly large values at times. Thus for a-c. service a large factor of safety is incorporated in the design. In addition, the critical stress for d-c. is much higher than for a-c.

For d-c. service the problem is different. Since there are no standardized d-c. voltages for radio broadcasting, the condenser can only be rated for absolutely maximum. The user must take into account poor voltage regulation which varies with every outfit, over a very broad range. A condenser for 3500 farads direct current is therefore maximum rated. If there is a large ripple in the direct current the peak value should be within the d-c. rating. All d-c. conde nsers are tested at twice d-c. operating voltage for one minute. It is intended that the rating should not be exceeded in service by surges, etc.

The d-c. working stress varies between 275 and 460 volts per mil, depending on the rating. As the voltage rating is increased, the working stress is reduced to allow for less uniform voltage distribution through the material.

Effects of Time and Frequency
on Insulation Test of Transformers

BY V. M. MONTSINGER
Associate, A. I. E. E.
Transformer Engineering Dept., General Electric Co.

Review of the Subject.—*Permanently grounded transformers must be given the insulation test by inducing the necessary voltage across the windings.*

The A. I. E. E. Standards specify that the time of induced voltage tests be the same as for high potential test. In certain cases where the transformers are of very large capacity the induced voltage must be made at a frequency several times higher than normal. Since the dielectric strength of most insulating materials decreases with an increase in the frequency, an investigation has been made to determine the proper and fair length of time to make induced voltage test when the frequency is higher than normal.

Following are the main points brought out in the investigation.

Above a certain voltage, **time** *of voltage application as well as* **voltage** *causes failure of insulation. The dielectric strength can be expressed as a function of both* **time** *and* **voltage** *by an equation of the form*

$$Kv. = A\left(a + \frac{1 - a}{\sqrt{T}}\right)$$

in which A is the kilovolts necessary to cause failure in one minute, "a" is a constant representing the ratio of strength for infinite time to the one minute strength and T is time in minutes. The value of "a" varies for different materials apparently depending mostly on the dielectric loss.

The breakdown by creepage over solid insulation with the electrodes either on the same side or on opposite sides of the sample (arranged in such a manner that the solid insulation is under considerable stress) is not affected by **time** *nearly so much as is the puncture voltage of solid insulation.*

The behavior of oil without barriers is so erratic that no very definite relation can be obtained between **time** *and dielectric strength. In general* **time** *decreases the strength quite rapidly for the first few seconds after which the effect decreases and probably disappears entirely after two or three minutes. The momentary strength ranges from 25 to 30 per cent higher than the one minute strength.*

The effect of **time** *on the strength of solid insulation and oil in series is about the same as for solid insulation alone until the oil distance exceeds the solid insulation thickness after which it begins to be the same as for oil without barriers.*

The strength-time curves for solid insulation are of approximately the same shape for all frequencies from 60 to 420 cycles, although the strength decreases with an increase in frequency F approximately in accordance with the formula $kv. = 1.75 / F^{0.137}$

Failure by creepage over the surface of solid insulation which is under no stress (i. e., with the electrodes on the same side of the barrier) takes place at approximately the same voltage for all frequencies from 60 to 420 cycles; but if the electrodes are so arranged (on opposite sides) that the insulation is under considerable stress the failure voltage decreases with an increase in frequency in about the same order as the puncture voltage of solid insulation does.

The rupture voltage of oil is the same for both 60 and 420 cycles.

The effect of frequency on the puncture voltage of solid insulation and oil in series is the same as for solid insulation until the oil distance exceeds the thickness of solid insulation, after which the effect decreases and as the oil distance increases the effect approaches that for oil without barriers.

By considering the effects of both time and frequency on dielectric strength it is shown how to determine the proper length of time to make the voltage strain at higher frequencies equal to the strain at 60 cycles for one minute.

INTRODUCTION

SECTION 6362 of the 1922 edition of the A. I. E. E. Standards reads as follows:

> *Testing Transformers by Induced Voltage*—Under certain conditions it is permissible to test transformers by inducing the required voltage in their windings in place of using a separate testing transformer. By "required voltage" is meant a voltage such that the line end of the winding shall receive a test to ground equal to that required by the general rules.

The increased number of permanently grounded transformers within the last few years has resulted in an increased use of the induced potential method for testing the insulation. In case the transformers are single phase, and when required to impose a strain equal to twice line potential on the end of the windings the induced voltage must be $2\sqrt{3}$ or 3.46 times normal. To keep the exciting current within a reasonable value at this high induction, the frequency must, of course, be greater than the rated frequency.

To maintain normal 60-cycle density at 3.46 times normal voltage requires 60×3.46 or 208 cycles. An idea of the large generator capacity required for testing some of the largest transformers of today when using, say, 208 cycles may be had from the following example: Assume a 30,000-kv-a., 60-cycle single-phase transformer to be given 3.46 times normal induced voltage. If the exciting current is 5 per cent of full-load current and to maintain normal iron density the necessary single-phase 208-cycle generator capacity would be $30{,}000 \times 3.46 \times 5 / 100 = 5200$ kv-a. As the generator should be three phase and as the single-phase rating is usually taken as 70 per cent of the three-phase rating the total capacity required would be $5200 \times 100 / 70 = 7450$ kv-a. This rating of course would be required only for intermittent service and an overload could be had, which would permit of reducing the continuous rating to possibly 5000 kv-a. Even this generator capacity of this odd frequency is out of the question for test purposes.

Since the exciting current decreases very rapidly with iron density the most practical thing to do in testing very large units, of course, is to use a generator of higher frequency than 208 cycles. In certain cases this has been done and with the consent of the customer, 420

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., Feb. 4-8, 1924.

cycles has been used with a reduction in the time of voltage application to give a total of 7200 cycles. This investigation shows that this test amply meets the standard insulation requirements.

It is obvious that, except for liquid insulations, to produce the same voltage strain, the *time* should be reduced as the frequency is increased, since dielectric loss increases with frequency and the heating is increased, and consequently the dielectric strength is reduced. But just how much the *time* should be reduced to make the tests at different frequencies of equal severity had not been extensively investigated on built up transformer insulations until recently. Based on the tests which had previously been made and on the results shown by F. W. Peek (pages 179, 182, 183 and 184 in *Dielectric Phenomena in High-Voltage Engineering*) we have considered that the voltage strain at different frequencies was approximately the same if the time was inversely proportional to the frequency. In fact it is logical to expect that within certain time limits the strain should be somewhat more severe for the higher than for lower frequencies for the reason that there is less chance for the heat in the solid insulation to escape. The results of this investigation bear this out as will be shown later.

The object of this paper is to give the results of a large number of tests made on solid insulation, built-up insulations and oil, and based upon these results to show the relation between the time of voltage application at different frequencies to produce approximately the same voltage strains on the classes of insulating materials commonly used in oil-immersed transformers. It is hoped that the data, especially the strength-time curves, will be useful not only for transformers but for other types of electrical apparatus.

As would be expected, it was found that the ratio of time necessary to cause failure at any two frequencies changed as the time of voltage application increased. For example referring to Fig. 23 and assuming for the moment that these curves which show the relation between *time*, frequency and dielectric strength, are correct, it will be seen that a test for 30 seconds at 25 cycles is equivalent to a test for 4 seconds at 120 cycles. In other words the ratio of time here is 7.5:1. However, these curves also show that a test for three minutes at 25 cycles is equivalent to a test at 120 cycles for 10 seconds. Here the ratio of time is 180 / 10 or 18:1 which is more than twice that for the first case. Likewise as the time chosen at the lower frequency for comparison becomes longer the ratio between this time and the time that gives an equivalent voltage strain at the higher frequency becomes larger and larger until finally the ratio becomes infinity.

Factors Considered in Experimental Observations

Test Factors.—Since the ratio of time changes for different frequencies it was of course necessary to determine the variation of dielectric strength with "time of voltage application" as well as the effect of frequency on the dielectric strength for a given time and voltage.

b. Insulation Factors.—When a transformer fails on insulation test it is usually due to one or a combination of the following causes:

1. Puncture of solid insulation
2. Creepage over solid insulation
3. Rupture of oil and
4. Puncture of solid insulation and oil in series.

The above four causes of failure have been investigated in determining (1) dielectric strength vs. time of voltage application and (2) dielectric strength vs. frequency.

Empirical Formula of Strength-Time Curves

An examination by the writer of all available strength-time curves made at different frequencies showed that these curves can best be expressed by an equation of the form first suggested by Peek (see page 179 *Dielectric Phenomena in High-Voltage Engineering*). The equation is:

$$E = \left[a + \frac{(1-a)}{4\sqrt[4]{T}} \right]$$

In which E is the ratio: "dielectric strength at any time divided by the strength for one minute," and a is a constant representing the ratio: "one minute dielectric strength divided by the strength for infinite time," and

T = time in minutes.

The above equation means, of course, that the dielectric strength decreases with time of voltage application in accordance with an exponential equation (of a straight line on double logarithmic paper) until whatever causes[1] failure, ceases to affect the strength. In other words the curve becomes parallel to the axis of time before the strength reaches zero, otherwise electrical apparatus having insulation under a constant moderate stress would fail in time due merely to this stress. We know, however, that this does not happen.

It would, of course, be expected that the value of a in equation (1) would be different for different materials depending probably in part on the density and partly upon dielectric losses. It is natural that the higher the loss the more quickly will the curve flatten out. The following tabulation gives maximum, average, and minimum values of a, and the densities for some of

1. Space and time do not permit of attempting to discuss why *time* and frequency affect the dielectric strength of insulation. This question, however, is being actively studied and it is hoped that at some future time something can be given on this very interesting and important subject of the mechanism of breakdown.

the usual insulating materials used in transformers and tested in this investigation.

Materials in oil	a	Density
0.003 in. untreated cable and kraft papers........................	0.85	0.7 to 0.8
0.012 in. varnished cambric (1 to 10 layers)........................	0.675	1.12
0.005 in. varnished bond paper (6 or 7 layers)......................	0.675	1.12
Combination of 3/32 in. pressboard and 3/32 in. oil ducts in series.....	0.675	
Pressboard at 75 and 100 deg. cent..	0.675	0.95—1.05
Pressboard at 25 deg. cent.........	0.50	0.95—1.05

It will be noted from the above that the values of a do not appear to bear any definite relation to the

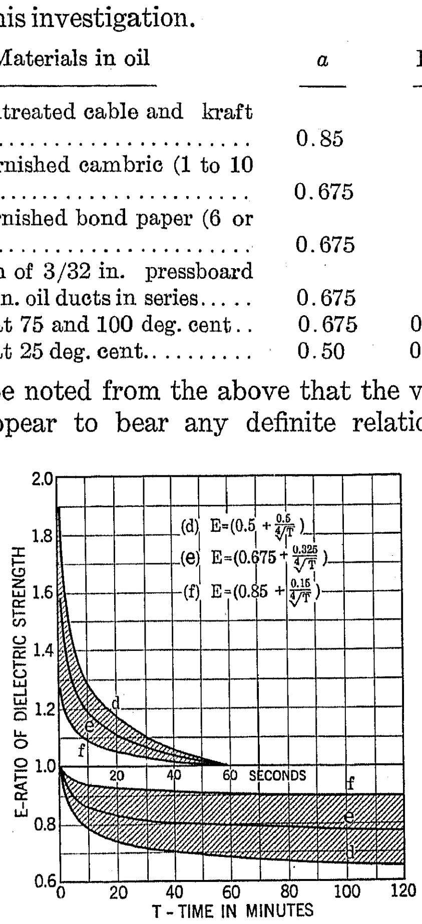

FIG. 1—STRENGTH-TIME CURVES PLOTTED FROM FORMULA: $E = \left[a + \frac{(1-a)}{\sqrt[4]{T}}\right]$ IN WHICH "A" IS A CONSTANT DEPENDING ON THE MATERIAL

density of the material. Probably dielectric loss is one of the main factors since paper generally has a high loss as compared with pressboard especially at 25 deg. cent.

Table No. 1 gives in tabulated form the ratios of dielectric strength calculated for different times T and for maximum average and minimum values of a in equation. (**1**).

	infinity	0.85	0.675	.50

Fig. 1 shows the data in Table No. 1 plotted in curve form. The shaded area or envelope of these curves represents the variations in dielectric strength with time of voltage application, that is likely to be obtained from representative Class A insulating materials used in electrical apparatus.

If desired to express the dielectric strength in kilovolts rather than by ratio values the form of the equation becomes

$$\text{Kv.} = A\left[a + \frac{(1-a)}{\sqrt[4]{T}}\right] \quad (2)$$

in which A is the one minute dielectric strength in kilovolts. a, and T have the same significance as in equation (**1**).

To have some convenient yard stick for measurement as we go along, all test data shown later will be compared with the values calculated by equation (**2**) using either the minimum, average or maximum value of a according to the one that fits best.

EXPERIMENTAL 60-CYCLE STRENGTH-TIME CURVES

Unless otherwise stated the voltage was applied to the sample by closing the field switch of the generator with the rheostat set for some predetermined value. An investigation showed that this is the only method

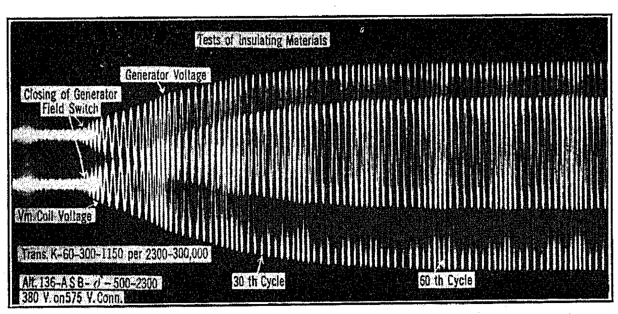

FIG. 2—OSCILLOGRAM SHOWING RATE AT WHICH 60-CYCLE TESTING TRANSFORMER VOLTAGE INCREASED TO A STEADY VALUE AFTER CLOSING GENERATOR FIELD SWITCH

It will be noted that no surge took place

of obtaining full voltage in a short time without producing an initial surge such as we know happens at times when full excitation is thrown on the primary side of a testing transformer. Tests showed also that a disturbance took place when full voltage was thrown across the electrodes by closing the circuit on the secondary side of the transformer while the transformer was excited.

The time given is that from the instant of closing the field switch until failure occurred. An oscillogram of the initial voltage waves, Fig. 2, shows that it required approximately one second for the voltage to build up to a constant value. The true value of time is probably from one-half to one second less than that shown.

All tests in this investigation were made with the

samples in a vertical position. The pressboard in all cases contained approximately 45 per cent of rag material.

The 2-in. and 4-in. diameter electrodes had a 3/32-in. and ½-in. curvature radius respectively on the edges. All kilovolt values given are the r. m. s. values of the peak of the wave as determined by spark gap.

a. Solid Insulation. Table II gives the comparison of calculated values and results of tests made on oil-treated, three-mil kraft papers.

It is, of course obvious, that, since the value of the constant a used for calculation was obtained from these tests, a comparison between the calculated and test results shows only how the curves agree with each other and how closely they can be expressed by an empirical formula.

Figs. 3 and 4 show two sets of strength-time curves obtained on single sheets of 3/32-in. pressboard in 25 deg. and 75 deg. cent. oil. The 75 deg. curve checks the average value of a while the 25 deg. curve agrees better with the minimum value of a. The writer has found that pressboard at 25 deg. cent. shows the greatest variation in strength with *time*, of any material tested, but at 75 and 100 deg. cent. (as will be shown later) the variation in strength corresponds to the average value of a. In making any tests at higher than room temperatures, the material was subjected to the tested temperature for at least 24 hours before being tested in order that the condition of the material would not change while undergoing the test.

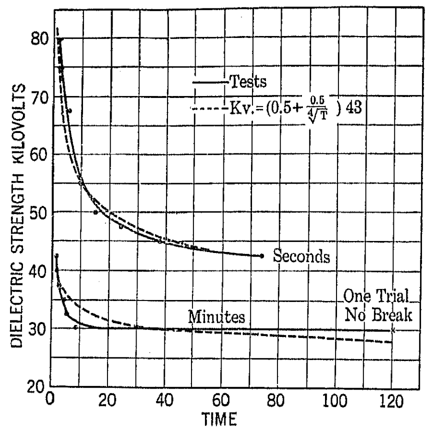

FIG. 3—60-CYCLE STRENGTH-TIME CURVE

One layer of 0.0935-in. oil-treated pressboard in oil at 25 deg. cent. Each point average of 10 tests. Time for voltage to build up (approx. 1 sec.) included 2-in. diam. electrodes

However, for most other materials such as varnished bond paper having a smooth film of oxidized varnish over the surface and for varnished cambric, the test curves check best the average value of the constant a from 25 deg. to 100 deg. cent. Figs. 5 and 6 give results of tests made on varnished bond paper and

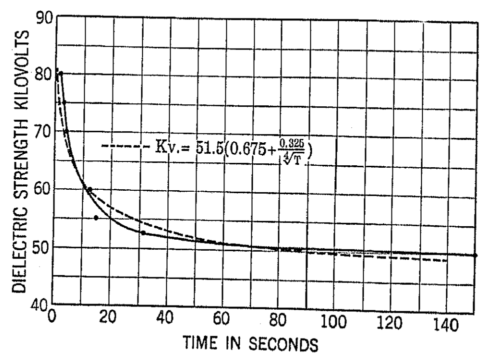

FIG. 4—60-CYCLE STRENGTH CURVE

varnished cambric in 25 deg. oil. These test points check the average value of a. Figs. 7 and 8 show the results of tests made on different numbers of layers of black varnished cambric in 30 deg. and 85 deg. cent. oil for longer periods of time than shown in Fig. 5. These curves also check average value of a fairly well from approximately one minute to about two hours.

(Sufficient tests were not made at this time, namely in 1915, for these latter curves to be of much value up to approximately one minute of time.) Apparently temperature of the oil has very little effect on the shape

b. Creepage over Solid Insulation.—The 60-cycle data on creepage is discussed along with the 420 cycle creepage data under section 5 b.

c. Rupture of Oil.—Oil alone is so erratic that no very definite strength-time curve can be obtained. However, the average of a large number of tests show that the strength decreases quite rapidly after the first few seconds of voltage applications and after this the effect becomes less and probably disappears after two or three minutes time.

Fig. 9 gives the results of time tests made on No. 10

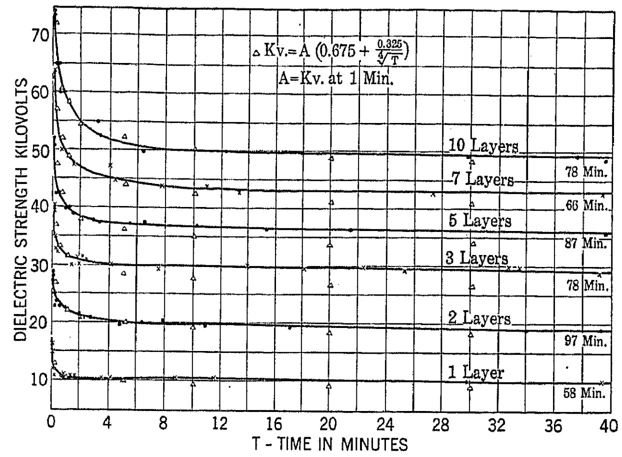

FIG. 8—60-CYCLE STRENGTH-TIME CURVES OF 0.012-IN. BLACK VARNISHED CAMBRIC

transil oil in which was submerged two 4-in. (10-cm.) round edged electrodes spaced 0.375 in. apart. The voltage was applied by closing the field switch of the generator. The scattered points illustrate well the erratic nature of oil as has already been pointed out by Hayden and Eddy.[2] (However when used in series

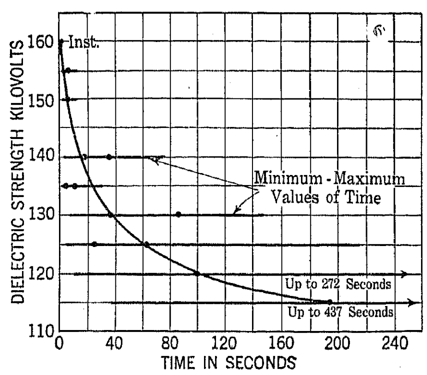

FIG. 9—STRENGTH-TIME TESTS MADE ON NO. 10 TRANSIL OIL AT 25 DEG. CENT.

with barriers of solid insulation, oil is one of our most reliable insulating materials).

The data shown in Table III is interesting in that it shows the effect of increasing the applied voltage. The *one second tests* were made by closing the

2. Three Thousand Tests on the Dielectric Strength of Oil," Hayden and Eddy, TRANS. A.I.E.E., Vol. XLI, 1922, p. 394.

generator field switch and holding it for approximately 1.5 seconds. The other tests were made by bringing up the voltage by means of the rheostats in the field. To make sure that the conditions were the same for each period of time, the tests were alternated with time, that is, each one-second test was followed by a rapidly applied and standard one-minute tests respectively. This was repeated until the series was completed. In each case (except the first column) the voltage was started at approximately 50 per cent of the breakdown value. For the one second tests (1st column) the voltage was started from 25 to 30 kv. less than the failure voltage, and increased in 5 kv. steps, but with rest periods between each step.

TABLE III.

EFFECT OF TIME OF VOLTAGE APPLICATION ON RUPTURE STRENGTH OF NO. 10 TRANSIL OIL

Per cent 127.5	116.5	100

The above shows that the short-time or momentary values were from 27.5 to 30 per cent greater than the approximate one-minute values, shown in last column. This is in fair agreement with the difference shown in Fig. 9 between the instantaneous and one minute values. Just why the strength should be 25 to 30 per cent higher for one second than for one minute duration of voltage is not fully known. One possible explanation is that it requires *time* for whatever impurities are present to fill up and bridge the gap. If the oil was absolutely pure it might be found that time of voltage application would have no effect on the rupture voltage. But commercial oils however are seldom, if ever, free from small particles of lint, etc., floating around.

d. Puncture of Solid Insulation and Oil in Series. The 60-cycle strength-time curves are given and discussed with the 420-cycle curves under section 5 d.

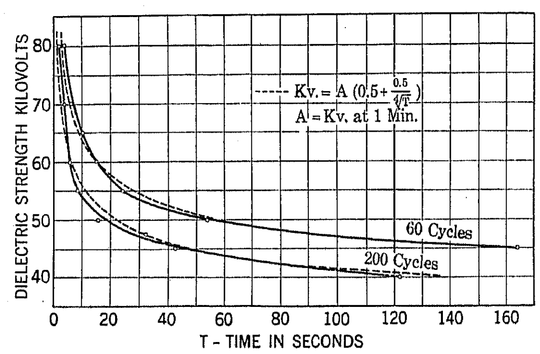

FIG. 10—60 AND 200-CYCLE STRENGTH-TIME CURVES

One layer 0.0935-in. oil-treated pressboard, in oil at 25 deg. cent. Two 4-in. (10 cm.) diam. electrodes. Each point average of 10 tests. Time for voltage to build up (approx. in 1 sec.) included

EFFECT OF FREQUENCY ON:

a. Strength-Time Curves of Solid Insulation. Up to the present we have discussed tests at only one frequency. Fig. 10 shows curves made at 60 and 200 cycles on single layer samples of 3/32 in. oil treated pressboard in oil at 25 deg. cent. The curves show

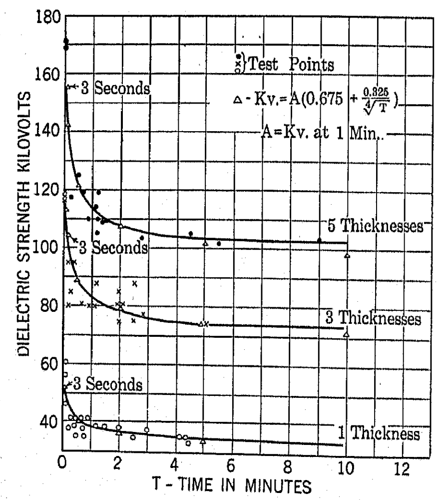

FIG. 11—60-CYCLE STRENGTH-TIME CURVES

0.0935-in. oil-treated pressboard, in oil at 100 deg. cent. two 4-in. (10 cm.) diam. electrodes, each test shown. Time shown from inst. voltage (rapidly applied) became constant until failure

approximately the same percentage difference in kilovolt values. This is an interesting fact even though it may not be known just why it is so. Perhaps some day it can be explained when the mechanism of insulation failure is fully understood.

Figs. 11 and 12 show strength-time curves made on

various numbers of layers 3/32-in. pressboard at 60 and 420 cycles.

To prevent absorption of moisture, the material was immersed under oil immediately after vacuum treatment and removed only as needed for test. The voltage for this series of tests was raised as rapidly as possible by the rheostats in the field circuit of the generator. The time shown on the curves is that which elapsed from the time the voltage reached a steady value and held at this value until break-down. The r. m. s. values of the peak values determined by spark gap were used in plotting the curves. Each test point is shown.

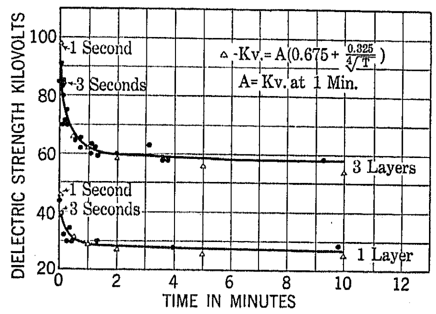

FIG. 12—420-CYCLE STRENGTH-TIME CURVES

0.0935-in. oil-treated pressboard, in oil at 100 deg. cent. Two 4-in. (10 cm.) diam. electrodes, each test shown, time shown from inst. voltage (rapidly applied) became constant until failure

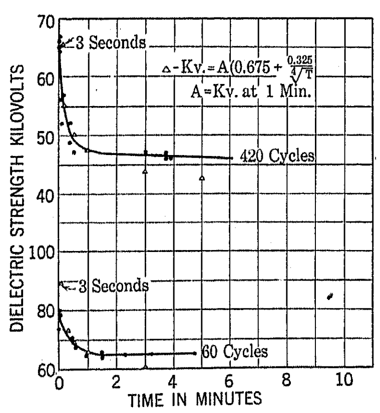

FIG. 13—60 AND 420-CYCLE STRENGTH-TIME CURVES

7 layers 0.012-in. black varnished cambric, in oil at 100 deg. cent.

It will be noted that these curves are of approximately the same shape for both frequencies and check fairly closely the average value of a in equation (2). It is interesting to note that the 420 cycle points are not so scattered as the 60-cycle points. This seemed to be characteristic of all tests made at the higher frequencies on all insulations except oil without any barriers.

Fig. 13 shows the results of tests made on black varnished cambric at 60 and 420 cycles. These curves show that the 420-cycle strength is approximately 75 per cent of the 60-cycle strength.

Fig. 14 gives the results of one and fifteen minute tests made at 60 and 420 cycles on various thicknesses of pressboard. These curves show that the 420-cycle values are approximately 75 per cent of the 60-cycle values for all thicknesses tested.

b. Variation of Dielectric Strength of Solid Insulation for any Given Time. Table IV gives a summary of the 420-cycle dielectric strength expressed as a percentage of the 60-cycle strength.

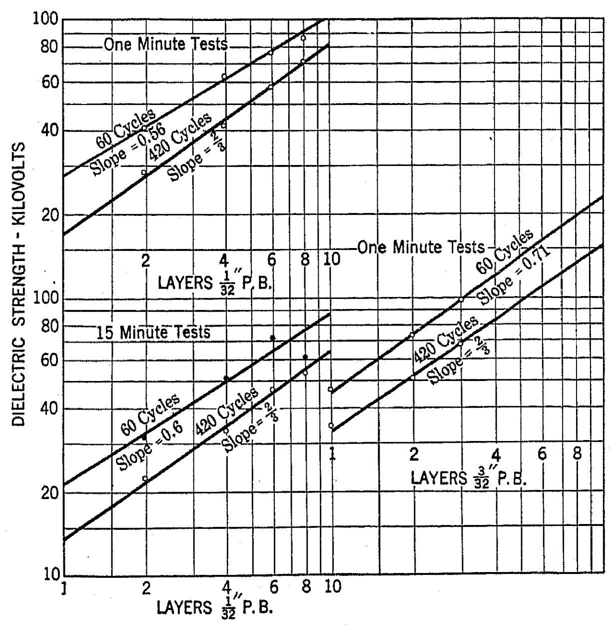

FIG. 14—EFFECT OF FREQUENCY AND THICKNESS ON DIELECTRIC STRENGTH OF PRESSBOARD AT 25 DEG. CENT.

4-in. (10 cm.) diam. electrodes

While the general average of the 420-cycle kilovolt values for solid insulation is approximately 75 per cent of the 60-cycle values it will be noted that the tendency is toward a little higher percentage for momentary values. However for practical purposes it appears that we can say that the percentage is constant regardless of time of voltage application.

The determination of the relation between the dielectric strength of solid insulation at 60 and 420 cycles, does not give the effect of other near and intermediate frequencies. To determine this, a large number of tests were made at 25, 60, 200 and 420 cycles, on solid insulation under as nearly as possible the same conditions. It was found that for all these frequencies at both 25 and 50 deg. cent. the dielectric

strength can be expressed by an exponential equation of the form kv. $= K'/F^n$ where K' is a constant, F is the frequency and n is a numerical value. For 60, 200 and 420 cycles at 100 deg. cent. an equation of the same form holds, but for 25 cycles at 100 deg. cent. the values were approximately 35 per cent higher than the 60-cycle values, whereas to fall in line they should be only 12 to 15 per cent higher. At first it was thought that this departure from the equation might be due to an error into tests, but check tests showed that it was correct. These tests are given in Table V.

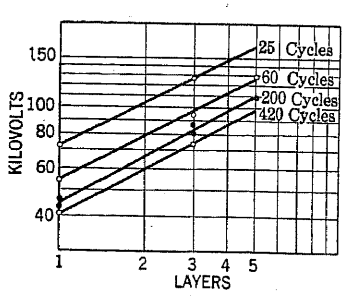

FIG. 15

Effect of frequency of dielectric strength of 3/32-in. oil-treated pressboard in oil at 100 deg. cent. Voltage increased at rate of 1 kv. per 5 seconds, 4-in. diam. electrodes.

The kv. values shown in Table V are plotted vs. layers of pressboard on double logarithmic paper in Fig. 15. When these values (expressed as a ratio of 60-cycle values) are again plotted against the reciprocal of the frequency it will be seen, Fig. 16, that except for the 25-cycle point around 100 deg. cent. they all fall in a straight line.

For practical purposes we can neglect the 25-cycle points at 75 deg. and 100 deg. (since we are concerned here only with frequencies ranging from 60 to about 500 cycles) and use an equation derived from the straight line.

The equation of dielectric strength vs. frequency, or of the line in Fig. 16, is:

$$E = 1.75/F^{0.137} \quad (3)$$

where E is, for any given time, the ratio of strength to 60-cycle strength and F is the frequency in cycles per second.

Although no claim is made for accuracy beyond about 500 cycles it is interesting to note that this

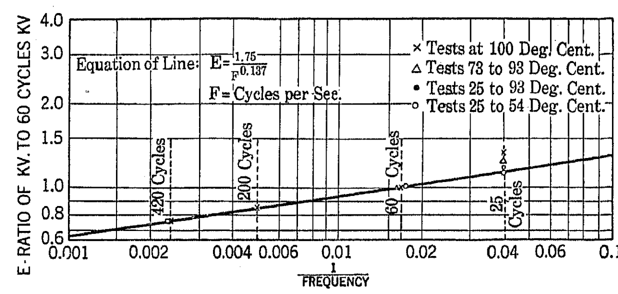

FIG. 16—EFFECT OF FREQUENCY ON RATIO OF DIELECTRIC STRENGTH OF SOLID INSULATION

method of calculation holds fairly closely in comparing Peek's results of tests made at 60 and 90,000 cycles as shown in Table VI.

b. Creepage Over Solid Insulation. Tests made with the electrodes on the same side of the sample piece, *i. e.* when the solid insulation was under no stress, gave very erratic results, corresponding more nearly to those obtained on rupture voltage of oil alone. Neither time nor frequency seemed to have any material effect on the failure voltage. But when the electrodes were placed on opposite sides of the test sample (that is when the material was under a stress) frequency had approximately the same effect on the arcover voltage as it had on the puncture voltage, *i. e.* the 420-cycle strength was approximately 75 per cent of the 60-cycle strength. As shown by the data given in Figs. 17 and 18, *time* had very little effect at either frequency.

c. Rupture Voltage of Oil at 60 *and* 420 *Cycles.* While it was not expected that the dielectric strength of transformer oil would vary with such a small difference in frequency as 60 and 420 cycles, tests were made using 4-in. (10 cm.) round edged electrodes spaced 0.375 in. apart in oil that tested 27 kv. with standard 1-in. electrodes spaced 0.1 in. apart. The voltage was increased at the rate of 1 kv. per 5 seconds. The results of these tests are shown in Table VII.

TABLE VII.
60- AND 420-CYCLE RUPTURE VOLTAGE OF NO. 10 TRANSIL OIL
Number of shots at each frequency 25. Temp. of oil 28 deg. cent.

Frequency	Kv. by Vm. Coil min.	Kv. by Vm. Coil Max.	Kv. by Vm. Coil Avg.	Kv. by Spark Gap
60 cycles	86	117	97	98
420 cycles	80	130	106.8	99

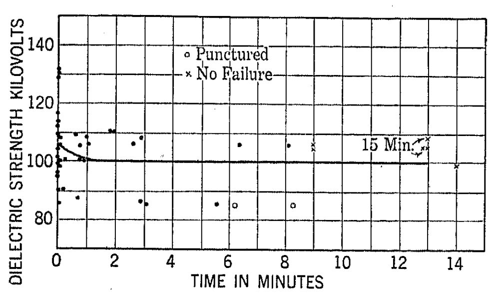

Fig. 17

60-cycle creepage tests on oil-treated, 0.0935-in. pressboard, in oil at 100 deg. cent. 4-in. diam. electrodes on opposite sides of barrier of 5 layers of pressboard. Total creepage distance 1.47-in. approx. stress on insulation 235 volts at 110 kv.

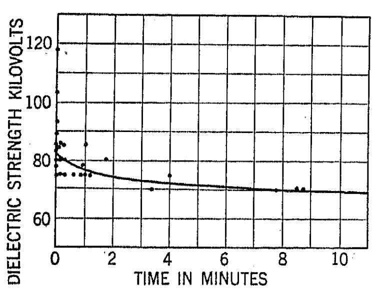

Fig. 18

420-cycle creepage tests on 0.0935-in. oil-treated pressboard, in oil at 100 deg. cent. 4-in. diam. electrodes on opposite sides of barrier of 5 layers of pressboard. Total creepage distance 1.47-in. (approx.). Stress on insulation 171 volts per mil at 80 kv.

Apparently frequency within the limits of 60 and 420 cycles has a negligible effect on the strength of oil.

d. Strength-Time Curves of Solid Insulation and Oil in Series. Referring to Figs. 19 and 20 it will be seen that the 60- and 420-cycle curves are of approximately the same shape as those (Figs. 11 and 12) for solid insulation, that is, they check the average value of a in equation (**2**). The oil duct was equal to the thickness of the pressboard sheets.

But when the oil duct is three times the thickness of the pressboard sheets, the strength-time curve taken at 25 deg. cent. Fig. 21 departs somewhat from the curve taken on solid pressboard at 25 deg. cent. (which we have seen checked the minimum value of a) and agrees more nearly with the average value of a up to about one minute. After one minute the curve apparently flattens out like the one for oil without barriers.

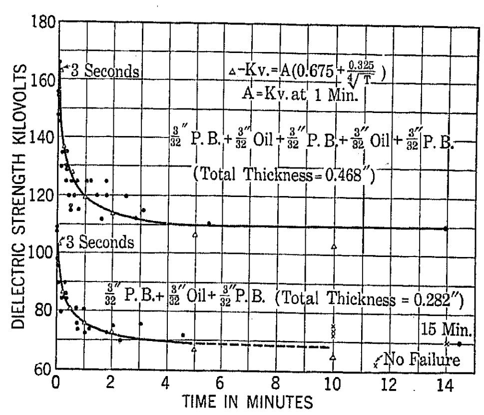

Fig. 19

60-cycle strength-time curves of oil-treated pressboard and oil in series at 100 deg. cent. oil ducts bridged by pressboard spacers. Time shown from inst. voltage (rapidly applied) became constant until failure, 4-in. diam. electrodes.

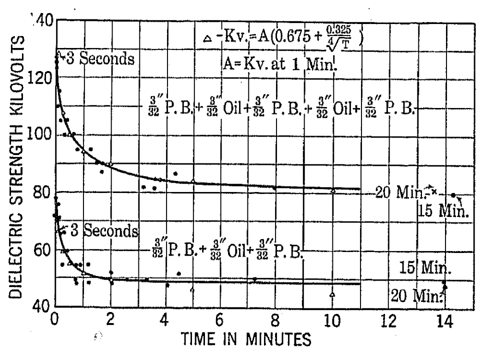

Fig. 20

420-cycle strength-time curves of oil-treated pressboard and oil in series at 100 deg. cent. Oil ducts bridged by pressboard spacers. Time shown from inst. voltage (rapidly applied) became constant until failure, 4-in. diam. electrodes

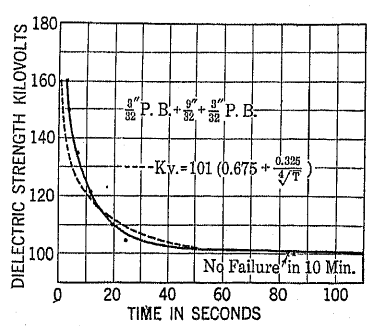

Fig. 21

60-cycle strength-time curve of solid insulation and oil in series at 25 deg. cent. Average of 10 tests, 4-in. diam. electrodes, time for voltage to build up (approx. 1 sec.) included. Material 3/32-in. oil-treated pressboard.

This is, as will be shown later, the worst condition to meet, *i. e.*, it requires the least reduction in time at the higher frequencies to make the strain equal to a 60-cycle test for one minute.

e. Variation of Dielectric Strength of Solid Insulation and Oil in Series for any Given Time. Table VIII gives the results of tests made at 60 and 420 cycles on four different combinations of oil and pressboard in series.

(Values taken from Strength-Time Curves Figs. 19 and 20). Each Value Average of 10 Tests.

Case No.	Thickness of Pressboard Sheet*	Oil Duct	60-cycle Kv.	420-cycle Kv.	Ratio: 420 cyc. kv. / 60 cyc. kv.
1	3/32 in.	3/32 in.	76 120	52 95	0.75
2	3/32 in.	3/16 in.	111.7	98.1	0.88
3	3/32 in.	9/32 in.	125.6	113.6	0.903
4	3/32 in.	3/8 in.	129.8	117.3	0.903

*Adjacent to each electrode

Assuming that the dielectric strength of solid insulation and oil in series is a function of the reciprocal of the frequency (the same as for solid insulation) the

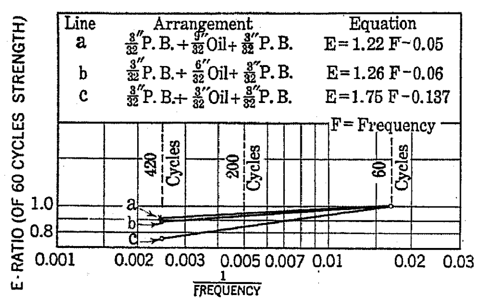

FIG. 22

Effect of oil in series with solid insulation on ratio of dielectric strength at different frequencies, 4-in. (10 cm.) diam. elec. points taken from data in Table 9.

results shown in Table IX and plotted as shown in Fig. 22 enable us to find the effect of frequency between the limits of 60 and 420 cycles on different arrangements of solid insulation and oil in series.

The equations for these conditions are as follows:

Arrangement	Equation
3/32 in. P. B. + 3/32 in. oil + 3/32 in. P. B.	$E = 1.75\ F^{-.137}$
3/32 in. P. B. + 3/16 in. oil + 3/32 in. P. B.	$E = 1.26\ F^{-.06}$
3/32 in. P. B. + 9/32 in. oil + 3/32 in. P. B.	$E = 1.22\ F^{-.05}$
3/32 in. P. B. + 3/8 in. oil + 3/32 in. P. B.	$E = 1.22\ F^{-.05}$

Relation Between Time Frequency and Dielectric Strength of Transformers

The question that naturally presents itself is: What condition shall we take to base the *time* on for various frequencies used in making induced potential tests?

The two extreme conditions are (1) oil alone which requires the same length of time no matter what frequency is used and (2) creepage over solid insulation which is under a fairly high voltage stress, *i. e.* with the electrodes on opposite sides of the barrier and where *time* had a small effect but the strength decreased with an increase in frequency. This condition would really require that the test voltage be reduced for the higher frequency even though the time be reduced. But the test voltage could not be reduced even if the time be kept the same because the test would not disclose any weak points in the oil distances.

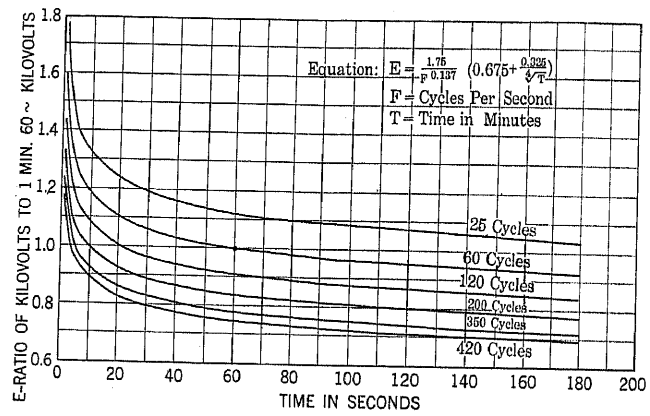

FIG. 23

Effect of frequency and time of voltage application on dielectric strength of solid insulation and solid insulation and oil in series (having equal parts of oil and pressboard) temperature 75 to 100 deg. cent.

General average conditions of either all solid insulation or of solid insulation and oil in series should be a fair basis for estimating the *time* of test.

If equation (**1**) which gives the variation in dielectric strength with time is multiplied by the equation ($E = k / F^n$) giving the variations of strength with frequency the resulting general equation is

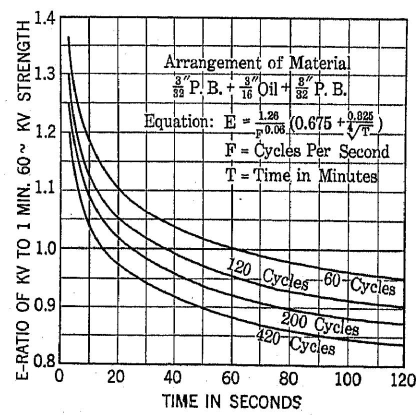

FIG. 24

Effect of frequency and time of voltage application on dielectric strength of pressboard and oil in series at 25 deg. cent.

$$E = k/F^n \left(a + \frac{1 - a}{\sqrt[4]{T}} \right) \quad (4)$$

Fig. 23 shows a series of curves plotted from equation (4) giving the relation between *time, frequency* anp *ratio of dielectric strength* for the average solid insulating materials and for a combination of solid

insulation and oil in series where the oil distance is equal to the thickness of solid insulation.

The curves shown in Fig. 24 are similar to those in Fig. 23 excepting that they are for the conditions where the oil duct is double the thickness of the press board pieces.

Expressed in seconds equation (4) becomes

$$t = \left[\frac{\dfrac{(1-a)}{E\,F^n}}{k} - a \right]^4 60 \qquad (5)$$

in which t is time in seconds, F is frequency in cycles per second, a and k are constants, n a numerical value depending on the material and arrangement of material and E is the ratio of dielectric strength, equal to unity when comparing with 60-cycle strength for one minute.

Table IX gives the relation between time and frequencies to produce the same voltage strain at 60, 200, 350 and 420 cycles.

TABLE IX.

TABULATION OF MATERIAL, TEMPERATURE, CONSTANTS AND TIME TO PRODUCE APPROXIMATELY THE SAME VOLTAGE STRAIN AT DIFFERENT FREQUENCIES—TIME CALCULATED BY EQUATION (5) ASSUMING $E = 1$

Material and Arrangement	Temp. deg. cent.	Value of Constants used in equa. (5)			Time in Seconds (Approx.) cycles			
		a	k	n	60	200	350	420
(1) Solid press board......	25	0.5	1.75	0.137	60	18	11	9.0
(2) Solid press board......	75–100	0.675	1.75	0.137	60	11	6	4
(3) Equal Dist. of P.B. and Oil..................	75–100	0.675	1.75	0.137	60	11	6	4
(4) Two 3/32 in. P.B. barriers separated by one 3/16 in. oil duct........	25	0.675	1.26	0.06	60	26	17	15
(5) Two 3/32 in. P.B. barriers separated by one 9/32 in. oil duct........	25	0.675	1.22	0.05	60	29	21	19

If we choose the constants for the arrangement of material, etc. as shown in case (5) of Table IX which condition requires the least reduction in *time*, the tabulation in Table X gives the duration of equivalent induced voltage test at various frequencies as estimated by equation (5).

TABLE X.

DURATION OF EQUIVALENT INDUCED VOLTAGE TESTS AT VARIOUS FREQUENCIES

Frequency cycles per sec.	Time of Voltage Application in Seconds
60	60
120	38
200	29
208 (3.46 × 60)	28
300	23
350	21
420	19

7. Conclusions

It is evident from the data in tables IX and X that recognition should be taken of the fact that induced potential tests when made at, say, more than double normal frequency, are far more severe that the requirements. In fact it is highly desirable that the *time* be reduced when making tests on large and expensive apparatus at considerably higher than normal frequencies, otherwise the insulation must be increased thus making it unnecessarily expensive.

8. Acknowledgements

It is desired to acknowledge the valuable assistance rendered in the Testing Department by Messrs. N. M. Albert, H. L. Garver, C. F. Green, L. D. Martin and W. F. Weikel in carrying on the long and tedious tests covering a period of three to four months.

Discussion

Insulation Tests of Transformers as Influenced by Time and Frequency

BY FRED. J. VOGEL

Assoc. A. I. E. E.

Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Review of the Subject.—*Many transformers are now being designed for service with one end of the high-voltage winding solidly grounded. These transformers require an overpotential test by induced voltage of either 2.73 or 3.46 times their normal line voltage above ground plus 1000 volts. These tests must be made at more than normal frequency, to avoid too high a flux density in the core, and also to reduce the power required for excitation. It has long been known that the breakdown voltage of solid materials was affected by the length of time of application of voltage. Likewise the frequency of the applied voltage is shown to affect the breakdown voltage for solid insulations, increase in the frequency resulting in a decreased breakdown voltage. The voltage required for creepage failure is shown to be relatively unaffected by frequency. From the results of the tests made it is concluded that induced voltage tests on transformers with graded insulation at higher than normal frequencies should not have the test voltage reduced, but should have the duration of the test shortened to make the severity of the test comparable to the test at 60 cycles on normally insulated transformers.*

WITH the advent of transmission voltages in the magnitude of 220,000 volts, on grounded neutral three-phase systems, there has been an increased tendency to design the transformers with graded insulation, that is, with insulation to ground or between windings in proportion to the actual existing voltages between these parts. With this design, the 60-cycle high-potential test from the high-voltage windings to the other windings and core, based on twice the three-phase line voltage plus 1000 volts, becomes impossible and a substitute in the form of an overpotential test by induced voltage is required. An overpotential test for such transformers frequently used by the Westinghouse Electric & Manufacturing Co. is 2.73 times the normal voltage above ground plus 1000 volts. This test requires the use of a frequency at least 2.73 times the normal frequency of the transformer, to keep the core density down to normal values. Therefore, it is seen that the insulation must be tested at higher than the normal frequency (60 cycles) used in the older high-potential tests. It is the purpose of this paper to discuss the relation of insulation breakdown to the frequency of the impressed voltage as determined experimentally for some special cases.

TYPES OF INSULATION FAILURE AND METHODS OF TESTING

There are two possible divisions of failure under oil, one in which oil failure alone is considered, that is, where no solid material is punctured, and one in which there is puncture of solid material. These can still be

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., Feb. 4-8, 1924.

further sub-divided into oil jump or creepage over the surface of solid material and puncture of solid material alone or with oil ducts intervening between the sheets of solid material. The investigation, therefore, naturally divides itself into two parts, and the methods of testing used are divided in this manner.

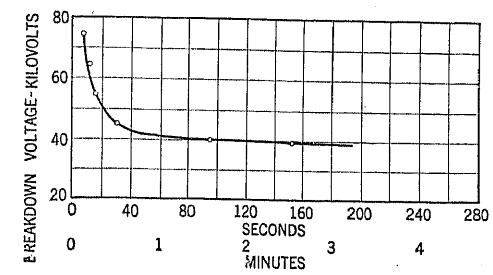

FIG. 5—TIME-VOLTAGE PUNCTURE CURVE AT 60 CYCLES
1/8-in. oil-impregnated fullerboard at 75 deg. cent.

Individual readings in the tests involving oil failure have a tendency to be erratic. In fact, this tendency is so pronounced that it was decided not to attempt to procure average values, but rather to determine the

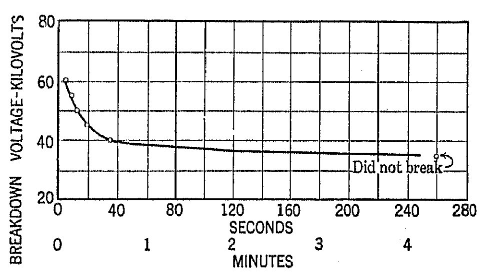

FIG. 6—TIME-VOLTAGE PUNCTURE CURVE AT 140 CYCLES
1/8-in. oil-impregnated fullerboard at 75 deg. cent.

maximum voltage which could be held a given length of time, for a considerable number of tests. To determine this, five minutes was selected as a unit of time, and tests made, starting at a fairly high value and

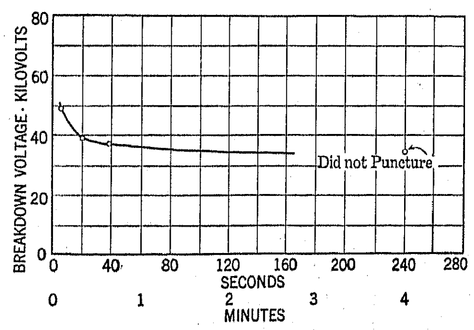

FIG. 7—TIME-VOLTAGE PUNCTURE CURVE AT 220 CYCLES
1/8-in. oil-impregnated fullerboard at 75 deg. cent.

decreasing the test voltage until the voltage was held four or five times for the desired length of time, in succession, with no breaks.

In making puncture tests where solid material was punctured, the effect of the duration of the test on the breakdown voltage was studied to determine the basis for comparison between the different frequencies. The following method was in general used to procure the individual time-breakdown voltage curves.

The field current leads of the generator supplying power were brought to the testing transformer regulating equipment, arranged so that the field current could be adjusted and the field circuit opened or closed. This permitted the most rapid application of voltage without surges by closing the generator field switch. The voltage corresponding to a given

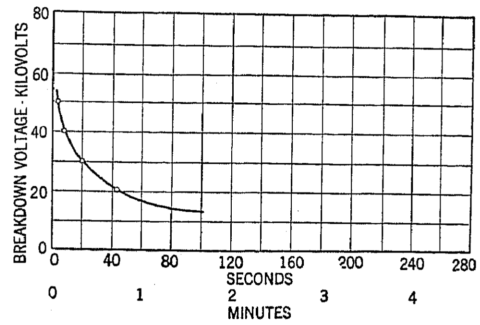

FIG. 8—TIME-VOLTAGE PUNCTURE CURVE AT 350 CYCLES
1/8-in. oil-impregnated fullerboard at 75 deg. cent.

setting of the regulator was then determined by spark gap. This setting was left undisturbed and the voltage then applied to the test piece by closing the generator field switch. Settings up to the continuous voltage strength of the test piece were checked with the spark gap and test piece in parallel, and the readings corrected to suit, as some variation occurred due to the charging current of the test piece. In the individual readings the time was noted at which failure occurred from the time the generator field switch was closed.

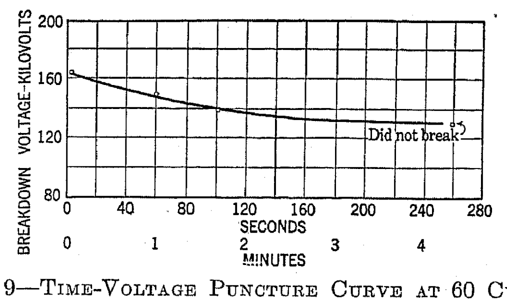

FIG. 9—TIME-VOLTAGE PUNCTURE CURVE AT 60 CYCLES AND 25 DEG. CENT.
3 sheets oil-impregnated 1/8-in. fullerboard with alternate 1/8-in oil ducts. Tested horizontally

In order that an idea of the times required for application of the voltage may be had, oscillograms showing the relation between the voltage, as it built up, and time were taken. These indicate the following times for building up of voltage after the generator field switch was closed: 50,000 volts, 60 cycles, built up in 1 second; 40,000 volts, 140 cycles, built up in 1.22 seconds; and 50,000 volts, 220 cycles, built up in 0.5 seconds. The same machine was used for the

350-cycle tests as for the 220-cycle, and the time should be less for the 350 cycles than for the 220 cycles, since for the same voltage less field current is required. In the worst case, therefore, the data taken give the

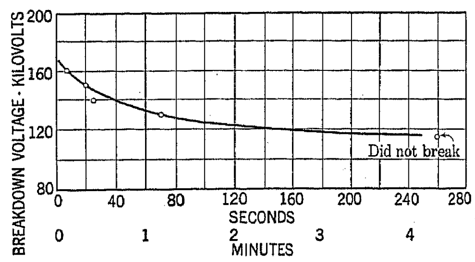

FIG. 10—TIME-VOLTAGE PUNCTURE CURVE AT 140 CYCLES AND 25 DEG. CENT.

3 sheets oil-impregnated, 1/8-in. fullerboard alternate 1/8-in. oil ducts. Tested horizontally.

times to within one or two seconds of time, except for certain tests on fullerboard at 60 cycles and in oil at 75 deg. cent. In these, nearly four seconds elapsed, but it was believed that it did not greatly affect the

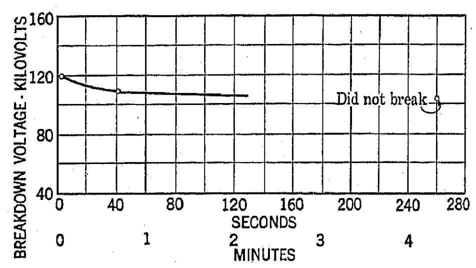

FIG. 11—TIME-VOLTAGE PUNCTURE CURVE AT 220 CYCLES AND 25 CENT. DEG.

3 sheets oil-impregnated, 1/8-in. fullerboard with alternate 1/8-in. oil ducts. Tested horizontally.

reading at one minute intervals of time, and hence these curves were not rechecked.

The wave form in each case was of pure sine form for the 60-cycle and 140-cycle frequencies. It was

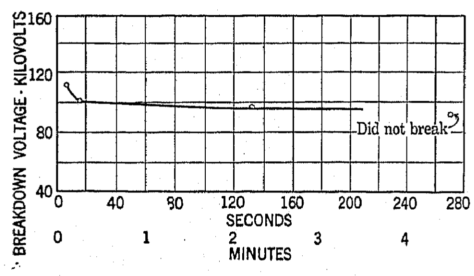

FIG. 12—TIME-VOLTAGE PUNCTURE CURVE AT 350 CYCLES AND 25 DEG. CENT.

3 sheets oil-impregnated 1/8-in. fullerboard with alternate 1/8-in. oil ducts. Tested horizontally.

impossible to make good oscillograms at 220 and 350 cycles, but the wave form is believed to be satisfactory. At all events, due to the method of test calibrating against spark gap, these data are based on crest values of the wave.

CREEPAGE TESTS

Creepage tests were made under oil, between electrodes on opposite sides of a barrier of four ⅛-in. oil-impregnated fullerboard sheets. The electrodes were located by gage ½ in. from the edge. The electrodes were of brass, 4 in. in diameter with ½ in. radius. The barriers were placed in a horizontal position.

The individual readings of the tests at 60 cycles varied so much that it was decided not to try to find average times for a given voltage setting, but rather

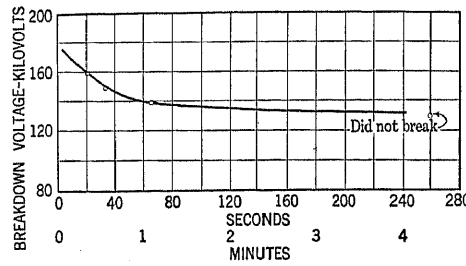

FIG. 13—TIME-VOLTAGE PUNCTURE CURVE AT 60 CYCLES AND 75 DEG. CENT.

3 sheets oil-impregnated 1/8-in. fullerboard with alternate 1/8-in. oil ducts. Tested horizontally.

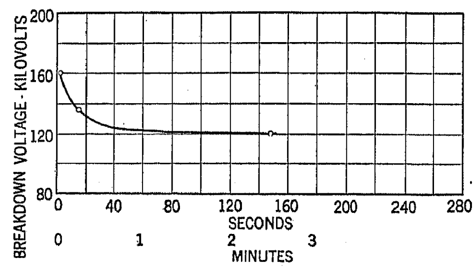

FIG. 14—TIME-VOLTAGE PUNCTURE CURVE AT 140 CYCLES AND 75 DEG. CENT.

3 sheets oil-impregnated 1/8-in. fullerboard with alternate 1/8-in. oil ducts. Tested horizontally.

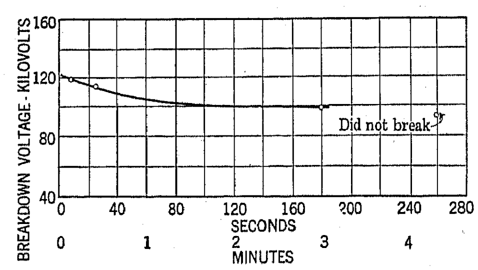

FIG. 15—TIME-VOLTAGE PUNCTURE CURVE AT 220 CYCLES AND 75 DEG. CENT.

3 sheets oil-impregnated 1/8-in. fullerboard with alternate 1/8-in. oil ducts. Tested horizontally.

to find the maximum voltage which could be held fairly continuously (5 minutes) for a number of trials with *no* failures. An idea of the variation of these readings is shown by the following data: Voltage setting, 75 kv.; oil temperature, 25 deg. cent.; time of application, 1 min., 56 secs.; 1 min. 8 secs.; 3 secs.; 4 ½ secs.; 4 min. 41 secs.; 2 min. 1 sec.; 7 min., 36 secs.; 8 secs. The above are the first eight of twenty-eight readings, of which the maximum was

13 min., 14 seconds, and the minimum, 3 seconds. Readings taken at 74 kv. were all of greater length of time than 15 minutes, no failures noted.

A table of the results obtained at other temperatures and frequencies follows:

TABULATION OF CREEPAGE DATA

Voltage held without break in five minutes.

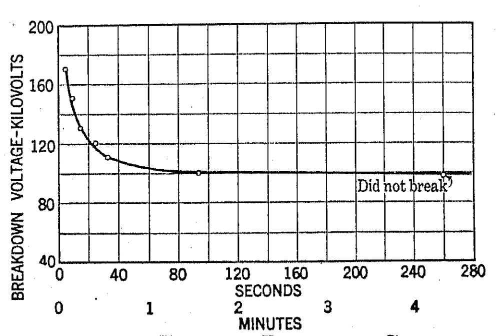

FIG. 17—TIME-VOLTAGE PUNCTURE CURVE AT 60 CYCLES AND 25 DEG. CENT.

2 sheets 1/8-in. oil-impregnated fullerboard separated by 3/8-in. oil duct. Tested horizontally.

VARIATION OF BREAKDOWN VOLTAGE OF BARRIERS UNDER OIL

A number of different conditions were investigated, at two temperatures, 25 deg. cent. and 75 deg. cent. These were, puncture voltage of ⅛-in. thick fullerboard, puncture voltage of three sheets of ⅛-in. fullerboard separated by ⅛-in. thick spacers, giving ⅝-in. puncture distance, and puncture voltage of two sheets of ⅛-in. thick fullerboard, separated by ⅜-in. thick spacers, giving ⅝-in. puncture distance also. The barriers were placed horizontally except for a special test which is reported later. All fullerboard was vacuum-dried and oil-impregnated.

The method of test has been described previously. These data will be reported in the same order as described above, and the typical curve shapes shown for the relation between time and breakdown voltage for any frequency. The electrodes used were four inch diameter brass disks, with one-half inch radius.

Curves of the original data for all the different tests are shown, in curves 1 to 24. It will be seen that the curves are of similar shape, but it is not believed that they are sufficiently so that a representative curve can be drawn.

From these data the relative times can be derived for a given voltage to cause failure at the different frequencies. A tabulation of these results, based on a voltage sufficient to cause failure at the end of one minute at 60 cycles, follows:

Tests on ⅛-in. fullerboard.
Fullerboard placed horizontally in tank.
Curves 1 to 8 inclusive.

Breakdown Voltage	60 cycles	140 cycles	220 cycles	350 cycles

	Times for breakdown, 75 deg. cent.			
106,000	1 min.	50 secs.	14 secs.	Inst.

APPLICATION OF DATA TO TESTS ON APPARATUS

From the above data, testing apparatus at higher frequencies increases the severity of the test rapidly. The principal reason for the adoption of the trans-

*1. The tests at 25 deg. cent. at 60 cycles and 350 cycles, were also made with the barriers and oil ducts vertical. It was felt that some increase might result due to freer oil circulation, and it was indeed noted that the shapes of the curves were more nearly the same, and that they were higher than those where the barriers were horizontal. See curve 25 for comparison with curves 9 and 12. The horizontal tests were made as illustrating worst possible conditions.

former with graded insulation is to reduce the amount of insulation required, and if it is found necessary to increase parts of the insulation, merely to meet tests, over that required for the normally insulated transformer tested at the lower frequency of 60 cycles, its

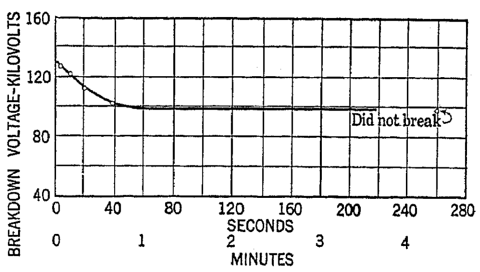

FIG. 18—TIME-VOLTAGE PUNCTURE CURVE AT 140 CYCLES AND 25 DEG. CENT.

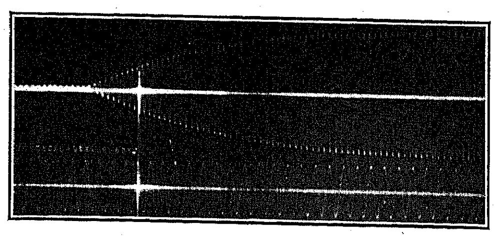
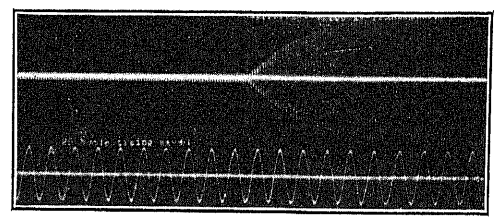
BUILDING UP OF FIELD ON 140-CYCLE GENERATOR TRANSFORMER REGULATOR SET FOR 40-KV.



BUILDING UP OF FIELD ON 60-CYCLE GENERATOR FIELD EXCITED BY 500 VOLTS INSTEAD OF 110 VOLTS

advantage is to some extent at least lost. For this reason the designer is interested to determine what insulation test, if any, would test such apparatus to the same severity as if it could be tested at 60 cycles.

Referring to the results of the creepage data, it would appear that failures due to creepage are not greatly affected by frequency. This is more or less to be expected, for the following reasons: Creepage breakdown, in the absence of foreign conducting material, is probably largely a question of oil failure. For fluids it would also be expected that frequency would not result in quite as large a decrease in the breakdown voltage as for solid material, due to the relative absence of the effect of heat. For air, indeed, the effect of frequency is very slight. Therefore no decrease in the actual voltage



BUILDING UP OF FIELD ON 220-CYCLE GENERATOR SUPPLYING 300-KV. TRANSFORMERS.

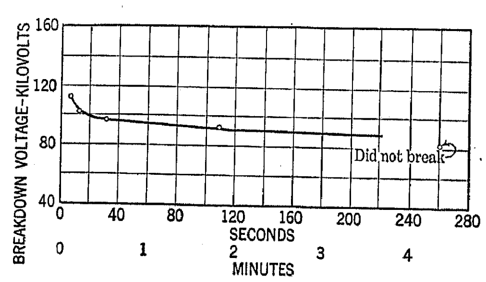


FIG. 20—TIME-VOLTAGE PUNCTURE CURVE AT 350 CYCLES AND 25 DEG. CENT.

applied for test would be desirable. On the other hand, the effect of time is not as great for this type of breakdown. Down to the point at which the applied voltage could be held permanently, the tests were erratic, but the point at which it would hold this voltage appeared to be quite definite. Very slightly above the critical voltage tests of relatively very short time might be obtained. It would be recommended, therefore, that for any test at over 60 cycles contemplated to equal the severity of a 60-cycle, one minute test, that no decrease

in the testing voltage be made, but rather that the duration be decreased to provide for decreased puncture strength of the solid material.

At some places in a transformer insulation failure would involve the puncturing of fullerboard entirely, at others only a portion of fullerboard and oil in series. Observation of the puncture curves would indicate that variations occur with the different percentages of fullerboard which are impossible to reconcile into any kind of average or representative data. Possible reasons for these variations are as follows: For the ⅛-in. fullerboard it is possible that the electrodes, of brass, reduced the heating of the fullerboard due to its large thermal capacity. This possibly would increase the duration of time for a given breakdown voltage and make it longer in the case of the higher frequencies than for the other combinations as tabulated above. For the barriers with the three sheets of fullerboard it is apparent that the higher frequency tests are very severe. For the barriers with two sheets, the conditions are less severe. This might be expected, since if oil is the less affected by frequency, the less the percentage of fullerboard in a given distance, the less the breakdown voltage should be affected by frequency.

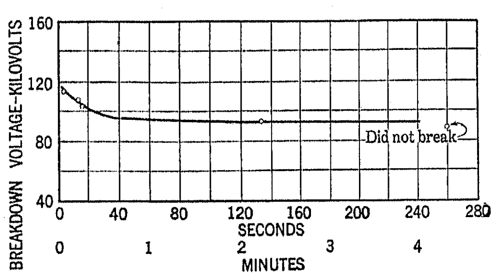

FIG. 23—TIME-VOLTAGE PUNCTURE CURVE AT 220 CYCLES AND 75 DEG. CENT.

2 sheets 1/8-in. oil-impregnated fullerboard separated by 3/8-in. oil duct. Tested horizontally.

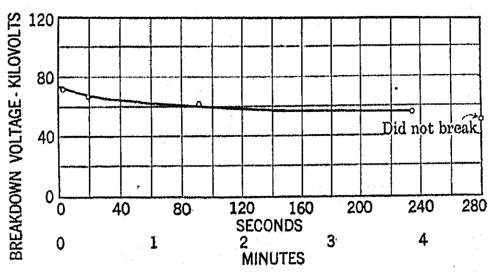

FIG. 24—TIME-VOLTAGE PUNCTURE CURVE AT 350 CYCLES AND 75 DEG. CENT.

2 sheets 1/8-in. oil-impregnated fullerboard, separated by 3/8-in. oil duct. Tested horizontally.

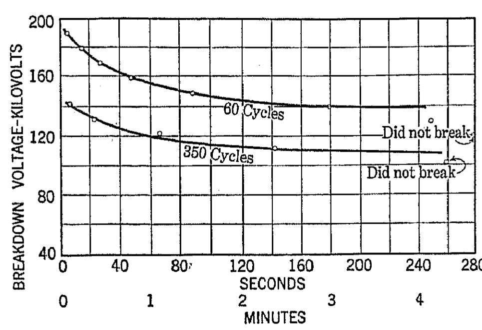

FIG. 25—TIME-VOLTAGE CURVE AT 60 AND 350 CYCLES 25 DEG. CENT.

3 sheets 1/8-in. oil-impregnated fullerboard with alternate 1/8-in. oil ducts. Tested vertically..

In an actual transformer, for the higher voltages, a large proportion of its insulation between windings is of less than fifty per cent fullerboard. It is believed that forty per cent is a fair average of the minimum amount between the windings. From the point of view of making the test on the part least affected by frequency sufficiently severe, it would seem that the condition represented by the two sheets of fullerboard should be chosen. Accordingly it would be logical that the test voltage should be its normal value and that its duration should be decreased in line with the results of the tests, using the lower percentage of fullerboard.

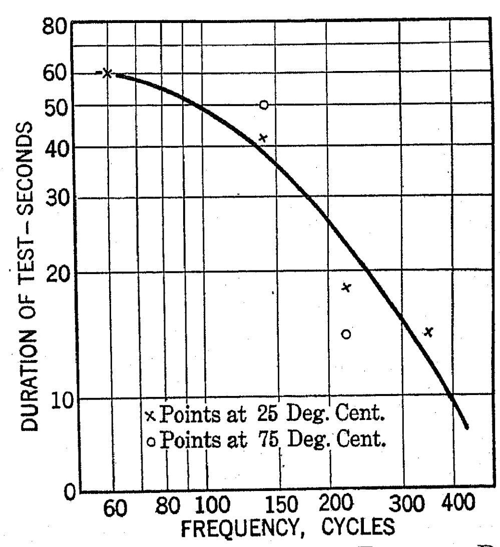

FIG. 26—TIMES FOR PUNCTURE TESTS AT DIFFERENT FREQUENCIES BASED ON VOLTAGE GIVING PUNCTURE IN 60 SECS. AT 60 CYCLES

X Points at 25 deg. cent.
⊙ Points at 75 deg. cent.

Fig. 26 shows points plotted between frequency and time, based on the voltage for puncture in one minute at 60 cycles, for both 25 deg. cent. and 75 deg. cent. These points, being values read from other curves whose individual accuracy may not be over 5 per cent, do not permit drawing a very accurate curve. The curve shown is fairly representative of conditions at both 25 deg. and 75 deg. cent., it is believed. It is perhaps slightly favorable to the apparatus at frequencies up to 150 or 160 cycles, but is decidedly unfavorable at frequencies much over 200 cycles, since apparatus is tested while hot, and the data show the higher frequencies, at 75 deg. cent. to be very severe.

From Fig. 26 the table which follows might then be proposed, for the application of induced test voltages, at higher than 60 cycles. The times are given for 164 and 208 cycles, since these are frequencies which are approximate multiples of test voltages required by the Standardization Rules of the American Institute of Electrical Engineers. The times given for the higher frequencies would require that extra insulation be given to the transformer above that needed if it could be tested at 60 cycles, but this is done to provide for the larger units, which may require testing at these frequencies to reduce the power required for testing.

Duration of Equivalent Induced Voltage Tests at Various Frequencies

Frequency	Time of Application
60 cycles	60 seconds
120 cycles	44 seconds
164 cycles (2.73 x 60)	33 seconds
208 cycles (3.46 x 60)	26 seconds
240 cycles	21 seconds
360 cycles	11 seconds
400 cycles	10 seconds

Discussion

EFFECT OF TIME AND FREQUENCY ON INSULATION TESTS OF TRANSFORMERS[1] (Montsinger)
and
INSULATION TESTS OF TRANSFORMERS AS INFLUENCED BY TIME AND FREQUENCY[2] (Vogel)

Philadelphia, Pa., February 7, 1924

Vladimir Karapetoff: For several years previous to his death, Dr. Steinmetz talked from time to time about third-class conductors and pyroelectric effects, and I often asked myself, why this interest in the third-class conductors. I did not see the point until the appearance of his paper in the "*Electrical World*," giving the so-called *pyroelectric theory of breakdown of insulation*. At the same time, but independently from Dr. Steinmetz, Dr. K. Willy Wagner in Germany was working on the same subject. He came to this country on a visit in 1922 and read a paper (printed in the 1922 A. I. E. E. Transactions) which for a long time will remain a classic on the subject. In other words, where Dr. Steinmetz only had time to go into the theory qualitatively, Dr. Wagner also gave us at least a beginning of a mathematical theory of the breakdown of solid dielectric.

The principle underlying this theory is as follows: Let there be a layer of solid dielectric between two metal electrodes and let this layer be subjected to a d-c. voltage. Let us also assume that somewhere in this dielectric there is a weak filament (or a succession of weak spots which later form a weak filament) along which a breakdown takes place. According to the pyroelectric theory, not only the whole dielectric has a negative temperature-resistance coefficient (which we know only too well to be true), but this weak filament in particular has a very marked negative temperature coefficient, so that the conductivity of this filament or thread increases as the temperature goes up. In this you see immediately an element of instability, which should lead to a breakdown. Being a weaker filament, in the sense of having initially a somewhat higher conductivity than the rest of the material, this filament conducts in proportion more current than the rest of the sheet and consequently becomes warmer than the rest. But, by supposition, when it becomes warmer, its conductivity increases; therefore, it begins to draw more current. Its conductivity again goes up, and so forth. Thus, naturally, a conductor of this kind, applied at a source of sufficient high potential, must ultimately take an infinitely great current. Before it does so, the material is carbonized, or otherwise changes, and we have a breakdown. In other words, according to both Dr. Wagner and Dr. Steinmetz, we have here a pure thermal or pyroelectric effect. There is no mysterious "breakdown," no critical voltage in that sense; it is simply a matter of heating a filament to a point where it becomes a piece of carbon.

Now, if that be so, then by using a source of constant current rather than a constant voltage, we should be able to go beyond the "limit" and yet not break a sample down. Dr. Wagner used wooden blocks for electrodes, with fibers in the direction of the current. Dr. Steinmetz used a Nernst filament, that is, a piece of material of very marked negative temperature coefficient. They both proved that you can go beyond the critical value of the current, but because there isn't enough voltage to cause an infinite current the material can be cooled again and it will be just as good as before, showing that there is no "electric breakdown" but only a thermal effect.

Perhaps it is a one-sided theory; perhaps the theory is only partly true; perhaps there are other factors to be considered. But if this theory be true at least in part, certain mathematical relations follow immediately. You can write a differential equation between the applied voltage and the temperature, and this equation, integrated, gives a function which a material ought to obey. Dr. Wagner uses three different conduction functions to start with, and carries his computations through, correctly stating that we haven't enough experimental evidence as yet to decide which of the three functions is the best. We at Cornell took still another function and also carried the mathematical deductions through to show that there are also other possibilities and that the pyroelectric theory is very elastic in its very foundation.

The papers under discussion interested me greatly as offering new material for a confirmation or a modification of the pyroelectric theory. Dr. Wagner has computed the theoretical effect of the frequency upon the breakdown, and also the effect of the time of application. No matter which of his three functions he takes, the effect of the frequency is linear. If you plot the breakdown voltage against the frequency as abscissa, you obtain a slanted straight line because as the frequency increases, the dielectric loss also increases. It heats the slab and thus prevents more heat from being radiated from the filament sidewise.

Referring first to Figure 16 in Mr. Montsinger's paper, he obtains a straight line when he plots his voltage, not to cycles but to log. of 1 over cycles. This being a straight line, plotting it to the frequency would give a curve of the shape of a hyperbola. So I thought at first that Wagner's theory was inadequate in this case. However, you will notice that the point corresponding to 25 cycles is rather uncertain, and it is the 25-cycle point that makes the curve go up so much. By changing it a

little, we can get a much closer approximation to a straight line. If we take the data given in Fig. 15 (I selected the data for four layers) and replot them to frequency, we obtain an almost straight line, except for 25 cycles.. Taking, furthermore, the first page of Mr. Vogel's paper and combining the ultimate voltages there for different frequencies, I also get practically a straight line. So that on the whole, I see in the new data a confirmation rather than a contradiction of Wagner's theory. I hope that from now on we shall not only multiply experimental data, but also analyse them so as to see whether they confirm or contradict the pyroelectric theory.

Everett S. Lee: Here we have an example of two investigations, made in different places by different men, both to answer the same question, and although they got together, I take it, before they started to make their tests, I am quite sure that they viewed their conclusions in finality before getting together, and if you will read both papers and go through them very carefully, you will note that they are remarkably consistent for this kind of work. One reason is because of the fact that the tests were taken under essentially the same conditions.

In that regard I would call to your attention the fact that at the present time the American Society for Testing Materials is doing quite a bit of work to try to standardize tests on electrical insulating materials. That is of interest to all of you, and if you will place yourself in the position of the man who has to make those tests and go to the standards of our own Institute to try to find out how those tests should be made, or what time should be used in making the tests, etc., you will find nothing there. In other words, it is a branch of the art that has not been taken up and put in the standards of our Institute. So that the American Society for Testing Materials is doing that work, and a considerable amount of the information that Mr. Montsinger and Mr. Vogel compiled has been used in allowing us, in turn, to standardize work requiring the determination of the dielectric strength of insulating materials.

I call your attention particularly to the fact that the curve between dielectric strength and time of voltage application is not a straight line and that tests made for dielectric strength of insulating materials, where the value of time may be low, may bring you on such a portion of the curve that a small difference in time will mean a large difference in dielectric strength; so that if an observer in New York compares some data with an observer some miles distant, those two observers may find that they have different results if they have not taken this into account. So I feel that in these two papers we have been helped considerably in that phase of the work.

Regarding Professor Karapetoff's discussion, we too noted, as he brought out, a tendency for that curve to bend upward at the lower frequencies, and I might state that Dr. Steinmetz had in mind making tests very carefully in the range of 25 cycles down to zero, and that portion of the work which he was carrying on is being continued, and we hope that it will throw additional light upon this particular phase of the question.

I hope that all of you have taken occasion to read the article entitled, "High Voltage Insulation," by Dr. Steinmetz and Mr. J. LeRoy Hayden, which appeared in the January issue of the JOURNAL, because that paper summarizes practically in toto the results of the work which Dr. Steinmetz had carried on in the last few years in his investigation of the mechanism of breakdown of insulating materials.

V. M. Montsinger: I am very glad to have Professor Karapetoff discuss this question from the pyro-electric theory standpoint. I have read very carefully both Dr. Wagner's and Dr. Steinmetz' articles on the pyro-electric theory of failure of insulation. Space, however, did not permit of making comparisons between my results and the formulas given by Dr. Wagner in the way it should be done. Furthermore, additional data on the strength at the lower frequencies, that is, from about 25 cycles down to 0 cycles (direct current) are needed before drawing any definite conclusions as to whether the data substantiates or refutes Dr. Wagner's formula which shows that the strength is a linear function of the frequency. From what tests I have made and according to Mr. Vogel's tests made on single sheets of pressboard (fullerboard) the linear function does not seem to hold very well. For example, taking the data from Mr. Vogel's curves, Figs. 1 to 8 inclusive, covering tests made at 60, 140, 220 and 350 cycles and at 25 deg. and 75 deg. cent. and plotting the 20-sec. kv. values (which points appear to be the most reliable) against the reciprocal of the frequencies, we get practically straight lines on log-log paper, the slopes of the lines being 0.146 at 25 deg. cent. and 0.136 at 75 deg. cent. The average slope of the two lines is approximately 0.141 as against the value of 0.137 which I obtained. From the available data, the indications are that the dielectric strength of solid insulation is not strictly a linear function of the frequency. Further work along this line is being done and it is hoped that enough additional data can be secured to settle this point one way or another.

Short Circuits of Alternating-Current Generators

BY C. M. LAFFOON

Power Engineering Dept., Westinghouse Electric and Mfg. Co.

Review of the Subject.—*In this paper, the author presents a physical conception and simple non-mathematical analysis of the short-circuit phenomena of alternating-current generators. Formulas are developed for the maximum instantaneous values of the armature and field short-circuit currents delivered by both single and poly-phase generators, which are equipped with and without damper windings.*

A similar analysis covering the rate of decay and the sustained values of the short-circuit currents will be presented in the near future.

THE physical phenomena resulting from the short circuit of alternating-current generators are becoming more or less familiar to the interested electrical designing, and operating engineers. In a general way, it is also well known that the normal flux interlinkages, currents, and induced voltages which are inherently associated with the magnetic and electric circuits of an alternator are thrown into a state of unstable equilibrium when the alternator is suddenly short-circuited at or near its terminals.

Oscillograph records of the armature current delivered by an alternating-current generator under short-circuit conditions show that it reaches a maximum peak value, either during, or at the end of the first half-cycle of the current wave. The peak values of the successive waves gradually decrease in amplitude until a constant or sustained value is reached, usually at the end of two or three seconds. Moreover, if several oscillograms are

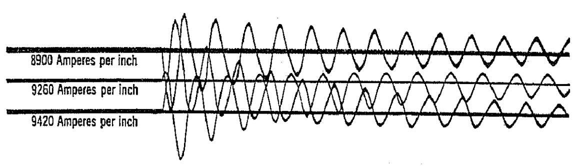

FIG. 1—SHORT-CIRCUIT TEST ON 6250-KV-A. TURBO-ALTERNATOR

60 cycles, 3600 rev. per min., 6600 volts per phase. Star-connected Oscillogram shows current in three phases, 100 per cent voltages.

taken at random, under the same apparent initial conditions, the armature current waves may be either totally, or partially displaced with respect to a zero reference axis during a short time interval immediately following the short circuit. The displacement of the wave is a maximum during the first cycle and then rapidly decreases to zero, so that the wave is, as a rule, approximately symmetrical by the end of the first half second. Similar oscillographic records of the field current show that it also rises in peaks to values several times normal, immediately after short circuit, and then the pulsations decrease in amplitude and are either completely damped out or reach a permanent value, depending on the kind of short circuit, *i. e.*, whether it is a polyphase or a single-phase short circuit.

Fig. 1 shows an oscillogram of the armature currents delivered by a three-phase a-c. generator under short-circuit conditions. The amount of displacement of the current waves, the maximum value of the currents, the rate of decrease of the peak values, and the time required for the waves to become symmetrical are all different for each phase of the generator winding. Fig. 2 is an oscillogram of the field current that flows when a three-phase alternator is suddenly short-circuited. The pulsations which are of line frequency are quickly damped out and the excess direct current gradually decreases to zero value. Figs. 3 and 4

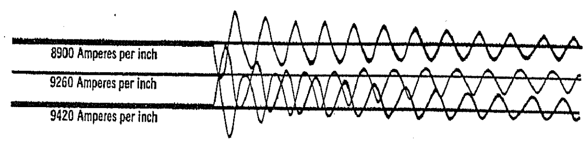

FIG. 1A—SHORT-CIRCUIT TEST ON 6250-KV-A. TURBO-ALTERNATOR

show oscillograms of the armature and field currents that flow when a single-phase generator, without a damper winding, is short-circuited. In this case the pulsations in the field current which are of double-frequency decrease in amplitude until a constant value is reached, but do not totally disappear.

From the practical standpoint, the most important phases of the short-circuit phenomena of a-c. generators are:

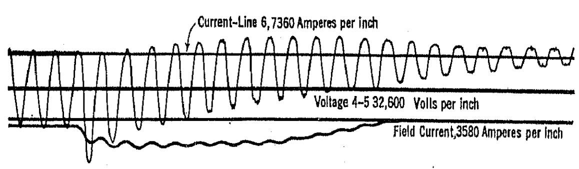

FIG. 2—SHORT-CIRCUIT TEST TURBO-GENERATOR

(a) the maximum peak values of the armature and field currents that are reached during the first half-cycle after the short circuit occurs:

(b) the rate of decrease of the peak and r. m. s. values of the current waves for the armature and field circuits; and

(c) the final or sustained values of the armature current.

The maximum peak values of the armature and field

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

currents are especially important for they impose the maximum torque on the rotor shaft; the maximum force between the armature conductors of different phase groups; and the maximum force between the end turns of the armature and field windings. The rate of decay of the r. m. s. values of the current determines the amount of energy the auxiliary control apparatus and circuit breakers must absorb before the short circuit is removed, and the successive peak values determines the duty imposed on the circuit breakers in removing the short circuit. The final or sustained values of the armature current determines the heating and consequently, the temperature rise of the armature winding in case the circuit breakers fail to function or the short circuit occurs between the generator and the circuit breakers.

Of the considerable number of articles which have

been written to explain the short-circuit phenomena of a-c. generators, the most noted and classic is the analysis presented by Dr. P. Boucherot in 1912.[1] However, in this case as well as in most of the others the mathematical considerations have predominated and the interpretation and results can not be effectively grasped by a large number of engineers who are not familiar with the mathematics involved. In view of this fact, it is the purpose of the writer in this discussion to present the physical conception and analysis of the short-circuit phenomena of a-c. generators in a simple manner so that it can be analyzed by the average interested engineer. Nothing but the simplest mathematics will be used in establishing the current and voltage relations. The simplest type of a-c. generator will be considered first, and later modifications will be made to cover actual practical machines.

FUNDAMENTAL FLUX RELATIONS FOR A SINGLE-PHASE GENERATOR

In the simple type of single-phase generator shown in Fig. 5, the stationary and rotating elements are both considered to be perfectly laminated and to have infinite permeability. The stationary element is provided with

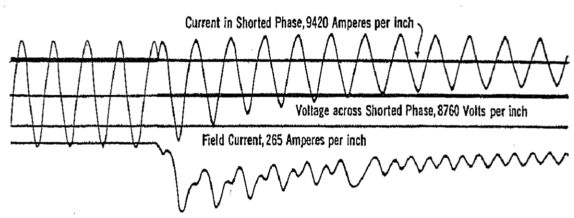

FIG. 4—SHORT-CIRCUIT TEST ON TURBO-ALTERNATOR, 6250 KV-A.

60 cycles, 3600 rev. per min., 6600 volts per phase. Single-phase test. Current and voltage in short-circuited phase and field current. 75 per cent voltage.

an armature winding, $A\,A_1$, which is uniformly distributed over a portion of the armature periphery and has N_a turns, all of which are connected in series. The salient pole rotor has a field winding, $P\,P_1$, of N_1 turns connected in series. When a direct current, I_1, flows in the field circuit a total magnetic flux, I_1, ϕ_1, is produced which interlinks these windings as shown by the dotted lines in Fig. 5. In the above expression, the symbol, ϕ_1, is defined as the total flux produced by the field circuit when one ampere flows in it. This total

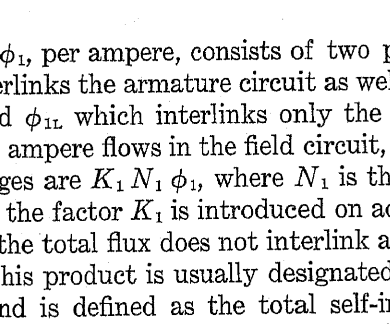

FIG. 5

field flux, ϕ_1, per ampere, consists of two parts; $\phi_{m1\,a}$, which interlinks the armature circuit as well as the field circuit and ϕ_{1L} which interlinks only the field circuit. When one ampere flows in the field circuit, its total flux interlinkages are $K_1\,N_1\,\phi_1$, where N_1 is the number of turns and the factor K_1 is introduced on account of the fact that the total flux does not interlink all of the field turns. This product is usually designated by the symbol, L_1 and is defined as the total self-inductance or coefficient of self-induction of the field winding. In a

1. Note: Since the present paper was written, another noteworthy paper on the short circuit of a-c. generators was presented by Mr. R. E. Doherty in June, 1923. (See JOURNAL A. I. E. E., Oct. 1923).

similar manner the quantity, $\mathcal{L}_1 = k_{1L} N_1 \phi_{1L}$, is defined as the coefficient of leakage self-induction of the field circuit. Similarly, the flux interlinkages of the armature circuit due to one ampere flowing in the field circuit are equal to, $K_{m1a} N_a \phi_{m1a}$, which is defined as the coefficient of mutual induction between the armature and field circuits and is represented by the symbol, m_{1a}.

Coefficient of Leakage Self Induction with Different Rotor Positions

By referring to Fig. 5, it is evident that none of the field flux interlinks the armature winding, when the axis of the field winding is at right angles to the axis of the armature winding, and the coefficient of leakage self-induction of the field winding is equal to its coefficient of total self-induction. When the axis of the two windings coincide, the coefficient of leakage self-induction is a minimum. Since these two rotor positions are displaced 90 degrees, it is obvious that the leakage induction coefficient of the field winding varies between maximum and minimum values at double frequency for the different rotor positions. This variation of the coefficient of leakage self-induction for the different rotor positions is shown by the double frequency curve in Fig. 6.

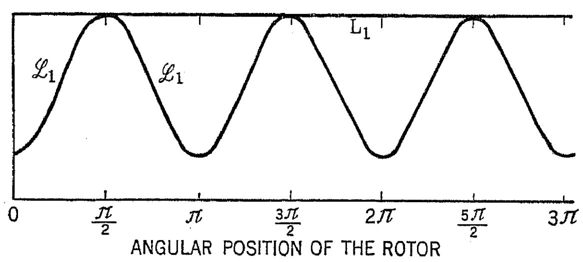

Fig. 6

Coefficient of Mutual Induction with Different Rotor Positions

The shape of the field pole projections is such that the density of the field flux which crosses the air gap and enters the stator core varies approximately as a sine law around the periphery of the armature. Since the field flux is carried mechanically around the stator core when the rotor is driven at a given speed, the flux interlinkages of the armature circuit per ampere in the field circuit vary between maximum and minimum values at the same or synchronous frequency. With the rotor in the angular position shown in Fig. 5, the mutual flux interlinkages of the armature circuit are a maximum. And 90 degrees later, when the field winding is at right angles to the armature winding none of the field flux interlinks the armature winding and its coefficient of mutual induction is zero. When the rotor is in the 180 degree position, the flux interlinkages of the armature winding are the same in magnitude as in Fig. 5, but the flux lines link the circuit in the reverse direction. Since the distribution of the field flux is sinusoidal with respect to the armature periphery, the actual value of the mutual induction coefficient will follow a cosine law as shown by curve 2 in Fig. 7.

Using a similar system of notation, the corresponding induction coefficients of the armature circuit can be written and defined as follows:

$L_a = K_a N_a \phi_a$, coefficient of total self-induction of the armature circuit.

$\mathcal{L}_a = K_{la} N_a \phi_{la}$, coefficient of leakage self-induction of the armature circuit.

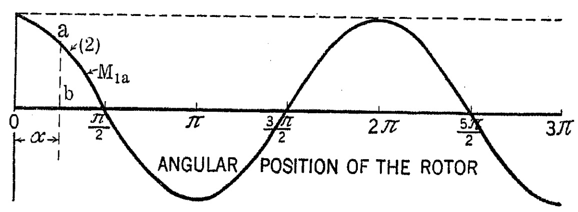

Fig. 7

$M_{a1} = K_{ma1} N_1 \phi_{ma1}$, coefficient of mutual induction of the armature and field circuits.

The coefficient of total self-induction of the armature circuit is not constant for all rotor positions on account of the salient pole construction of the rotor. The leakage induction coefficient of the armature circuit varies between maximum and minimum values according to the same general law as for the similar coefficient of the field circuit. The relation between the total and leakage induction coefficients of the armature circuit is shown by the curves in Fig. 8.

It is well known from the laws of physics that the mutual induction coefficient of two inductively coupled circuits is the same for either circuit with respect to the other; that is, in the case under consideration, $M_{a1} = M_{1a}$, and $K_{m1a} N_a \phi_{m1a} = K_{ma1} N_1 \phi_{ma1}$. Under this condition the curve in Fig. 7 shows the variation of the mutual induction coefficient of either the field circuit with respect to the armature circuit or the armature circuit with respect to the field circuit for any angular position of the rotor.

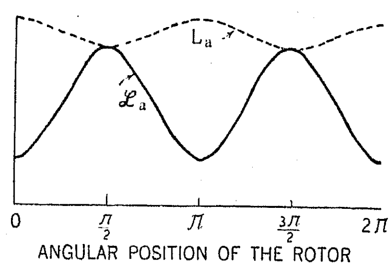

Fig. 8

If the induction and resistance coefficients of the circuits are known, the magnitude of the currents can be readily determined for both stable and transient

conditions when the voltage or flux relations are known. However, under transient short-circuit conditions a better physical conception and simpler analysis of the flux and currents during the first half cycle after the short circuit occurs can be had by assuming the armature and field circuits, both, to have zero resistance. Under this assumption, the instantaneous values of the short-circuit currents for the different circuits can be easily obtained by applying Lenz's fundamental law which can be stated as follows:

"If a closed electric circuit has a given number of flux lines interlinking it, any *change* or *variation* in the number of flux interlinkages will cause a current of sufficient magnitude to flow in the circuit in such direction that the initial flux interlinkages of the circuit are maintained constant."

Maximum Instantaneous Value of Short-Circuit Current

Single-Phase Generator Without Damper Winding. If the armature circuit of the single-phase generator is suddenly short-circuited at the instant the axis of the

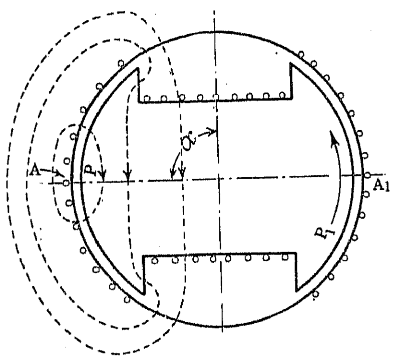

Fig. 9

field winding coincides with the axis of the armature winding, as shown in Fig. 5, the initial flux interlinkages which must be maintained constant, are $I_1 L_1$, and $I_1 M_{1a}$, respectively for the two circuits. At an instant later, when the rotor has turned through a small angle α the initial flux interlinkages of the armature circuit are decreased. Consequently, a current will flow in this winding tending to supply the decreased amount of flux interlinkages. However, when a current flows in the armature circuit it not only produces a flux interlinkage with itself, but also adds additional flux interlinkages to the field circuit. These additional flux interlinkages of the field circuit will in turn tend to be neutralized by an opposing flux set up by a secondary current in the field circuit. At any instant the currents in the two circuits must be of such magnitude that the resultant flux interlinkages of each circuit due to the combined action of all currents are the same as at the instant that the short circuit occurred.

When the rotor is in the angular position shown in Fig. 9, none of the field flux interlinks the armature circuit and the total change of its flux interlinkages are I_1, M_{1a}. At this instant the leakage and total self-induction coefficients of the armature circuit are one and the same as shown by Fig. 8. Consequently, the current, i_a, that flows in the armature circuit must be such that its total flux interlinkages are equal to the change in its initial flux interlinkages.

That is,

$$i_a L_a = i_a \mathfrak{L}_a = I_1 M_{1a}, \text{ or}$$

$$I_a = \frac{I_1 M_{1a}}{L_a} = \frac{I_1 M_{1a}}{\mathfrak{L}_a} \quad (1)$$

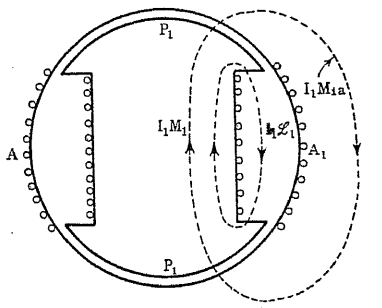

Fig. 10 A

α = 180 deg. $I_1 L_1 = I_1 L_1 + I_1 M_1$

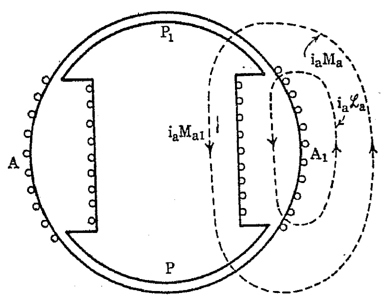

Fig. 10 B

α = 180 deg. $i_a L_a = i_a L_a + i_a M_a$

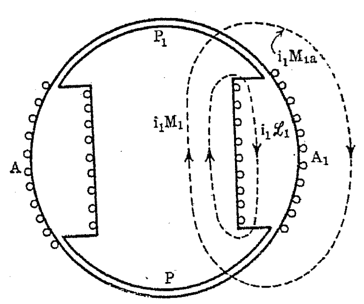

Fig. 10 c

α = 180 deg. $i_1 L_1 = i_1 L_1 + i_1 M_1$

At this instant, there is no current flowing in the field circuit except the normal exciting current, I_1.

When the rotor has turned through 180 degrees as shown in Fig. 10A, the interlinkages of the armature circuit due to the exciting current, I_1, in the field circuit are the same as at the instant of short circuit but interlink it in the reverse direction. Hence, the total change in the normal field flux interlinking the armature circuit is from $I_1 M_{1a}$ to $- I_1 M_{1a}$ or $2 I_1 M_{1a}$. The current,

i_a, that flows in the armature circuit produces a total flux interlinkage, $i_a L_a$, with itself. This total flux interlinkage consists of the leakage flux interlinkages, $i_a \mathcal{L}_a$, and the flux interlinkages $i_a M_a$ due to the mutual flux as shown in Fig. 10B. The corresponding flux interlinkages of the field circuit, due to the normal flux are, $i_a M_{a1}$. Since the interlinkages of the field circuit must be maintained at a constant value $I_1 L_1$, the flux interlinkages of the field circuit due to its secondary current, i_1, must be equal to the mutual flux interlinkages from the armature circuit.

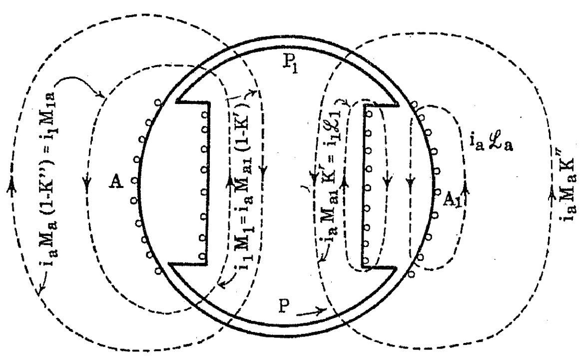

FIG. 11
$\alpha = 180$

That is,

$$i_1 L_1 = - i_a M_{1a}\text{, or}$$
$$i_1 = - i_a M_{1a}/L_1 \qquad (2)$$

For the purpose of analysis, the flux interlinkages $i_a M_{a1}$, of the field circuit due to the armature current can be separated into the two components, $K' i_a M_{a1}$, and $(1 - K') i_a M_{a1}$, where K' is a constant for this particular rotor position. In a like manner, the flux interlinkages of the armature circuit due to its own mutual flux can be divided into two components, $K'' i_a M_a$, and $(1 - K'') i_a M_a$. Fig. 11 shows the components of the flux interlinkages of both circuits due to the currents, i_a and i_1, on the basis that the resultant flux interlinkage of each circuit is the same as at the instant of short circuit. (The flux interlinkages due to the normal field current are not shown for the sake of clearness.)

From Fig. 11 the following flux interlinkage relations for the field circuit are evident.

$$i_1 M_{1a} = - i_a M_{a1} (1 - K') \qquad (3)$$
$$i_1 \mathcal{L}_1 = - i_a M_{a1} K' \qquad (4)$$

Therefore,

$$i_1 M_{1a} + i_1 \mathcal{L}_1 = - i_a M_{a1} (1 - K') - i_a M_{a1} K'\text{, or}$$
$$i_1 L_1 = - i_a M_{a1} \qquad (5)$$

That is, the total flux interlinkages of the field circuit due to the current, i_1, are equal to and neutralized by the total mutual component of the armature flux interlinkages, consequently the only flux interlinkages of the field circuit are $I_1 L_1$ which are the same as the initial value.

From Fig. 11 the following flux interlinkage relations must be satisfied for the armature circuit at this angular position,

$$i_a M_a (1 - K'') = i_1 M_{1a} \qquad (6)$$
$$i_a M_a K'' + i_a L_a = \text{resultant flux interlinkages for the armature circuit} \qquad (7)$$

Since the resultant flux interlinkages of the armature circuit must be equal in magnitude to the total change in its initial flux interlinkages.

$$i_a M_a K'' + i_a \mathcal{L}_a = 2 I_1 M_{1a} \qquad (8)$$

In other words, the magnitude of the armature current must be such that its leakage flux interlinkages plus the leakage flux interlinkages of the field circuit (expressed in terms of the armature circuit constants) due to the proportional secondary current, i_1, equals the total change in the initial flux interlinkages of the armature circuit. It is usually more convenient to express the sum of the leakage flux interlinkages of the two circuits in terms of an equivalent leakage flux interlinkage of the armature circuit alone. Substituting the value of i_1 from equation (2) in equation (6) gives

$$K'' = 1 - \frac{M_{a1}^2}{L_1 \; M_a} \qquad (9)$$

But $\qquad \mathcal{L}_a = L_a - M_a \qquad (10)$

Substituting the values of K'' and $\mathcal{L}_a$ in equation (8) gives

$$i_a (L_a - M_{a1}^2/L_1) = 2 I_1 M_{1a}\text{, or}$$
$$i_a = \frac{2 I_1 M_{1a}}{L_a - M_{1a}^2/L_1} \qquad (11)$$

And from equation (2)

$$i_1 = - i_a M_{1a}/L_1\text{, or,}$$
$$i_1 = - \frac{2 I_1 M_{1a}}{L_a - M_{1a}^2/L_1} \times M_{1a}/L_1 \qquad (12)$$

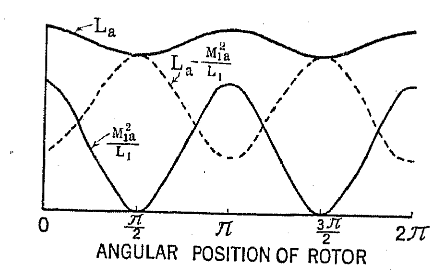

FIG. 12

The quantity, $L_a - M_{1a}^2/L_1$, is defined as the coefficient of the equivalent leakage induction of the armature circuit when the angular position of the rotor is such that the axes of the two windings coincide. The value of this coefficient of equivalent leakage self-induction of the armature circuit can be determined for any other angular position of the rotor from the curves in Figs. 7 and 8 and plotted as shown by curve 3 in Fig. 12. Then the instantaneous values

of the armature and field currents, can be determined from the curve in Fig. 7 and curve 3 in Fig. 12. Figs. 13 and 14 show the approximate wave form of the armature and field currents during the first cycle when the short circuit occurs at the instant the axis of the field winding coincides with the axis of the armature winding.

It is evident from Figs. 13 and 14 that both armature and field currents reach maximum values at the end of the first half-cycle when the short circuit occurs at the instant the armature winding interlinks the maximum field flux. Under these conditions the armature current wave is also totally displaced from the zero reference axis. The maximum value of the armature current under these short circuit conditions, is the maximum possible value that the generator will deliver with the given excitation, for under this condi-

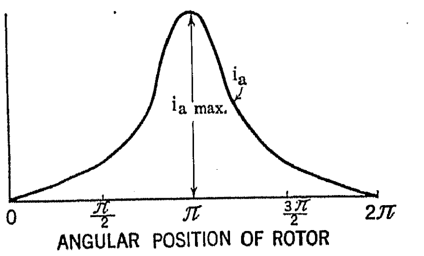

Fig. 13

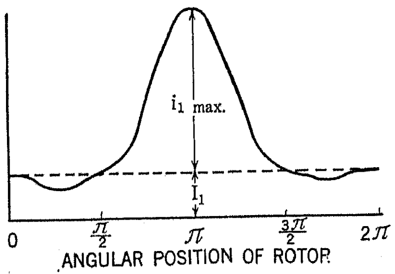

Fig. 14

tion the total flux change (due to rotation) has a maximum value and the coefficient of equivalent leakage induction of the armature circuit is a minimum.

The general equations for the values of the armature and field currents under any short circuit can now be stated as follows:

$$i_a = \frac{\text{Change (due to rotation) in normal field flux interlinkages of the armature circuit}}{\text{Coefficient of equivalent leakage self-induction of the armature circuit}} \quad (13)$$

$$i_1 = -\, i_a \times \frac{\text{Mutual induction coefficient of the armature circuit with respect to field circuit}}{\text{Total self-induction coefficient of the field circuit}} \quad (14)$$

From these general relations the currents can be determined for any short-circuit condition. If the short circuit occurs at the instant the field winding is at right angles to the armature winding none of the

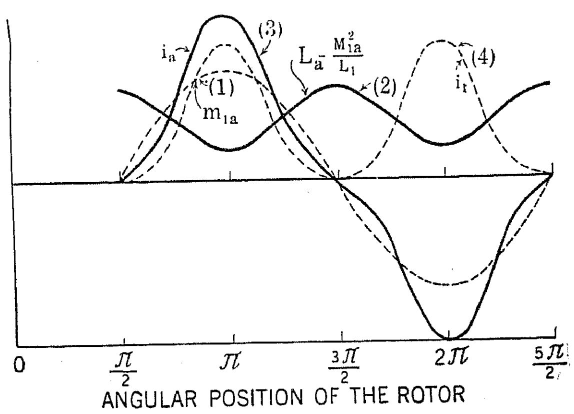

Fig. 15

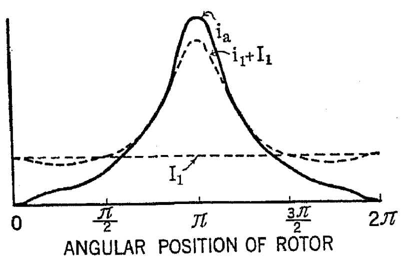

Fig. 16 A

$\alpha_0 = 0$

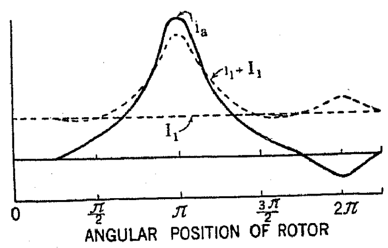

Fig. 16 B

$\alpha_0 = \pi/4$

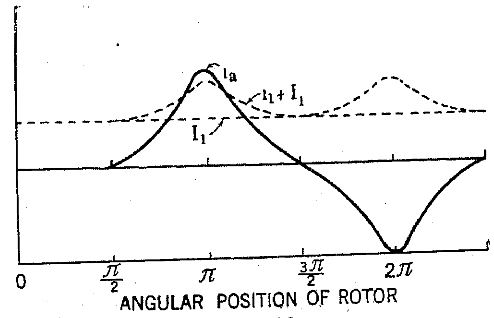

Fig. 16 C

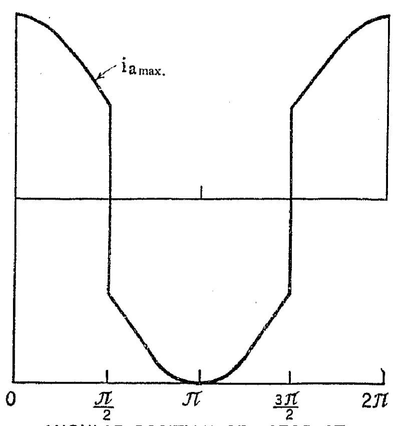
$\alpha_0 = \pi/2$

field flux interlinks the armature circuit. As the rotor changes positions the change in flux interlinkages of the armature circuit will follow approximately a sine law as shown by curve 1 in Fig. 15. The total

equivalent leakage induction coefficient of the armature circuit is shown by curve 2 in Fig. 15.

Curves 3 and 4 represent the general form of the armature and field current waves. In this case, the armature current wave is entirely symmetrical with respect to the zero reference axis. The maximum values of both currents occur at the same angular position of the rotor as in the previous case, but the magnitude of the currents are only one-half of those in the former case.



ANGULAR POSITION OF ROTOR AT INSTANT OF SHORT-CIRCUIT

FIG. 17

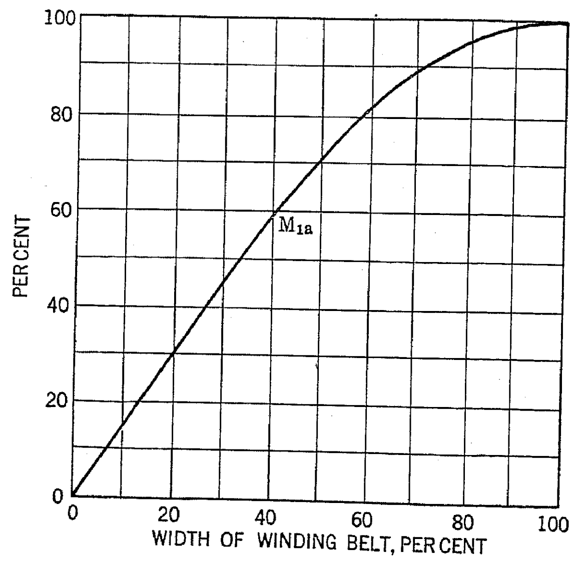


FIG. 18

$$i_a = \frac{I_1 M_{1a}}{L_a - M_{1a}^2/L_1} \tag{15}$$

$$i_1 = -\frac{I_1 M_{1a}}{L_a - M_{1a}^2/L_1} \times M_{1a}/L_1 \tag{16}$$

The curves in Figs. 16A, 16B and 16C show the general form of the calculated currents for both the armature and field circuits when the short circuit occurs at three different rotor positions, namely: $\alpha = 0$, $\alpha = 45$ deg. and $\alpha = 90$ deg.

The curve in Fig. 17 shows the variation of the maximum values of the armature current for the different angular positions of the rotor at the instant of short circuit.

In the preceding discussion the circumferential width of the armature phase band has not been limited to any specific value. It is well known that the flux interlinkages of a single-phase armature winding vary approximately as the sine of one-half the width of the phase belt as shown in Fig. 18, even though the field form does not have a sinusoidal distribution around the armature periphery. The relation between the total equivalent leakage self-induction coefficient, $L_a - M_{1a}^2/L_1$, and the width of the armature belt can be obtained either by calculation or test. The total induction coefficient increases faster than the first power of the phase belt width as shown by curve 1 in Fig. 19. Since the mutual induction coefficient

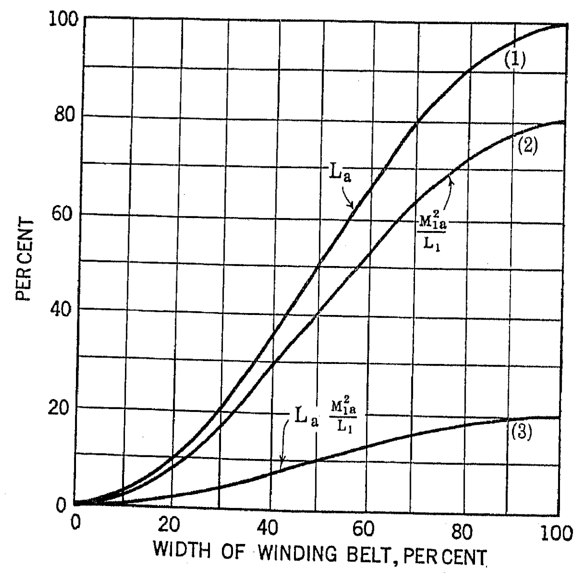

FIG. 19

varies sinusoidally with respect to the width of the phase belt and the magnitude of the field self-induction coefficient is independent of the width of the armature phase belt, the quantity, M_{1a}^2/L_1 will vary approximately as the sine square law as shown by curve 2 in Fig. 19. Curve 3 of this figure shows that the equivalent leakage self-induction coefficient increases faster than the first power of the width of the winding belt. Then by changing the scale of the curve in Fig. 18 to represent total change in flux interlinkages, $K I_1 M_{1a}$, and using the total equivalent leakage induction coefficient of the armature circuit from curve 3 of Fig. 19, the maximum possible instantaneous value of the armature current under particular short-circuit conditions can be determined from Equation 11 and plotted as shown by curve 3 of Fig. 20. This curve indicates that the maximum value of the armature current increases as the width of the phase belt decreases. This relation is based on the fact that the

field flux is constant and the number of conductors in the armature circuit increases directly with the width of the phase belt. Hence, the ordinate $\overline{a_1 b_1}$ gives the maximum value of armature current when one leg of a delta-connected winding or one leg,—terminal to neutral, of a start-connected winding is short-circuited. Ordinate $\overline{a_2 b_2}$ shows the maximum value of the armature current when one leg of a two-phase winding is short-circuited. Similarly, $\overline{a_3 b_3}$ is the maximum armature current delivered when a star-connected winding is short-circuited between two terminals. And $\overline{a_4 b_4}$ shows the current delivered by a single-phase generator with all of the periphery wound.

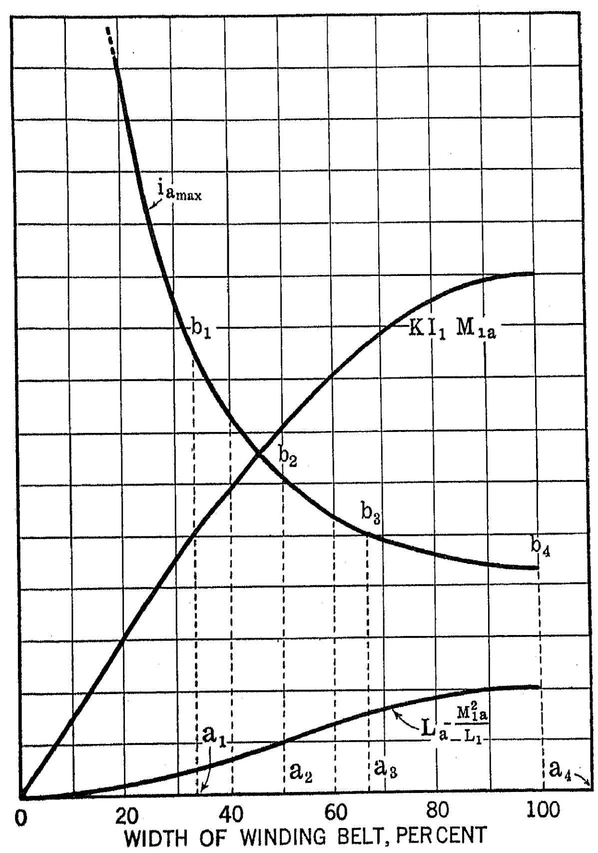

FIG. 20

If the comparison is made between the two-phase and star-connected three-phase machines on the basis of equal and constant voltages, the field flux interlinkages of the two-phase winding will have to be increased approximately 22.5 per cent; *i. e.*, the number of turns will have to be increased 22.5 per cent. The coefficient of equivalent leakage self induction varies as the second power of the number of armature conductors per inch. On the basis of equal terminal voltage, its value for the two-phase winding will be 1.225^2 or 1.50 per cent of its former value. From curve 2 of Fig. 20 the former values for one-phase of the two and three-phase windings are in the ratio of 2 to 3, consequently, the present values on the basis of equal voltages will be proportional to 1.5×2 or 3 for the two-phase winding and also proportional to 3 for the phase group (terminal to terminal) of the three-phase winding. Since the initial flux interlinkages of both cases are equal, the short-circuit current delivered by one-phase of the two-phase winding will be the same in value as that delivered by one phase, terminal to terminal, of the three-phase star-connected winding.

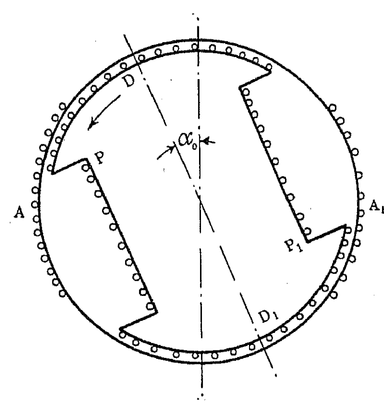

FIG. 21

$\alpha = \alpha_0$

SINGLE-PHASE GENERATOR WITH DAMPER WINDING

If the rotor of the single-phase generator is equipped with a damper winding, $D D_1$, located at right angles to the field winding, $P P_1$, the resultant flux interlinkages of it due to the field current are zero. Under no-load conditions, the flux interlinkages of the armature circuit, due to the normal field flux are the same as for the single-phase generator without a damper winding as was shown in Fig. 7. Hence, in this case,

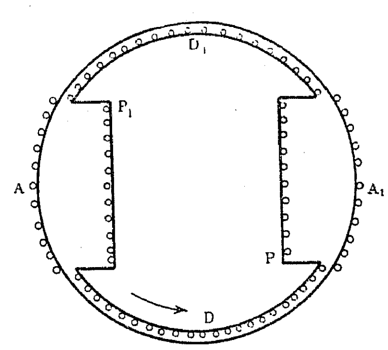

FIG. 22

$\alpha = \pi$

if the armature is suddenly short-circuited at any angular position, of the rotor the initial flux interlinkages, $I_1 L_1$, for the field current $I_1 M \alpha_{1a}$, for the armature circuit, and zero for the damper circuit must be maintained constant for all other angular positions of the rotor. When the rotor is in the angular position, $\alpha = \pi$, shown in Fig. 22, the damper winding, $D D_1$, is at right angles to $A A_1$ and consequently, is

unaffected by the current in $A A_1$ or $P P_1$. Hence, at this position the generator acts as if it had no damper winding and the maximum values of the i_a and i_1 are the same for both cases.

When the rotor is in the angular position, $\alpha = \pi/2$, the axis of the damper winding coincides with that of the armature winding. It is obvious from the previous analysis that the value of the armature current at this instant is equal to the total change in flux interlinkages of $A A_1$ divided by the coefficient of equivalent leakage self-induction of $A A_1$, with respect to the damper winding, $D D_1$. The current in the damper winding will likewise be equal to $i_a M_{ad}/L_d$ and will have its maximum value at this position. Since the field winding is at right angles to both of the other windings, there will be no mutual effect on it and the current, i_1, will be zero. That is, at $\alpha = \pi/2$

$$i_a = \frac{I_1 M_{1a} \cos \alpha_0}{L_a - M_{ad}^2/L_d} \qquad (18)$$

$$i_d = -\frac{I_1 M_{1a} \cos \alpha_0}{L_a - M_{ad}^2/L_d} \times M_{ad}/L_d \qquad (19)$$

$$i_1 = 0 \qquad (20)$$

At all other rotor positions both the field and damper windings act as secondary windings with respect to the armature winding, and the demagnetizing currents that flow in these two windings react on the current in the single-phase armature winding as those of a polyphase armature react on the field winding. The actual value of the coefficient of the equivalent leakage self-induction can be determined from the following simple mathematical relations.

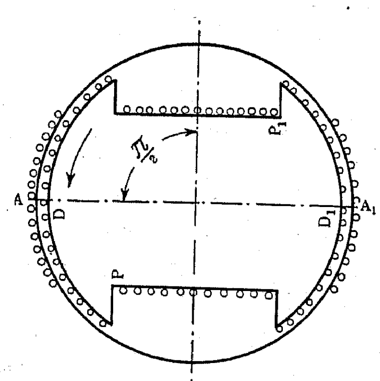

FIG. 23
$\alpha = \pi/2$

$$i_a L_a + i_1 m_{1a} + i_d m_{ad} = I_1 M_{1a} \cos \alpha_0 - I M_{1a} \cos \alpha \qquad (21)$$

$$i_a m_{ad} + i_d L_d = 0 \qquad (22)$$

$$i_a m_{a1} + i_1 L_1 = 0 \qquad (23)$$

Solving these equations gives

$$i_a = \frac{I_1 M_{1a} (\cos \alpha_0 - \cos \alpha)}{L_a - m_{a1}^2/L_1 - m_{ad}^2/L_d} \qquad (24)$$

$$i_1 = -\frac{I_1 M_{1a} (\cos \alpha_0 - \cos \alpha)}{L_a - m_{a1}^2/L_1 - m_{ad}^2/L_d} \times M_{a1}/L_1 \qquad (25)$$

$$i_d = -\frac{I_1 M_{1a} (\cos \alpha_0 - \cos \alpha)}{L_a - m_{a1}^2/L_1 - m_{ad}^2/L_d} \times M_{ad}/L_d \qquad (26)$$

The equivalent leakage self-induction coefficient $L_a - m_{a1}^2/L_1 - m_{ad}^2/L_d$ will be constant for all rotor positions if the two windings on the rotor are identical and have sinusoidal field forms, for the following relations would then be true:

$$L_1 = L_d,\ M_{ad} = M_{a1},\ m_{ad} = M_{a1} \sin \alpha, \text{ and } m_{a1}^2 = M_{a1} \cos \alpha$$

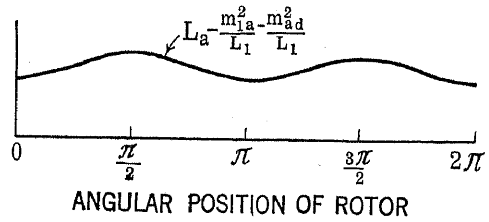

FIG. 24

Then

$$L_a - m_{a1}^2/L_1 - m_{ad}^2/L_d = L_a - \frac{M_{a1}^2 \sin^2 \alpha}{L_1} - \frac{M_{a1}^2 \cos^2 \alpha}{L_1} = L_a - m_{1a}^2/L_1 \qquad (27)$$

However, in actual salient pole machines the two windings cannot be made identical and consequently, the coefficient of equivalent leakage self-induction is slightly pulsating as shown by curve 1 of Fig. 24. Consequently, the damper winding decreases the coefficient of equivalent leakage self-induction of $A A_1$ at the intermediary positions. Hence, the effect of the damper winding at these intermediate positions is to increase the armature current and modify its wave shape, but does not effect the maximum possible value of the armature current.

Two-Phase Generator without Damper Winding

In the case of the two-phase generator with windings $A A_1$ and $B B_1$ placed at right angles to each other the flux interlinkages of $A A_1$ due to the field current, under no-load conditions are the same as for the single-phase generator. The flux-interlinkages of $B B_1$ are the same in magnitude as for $A A_1$ but occur 90 degrees later as shown by curve 2, Fig. 26. The two armature circuits are at right angles and have no mutual effect on each other. If the short-circuit occurs at any position α it is obvious from the previous analysis that the value of the currents, i_a and i_b, must be such that the total equivalent leakage flux produced by each circuit is equal to the corresponding change in flux interlinkages of the respective circuits when the rotor is

in the angular positions, $\alpha = \pi/2$, Fig. 27 and $\alpha = \pi$, Fig. 28 the values of the current in $A\,A_1$ are the same as for the single-phase generator with or without a damper winding, when the short-circuit occurs at the same angular position of the rotor in both cases. Similarly, the currents in $B\,B_1$ at these two positions,

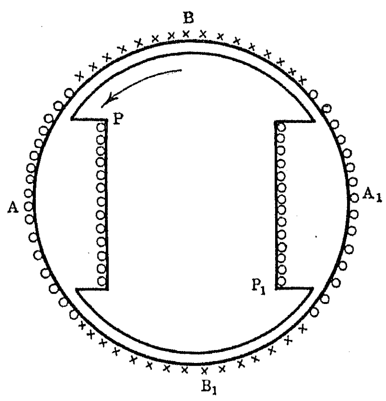

FIG. 25
$\alpha = 0$

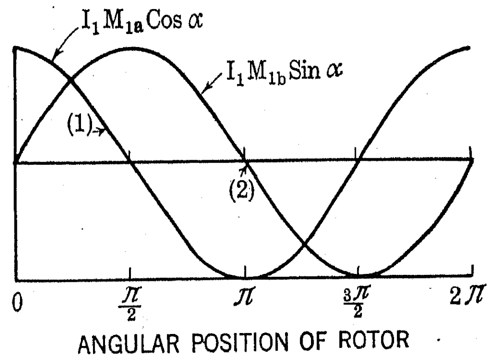

FIG. 26

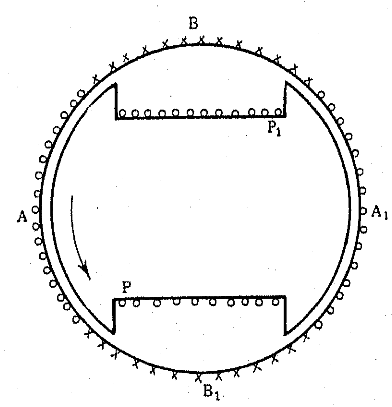

FIG. 27
$\alpha = \pi/2$

are the same as for the case of the single-phase generator, with the short circuit occurring 90 degrees earlier. The currents in $A\,A_1$ and $B\,B_1$ will also reach their maximum possible values at one of these two positions for the total change in flux interlinkages of each circuit is a maximum at one of these positions and the equivalent leakage self-induction coefficients are equal and a minimum.

For all other rotor positions, the equivalent leakage self-induction coefficients of the armature circuits are more complicated to determine on account of the fact that the field circuit $P\,P_1$ acts as an electric coupling between them. That is, if an alternating circuit flows in one of the armature circuits a secondary current, i_1, will flow in the field circuit and this field current in turn reacts on the other armature circuit and produces a secondary current in it. The actual values of the

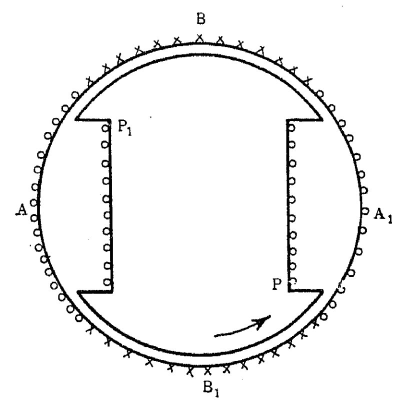

FIG. 28
$\alpha = \pi$

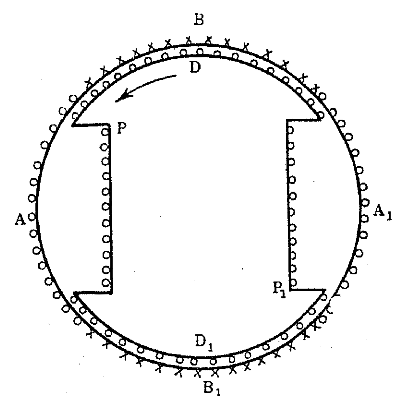

FIG. 29
$\alpha = 0$

coefficients can be readily determined by solving the following simple equations:

$$i_a\,L_a + i_1\,m_{1a} = I_1\,M_{1a}\,(\cos\alpha_0 - \cos\alpha) \qquad (28)$$

$$i_a\,m_{a1} + i_1\,L_1 + i_b\,m_{b1} = 0 \qquad (29)$$

$$i_1\,m_{1b} + i_b\,L_b = I_1\,M_{1b}\,(\sin\alpha_0 - \sin\alpha) \qquad (30)$$

TWO-PHASE GENERATOR WITH DAMPER WINDING

If the rotor of the two-phase generator is provided with a damper winding, $D\,D_1$ located at right angles to the field winding the flux interlinkages of the armature circuits due to the normal field current are the same as for the two-phase generator without a damper

winding. If the short circuit occurs at $\alpha = \alpha_0$ Fig. 30, the initial flux interlinkages of the circuits are:

$I_1 L_1$ for circuit $P P_1$
$I_1 M_{1a} \cos \alpha_0$ for circuit $A A_1$
$I_1 M_{1b} \sin \alpha_0$ for circuit $B B_1$, and
Zero for circuit $D D_1$

When the rotor is in the position $\alpha = \pi/2$ the changes in flux interlinkages are

$I_1 M_{1a} (\cos \alpha_0 - \cos \pi/2)$ for $A A_1$
$I_1 M_{1b} (\sin \alpha_0 - \sin \pi/2)$ for $B B_1$
Zero for $D D_1$ and $P P_1$

The current i_a must be such that its equivalent leakage flux interlinkages with respect to the damper winding are equal to the change in flux interlinkages of $A A_1$. A similar condition must be true for the circuits $B B_1$ and $P P_1$. That is, at $\alpha = \pi/2$.

$$i_a = \frac{I_1 M_{1a} \cos \alpha_0}{L_a - M_{ad}^2/L_d} \qquad (31)$$

$$i_d = - \frac{I_1 M_{1a} \cos \alpha_0}{L_a - M_{ad}^2/L_d} \times M_{ad}/L_d \qquad (32)$$

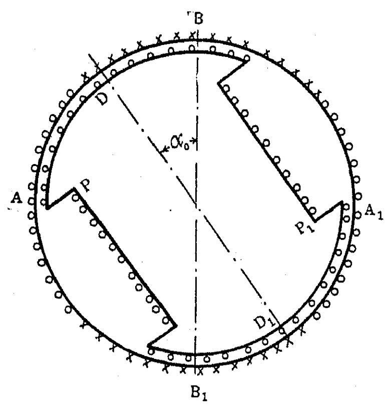

FIG. 30
$\alpha = \alpha_0$

$$i_b = \frac{I_1 M_{1b} (\sin \alpha_0 - 1)}{L_a - M_{1b}^2/L_1} \qquad (33)$$

$$i_1 = - \frac{I_1 M_{1b} (\sin \alpha_0 - 1)}{L_a - M_{1b}^2/L_1} \times M_{1b}/L_1 \qquad (34)$$

Similarly, when the rotor is at the position $\alpha = \pi$ the currents are

$$i_a = \frac{I_1 M_{1a} (\cos \alpha_0 - \cos \pi)}{L_a - M_{1a}^2/L_1} \qquad (35)$$

$$i_1 = - \frac{I_1 M_{1a} (\cos \alpha_0 - \cos \pi)}{L_a - M_{1a}^2/L_1} \times M_{1a}/L_1 \qquad (36)$$

$$i_b = \frac{I_1 M_{1b} (\sin \alpha_0 - 0)}{L_b - M_{1b}^2/L_d} \qquad (37)$$

$$i_d = - \frac{I_1 M_{1b} (\sin \alpha_0 - \sin \pi)}{L_b - M_{1b}^2/L_d} M_{bd}/L_d \qquad (38)$$

Hence at these two positions the currents in the same as for the single-phase generator with winding and the currents in $B B_1$ are the s would flow in $A A_1$ if the short circuit occurr grees earlier. At all other rotor positions, the in the two windings of either element react on cuit of the other element as a polyphase windi on a field winding. Consequently, the equiva

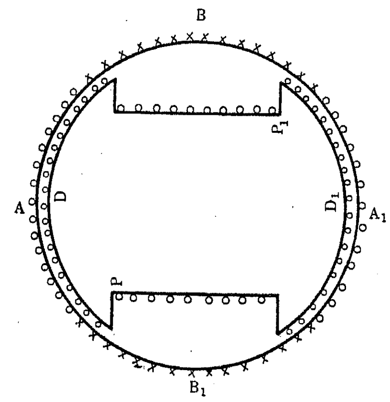

FIG. 31
$\alpha = \pi/2$

induction coefficients of each rotor winding is for all rotor positions and equal in magnitude t

$L_1 - M_{1a}^2/L_a$ for $P P_1$, and
$L_d - M_{1a}^2/L_a$ for $D D_1$

The similar coefficients,

$L_a - (M_{1a}^2/L_1 + M_{ad}^2 \alpha_d)$ for $A A_1$, and
$L_b - (M_{1b}^2/L_1 + M_{bd}^2/L_d)$ for $B B_1$

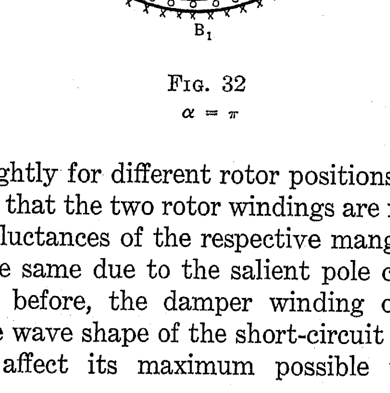

FIG. 32
$\alpha = \pi$

pulsate slightly for different rotor positions on of the fact that the two rotor windings are not i and the reluctances of the respective mangetic are not the same due to the salient pole const Hence, as before, the damper winding only modify the wave shape of the short-circuit curr does not affect its maximum possible valu

maximum possible value of the armature current is the same for a two-phase machine, with or without a damper winding as for a single-phase machine with or without a damper winding and having the same width of phase belt.

Three-Phase Generator Without Damper Winding

The magnitude and variation of the no-load flux interlinkages of any given phase group of a three-phase

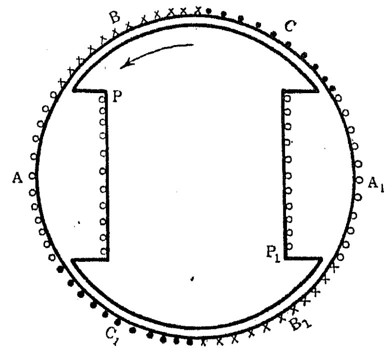

Fig. 33

$\alpha = 0$

winding are the same as in the case of a similar single-phase armature winding for the different rotor positions. The cyclic variations of the flux interlinkages for the different phases are displaced 60 degrees as shown by the curves in Fig. 34. The three-phase generator is not as simple to analyze under load or short-circuit conditions as the two-phase generator on account of the fact that the armature windings have mutual flux relations with respect to one another.

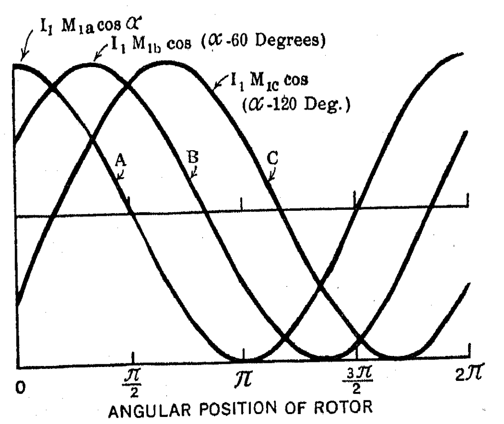

Fig. 34

That is, if one ampere flows in the circuit $A\,A_1$, the flux interlinkages will be L_a, M_{ab}, and $-\,M_{ac}$ for the armature windings, A, B, and C respectively, and M_{a1} for the field winding. The negative sign is applied to the coefficient M_{ac} on account of the fact that the flux interlinks $C\,C_1$ in the reverse direction as compared to the direction of the interlinkages of the other circuits. Using a similar system of notation the induction coefficients of phase B and C are L_b, L_c, and M_{bc}. On account of the salient pole construction of the rotating element the corresponding induction coefficients for the armature circuits are neither equal nor constant for the different angular positions of the rotor.

On account of the complexity of the analysis, the values of the armature currents will be determined for only two short-circuit conditions. One in which the short circuit occurs at the instant the axis of the field winding coincides with the axis of one of the armature windings, and the other in which the axis of the field winding is at quadrature with the axis of one armature winding. If the three-phase short circuit occurs under the first condition as shown in Fig. 33, the initial flux interlinkages of the armature circuits A, B, and C are $I_1\ M_{1a}$, $1/2\ I_1\ M_{1a}$, and $-\ 1/2\ I_1\ M_{1a}$, respectively, on the basis that the windings are delta-connected star-connected with a neutral lead, or each phase group connected independently. After the rotor turns through 180 degrees the total changes in flux interlinkages are $2\,I_1\,M_{1a}$, $I_1\,M_{1a}$, and $I_1\,M_{1a}$ for the re-

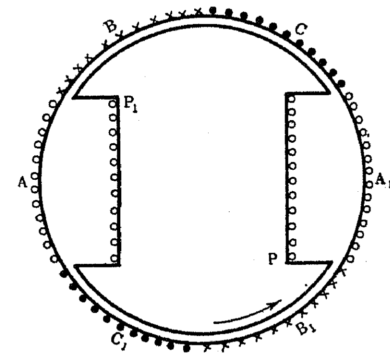

Fig. 35

$\alpha = \pi$

spective A, B, and C armature windings. The currents i_a, i_b, i_c, and i_1 that flow in the windings must be such that the resultant interlinkages of each circuit are maintained at the corresponding initial value. The direction of the current flow in each armature circuit must also be such that the flux opposes the field flux. The current in phase C at this instant will be of opposite sign to that in phases A and B. It is obvious from Fig. 35 that the armature windings are acting in parallel and each furnishing a proportionate part of its required flux interlinkages. Since the armature windings B and C are symmetrically situated with respect to the field winding and phase A of the armature winding, the currents in the A and B phases will be equal in magnitude. The approximate values of the armature currents can be analytically determined by assuming that the corresponding induction coefficients of the armature circuits are equal in magnitude; that is, $L_a = L_b = L_c$ and $M_{ab} = M_{bc} = M_{ac} = 1/2\ M_{1a}$. These relations are only approximately true in the case of salient pole rotors. In this case the currents would

divide between phases A and B in proportion to their changes in flux interlinkages, that is $i_b = 1/2\, i_a$. So far as the current that flows in phase A is concerned the contributory effect of phases B and C can be attributed to phase A as increased induction coefficients. Hence the equivalent coefficients of self-induction of A is $(L_a + M_{ab})$ and the equivalent coefficient of mutual induction with respect to the field winding is $(M_{1a} + M_{ab}) = 3/2\, M_{1a}$. Therefore, it follows by analogy from the analysis of the previous cases that the total equivalent leakage induction coefficient of the phase A is $(L_a + M_{ab} - 3/2\, M_{1a}^2/L_1) = (L_a - M_{1a}^2/L_1) + 1/2\,(M_{1a} - M_{1a}^2/L_1)$ and the value of the armature current is

$$i_a = \frac{2\, I_1\, M_{1a}}{L_a - M_{1a}^2/L_1 + 1/2\,(M_{1a} - M_{1a}^2/L_1)} \qquad (39)$$

It can readily be shown that total equivalent leakage induction coefficients of phases B and C are the same as for phase A and the current values consequently are

$$i_b = \frac{I_1\, M_{1a}}{L_a - M_{1a}^2/L_1 + 1/2\,(M_{1a} - M_{1a}^2/L_1)} \qquad (40)$$

$$i_c = -\frac{I_1\, M_{1a}}{L_a - M_{1a}^2/L_1 + 1/2\,(M_{1a} - M_{1a}^2/L_1)} \qquad (41)$$

It also follows from the previous analysis that the field current is

$$i_1 = \frac{2\, I_1\, M_{1a}}{L_a - M_{1a}^2/L_1 + 1/2\,(M_{1a} - M_{1a}^2/L_1)} \times 3/2\, M_{1a}/L_1 \qquad (42)$$

The equations of the currents for three-phase generator with salient-pole rotors are of the same general form and the values can readily be determined mathematically by solving the simultaneous flux-interlinkage-equations for the different circuits.

Hence in the case of three-phase generators with the three winding connections specified above, the total equivalent leakage induction coefficient, at the rotor position for maximum possible current in one phase, is the same as that for a single-phase machine except that it has an added term. Then for the same total flux change the three-phase armature currents will be correspondingly lower, and the field current will be approximately 50 per cent higher than for a single-phase machine which has the same width of phase belt.

If a star-connected three-phase generator is short-circuited at the terminals when the rotor is in the angular position shown in Fig. 36, the flux interlinkages of the armature winding between terminals, A and B_1 are a maximum and equal to $I_1\, M_{1A}$. The flux interlinkages of the windings a, b and c between the terminals and the neutral are $I_1\, M_{1A}/2$, and zero respectively. Since the interlinkages of the leg c are zero the flux interlinkages of circuits B and C are $I_1\, M_{1A}/2$ and $I_1\, M_{1A}/2$. When the rotor turns through 180 degrees the changes in flux interlinkages are $2\, I_1\, M_{1A}$, $I_1\, M_{1A}$ and $I\, M_{1A}$ for circuits A, B and C. Since, at this position there is no flux change in the leg c of circuits B and C, the current that flows in circuit A and maintains its resultant flux interlinkage equal to its initial value, also satisfies the flux conditions for circuits B and C. It follows directly that the maximum possible value of the current for a three-phase star-connected generator is the same as for a single-phase generator which has a phase belt that covers two-thirds of the armature periphery.

$$i_A = i_a = i_b = \frac{2\, I_1\, M_{1A}}{L_A - M_{1A}^2/L_1} = \frac{2\sqrt{3}\, I_1\, M_{1a}}{3\,(L_a - M_{1a}^2/L_1)} \qquad (43)$$

Similarly, the currents in leg c and in the field winding are

$$i_c = 0 \qquad (44)$$

$$i_1 = \frac{2\, I_1\, M_{1A}}{L_A - M_{1A}^2/L_1}\, M_{1A}/L_1 = \frac{2\sqrt{3}\, I_1\, M_{1a}}{3\,(L_a - M_{1a}^2/L_1)} \times \frac{\sqrt{3}\, M_{1a}}{L_1} \qquad (45)$$

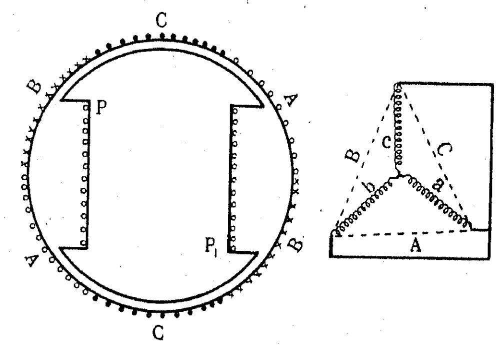

Fig. 36
$\alpha = 0$

Three-Phase Generator with Damper Winding

If the rotor of the three-phase generator is equipped with a damper winding located at right angles to the field winding the maximum possible value of the armature short-circuit current is unaffected by the damper winding for any given armature winding connection. For example, in case the short circuit occurs under the conditions shown in Fig. 33, and the rotor moves to the position shown in Fig. 35 the damper winding is at right angles to phase $a\, a_1$ and hence has no effect on it. Similarly, the damper winding is also unaffected by the other two phases on account of the fact that these windings are symmetrically situated with respect to it and have equal and opposite currents flowing in them. If the winding is star-connected without a neutral lead and the short circuit occurs at the instant shown in Fig. 36 and the rotor is in the position for maximum armature current in phase A, the damper winding is

TABLE I

Case	Phase	Winding Connection	Maximum Peak Value of Armature Current for Constant Conductors per Inch: Amperes	Ratio	Maximum Peak Value of Armature Current for Constant Terminal Voltage: Amperes	Ratio
1	1		$i_{a_{max}} = \frac{2\, I_1\, M_{1a}}{N_a}$	1.732	$i_{a_{max}} = \frac{2\, \sqrt{3}\, I_1\, M_{1a}}{3\, N_a}$	1.0

$I_1\, M_{1a}$ = flux interlinkages of one leg of a 3 phase armature winding due to the field current, when the axes of the field winding and the given leg of armature winding coincide.

$N_a = L_a - M_{1a}^2/L_1$ = total equivalent leakage flux interlinkage coefficient of one leg armature winding and field winding when the axes coincide.

unaffected magnetically for the current in leg C in zero and windings A and B are in series and at right angles to the damper winding. In general, the same

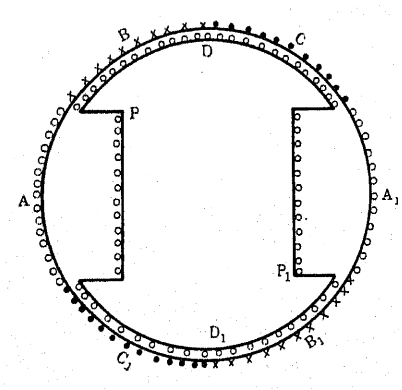

FIG. 37
$\alpha = 0$

conclusions previously given for damper windings of one and two-phase generators under short circuit also apply to the three-phase generator.

The data in Table I give the relative magnitude of the theoretical maximum possible values of short-circuit current delivered by alternating-current generators with different phases and winding combinations on the basis of a given field flux, for (a) constant armature wires per inch of periphery, and (b) constant terminal voltage.

EFFECT OF SATURATION

In general, the iron part of the magnetic circuit does not have infinite permeability but is partially saturated at the condition of normal flux interlinkages. Since under the short-circuit condition which give maximum armature current a major portion of the flux interlinkages must traverse the leakage flux paths, saturation of the iron causes a decrease in the value of the induction coefficients and thus an increased armature current value for a given resultant flux interlinkage. This effect is apt to be quite pronounced at the condition for the maximum possible armature current for approximately double the normal flux interlinkages

must traverse the leakage flux paths and the densities in the iron are necessarily extremely high. It is practically impossible to calculate the effect due to saturation on account of the complexity and indefiniteness of the leakage flux paths and distribution of the leakage fluxes.

Effect of Rotor Construction

In most practical alternating-current generators the rotating element is either solid or built up of reasonably thick laminations which are not insulated from one another, but are short-circuited by assembling rivets and bolts. Hence the iron of the rotor acts as an imperfect or unbalanced polyphase damper winding of high resistance and reactance. Part of this winding acts in parallel with the field winding and consequently, the values of the field current under short circuit will be less than was previously indicated for the thoroughly laminated rotor. This feature modifies the value of the maximum possible armature current only to the extent that it changes the leakage flux interlinkages of the rotor due to the secondary demagnetizing current. At the other rotor positions the values of the armature current are increased and the wave shape modified to a certain extent depending upon the effectiveness of the rotor material as a damper winding.

Effect of Resistance

If the resistances of the electric circuits are not negligible Lenz's Fundamental Law must be modified

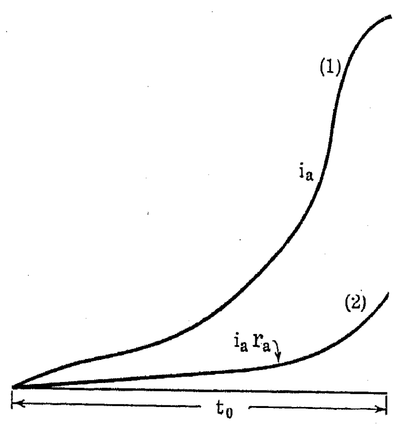

Fig. 38

to take care of the changes in flux interlinkages that are necessary to overcome the $i\,r$ drops of the respective circuits. For instance, in case the armature circuit only has an appreciable resistance there must be a change of its flux interlinkages at any instant proportional to the $i_a\,r_a$ drop. Then referring to the armature current wave under the condition for maximum possible short-circuit current, curves I and II of Fig. 38 show the values of the current and the $i_a\,r_a$ drops for one-half cycle. The total change in flux interlinkages due to the $i_a\;r_a$ drop at the instant of maximum possible current is proportional to the area under curve II for the entire half-cycle. If $i_{a_{max}}\;r_a$ is the maximum resistance drop, the total (decrease) in the flux interlinkages due to the resistance is proportional to $K\,t_0\,i_{a_{max}}\,r_a = \int_0^{t_0} i_a\,r_a\,d\,t$, where K is the ratio of the average to the maximum $i_a\;r_a$ drop. Then applying Lenz's Law it follows from the previous analysis that the total equivalent leakage flux of the armature circuit plus the change in flux

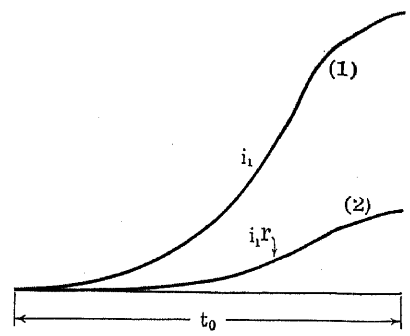

Fig. 39

interlinkages required to offset the $i_a\;r_a$ drop must equal the total change, due to rotation, of its initial flux interlinkages. That is, for the single-phase generator

$$i_a\,(L_a - M_{1a}^2/L_1) + K\,t_0\,i_{a_{max}}\,r_a = 2\,I_1\,M_{1a} \text{ or}$$

$$i_a = \frac{2\,I_1\,M_{1a}}{(L_a - M_{1a}^2/L_1) + K\,t_0\,r_a}$$

$$= \frac{2\,I_1\,M_{1a}}{(L_a - M_{1a}^2/L_1) + K\,t_0\,r_a} \qquad (46)$$

Consequently if the armature circuit has appreciable resistance, a resistance component must be added to the total equivalent leakage induction coefficient, and the maximum values of both the armature and field currents will be decreased.

On the other hand, an appreciable resistance of the field winding also results in a decrease in the short-circuit current values. In the case of a single-phase generator which is short-circuited at the instant of zero voltage or maximum flux interlinkages, the general form of the variation of the circulating current in the field winding, over a period of one-half cycle, is shown in Figs. 16 and 39. Curve II of Fig. 39 shows the $i_1\;r_1$ drop and the integrated area of this curve during the first half cycle, is proportional to the total change in the value of the field flux interlinkages during this time interval. At the end of the first half cycle the actual flux interlinkages of the field circuit are $I_1\,L_1 - \int_0^{t_0} i_1\,r_1\,d\,t$. Consequently the total change (due

to rotation) in the mutual flux interlinkages of the armature circuit is $2\,I_1\,M_{1a} - M_{1a}/L_1 \int_0^{to} i_1\,r_1\,d\,t$ instead of $2\,I_1\,M_{1a}$, as in the case when the field resistance is zero. The maximum values of the armature and field currents are,

$$i_{a_{max}} = \frac{2\,I_1\,M_{1a} - M_{1a}/L_1 \int_0^{to} i_1\,r_1\,d\,t}{L_a - M_{1a}^2/L_1}\text{, and,}$$

$$i_{1_{max}} = -\frac{2\,I_1\,M_{1a} - M_{1a}/L_1 \int_0^{to} i_1\,r_1\,d\,t}{L_a - M_{1a}^2/L_1} \times M_{1a}/L_1$$

If both circuits have appreciable resistance, the decrease in the maximum values of the short-circuit currents will be more pronounced. In this case the maximum current values are,

$$i_{a_{max}} = \frac{2\,I_1\,M_{1a} - M_{1a}/L_1 \int_0^{to} i_1\,r_1\,d\,t}{(L_a - M_{1a}^2/L_1) + K\,r_0\,t_0}$$

$$i_{1_{max}} = \frac{2\,I_1\,M_{1a} - M_{1a}/L_1 \int_0^{to} i_1\,r_1\,d\,t}{(L_a - M_{1a}^2/L_1) + K\,r_0\,t_0} \times M_{1a}/L_1$$

However, in general, the resistances are so small in comparison to the induction coefficients of the electric circuits that the currents will not be materially reduced at the end of the first half cycle. At the outset, the reduction due to the effect of resistance is usually considerably less than the increase due to the saturation effect.

Discussion

P. L. Alger: I have only one comment to make, and that is to remark that I believe the effect of saturation is quite an important one, especially in the application of the same type of theory to the initial currents of induction motors when they are thrown on the line in starting. Saturation makes the actual reactance of the machine much lower than it is when measured under normal conditions, and consequently, the initial current rush is much higher than might be expected, as in 25-cycle transformers, for example, where the ordinary flux is so high as to make the current rush saturate the iron very materially.

I believe that Professor Lyon's A. I. E. E. paper about a year ago, gave a very complete mathematical theory of the subject, taking into account both the resistance or decay effect and the displacement effect, but he did not allow for saturation, and that appears to me to be the most important factor to be added to the theory of this subject.

R. E. Doherty: As Mr. Laffoon has said, the increase in the size of generators and the importance of short-circuit problems in generating and distribution systems makes it important and very desirable that this matter be reviewed at intervals so that the engineers can become at least somewhat familiar with what happens in generators when short circuit occurs.

I think that any one who has gone over this paper will agree that in presenting it from the physical viewpoint the subject is ably handled and an insight given to the phenomena of short circuit in synchronous machines.

I should like to call attention, in a friendly way, to a bit of interesting, if unimportant history. In papers read in 1918, and also in 1920 I made a mistake. I stated the constant linkage theorem which Mr. Laffoon again presents to you, and he makes the same mistake. I said that this theorem follows from Lenz's law. Now, as Professor Karapetoff pointed out in discussing my paper in '19 and '20 the theorem does not follow from Lenz's law. It can be shown, however, that the theorem is perfectly sound. I have given such a proof, based on classical differential equations, in a paper, "A Simplified Method of Analyzing Short-Circuit Problems," at the Swampscott Convention last year.

R. F. Franklin: Expressions for the initial short-circuit current can be derived in a very simple manner by a direct translation of the constant-linkage theorem into mathematics. This method makes it unnecessary to separate the field current into two components as done in the paper.

The linkage theorem, as previously stated by Mr. Doherty is,[2] "*If the resistance of a closed circuit is zero, then the algebraic sum of the magnetic linkages of the circuit must remain constant.*" Take the first case considered, namely, that of the short circuit of a single-phase generator without damper winding. There are only two circuits involved, the field circuit and the armature circuit. Let i_1' and i_a be the instantaneous values of the currents in these two circuits. Then the linkages of the field circuit due to the field current are equal to

$$i_1' L_1$$

and the linkages of the field circuit due to current in the armature circuit are

$$i_a\,M_{1a}$$

Applying the linkage theorem,

$$i_1'\,L_1 + i_a\,M_{1a} = \Omega_1 \qquad \textbf{(a)}$$

where Ω_1 is a constant giving the flux linkages of the field circuit at the instant of short circuit. In a similar manner applying the linkage theorem to the armature circuit,

$$i_a\,L_a + i_1'\,M_{a1} = \Omega_a \qquad \textbf{(b)}$$

where Ω_a is the linkages of the armature circuit at the instant of short circuit. We thus have two equations involving the currents i_1' and i_a which when solved simultaneously give,

$$i_a = \frac{\Omega_a - \Omega_1 \dfrac{M_{1a}}{L_1}}{L_a - \dfrac{M_{1a}^2}{L_1}} \qquad \textbf{(c)}$$

and

$$i_1' = \frac{\Omega_1 \dfrac{L_a}{L_1} - \Omega_a \dfrac{M_{1a}}{L_1}}{L_a - \dfrac{M_{1a}^2}{L_1}} \qquad \textbf{(d)}$$

This method can be used with equal facility for the calculation of the short circuit currents for any winding connection.

It can readily be shown that equations **(c)** and **(d)** correspond to **(13)** and **(14)** except that **(d)** is the expression for the total field current instead of the induced component as in **(14)**. Thus, in equation **(c)** Ω_a is the flux linkages of the armature circuit at the instant of short circuit and $\Omega_1 \dfrac{M_{1a}}{L_1}$ the flux linkages of the armature circuit due to the field circuit for any rotor position after short circuit. Hence the numerator is the change in armature linkages produced by the field circuit due to rotation. The denominator has been defined in the paper as "the coefficient of equivalent leakage self-induction of the armature circuit." Also **(d)** can be written in the form

$$i_1' = I_1 - \frac{M_{1a}}{L_1}\left(\frac{\Omega_a - \Omega_1 \dfrac{M_{1a}}{L_1}}{L_a - \dfrac{M_{1a}^2}{L_1}}\right)$$

or $$i_1' = I_1 - \frac{M_{1a}}{L_1} i_a \tag{e}$$

The two components of (**e**) are the d-c. and a-c. components of the field current respectively, the latter component being the same as (**14**) in the paper.

The inductance coefficients vary with the rotor position as shown in Figs. 6, 7 and 8, so that the current in the two circuits can be calculated for any rotor position by substituting values from the curves of these figures in (**c**) and (**d**) in the manner used by Mr. Laffoon. However, it is easier to express them as trigonometric functions and substitute these functions in (**c**) and (**d**). It is then necessary to calculate only the maximum and minimum values of the inductance coefficients. For instance, the mutual coefficient M_{1a} (Fig. 7) can be expressed as

$$M_{1a} = M_0 \cos \alpha$$

where M_0 is the maximum value of mutual inductance between armature and field circuits. The coefficient L_a (Fig. 8) can likewise be expressed as a function of α. However, the effect of saturation in this coefficient on the resultant short-circuit current is so slight that for all practical purposes L_a can be assumed constant.

I used this method two or three years ago for the calculation of the short-circuit currents for all cases given in Table I. The results I obtained do not check the values in the table. Thus for all three, 3-phase short-circuit conditions, cases 8, 9 and 10, I obtained the same maximum peak value of armature current for constant conductors per inch; and for the single-phase condition, case 1. 1.5 times the current for the three-phase conditions. For the other cases the ratio to three-phase values I obtained are slightly less than those given in the table.

On page 3 the statement is made that, "It is well known from the laws of physics that the mutual-induction coefficients of two inductively coupled circuits is the same for either circuit with respect to the other." This statement, while correct for the condition of no saturation, should be more accurately stated since it is not true when saturation is involved.

N. S. Diamant: I am very glad to note that Mr. Laffoon in his paper makes a free use of the conceptions of the four kinds of "Inductance;" it is gratifying also that he is consistent and employs the usual terminology as given in detail by Boucherot in his excellent paper presented at the International Congress in 1911.

In my paper on "Calculation of Sudden Short Circuit Phenomena of Alternators" presented in San Francisco in 1915, I did not feel that I could make free use of these ideas as they seemed rather novel; though they were by no means new. Briefly we have: (1) the self-inductance L. (2) the leakage inductance L (3) the mutual inductance M and (4) the total leakage inductance reduced to the armature or field; this is designated by Laffoon as N_a or N_f and in my several papers and discussions I have used the symbol λ. I am calling attention to these various coefficients of inductance because there has been and there is considerable confusion on the subject. (See Discussion of Doherty and Shirley's paper in the A. I. E. E. TRANS. for 1918). From a study of transient phenomena and also from the study of the ordinary transformer we learn that the amount of current and the rate of decay of current depends not on L but on the total leakage inductance λ or N as is indicated in the paper.

The simplest physical conception of sudden short circuits, it seems to me is as follows: Consider a two-phase generator having no mutual induction between phases A and B. Just before short circuit there is a certain flux in phase A, say ϕ_a; this dies down to practically zero at the end of the short circuit.

Thus the flux in phase A during short circuit is $\phi_a \, \epsilon^{\frac{r_a}{\lambda_a} t}$ where r_a = armature resistance λ_a = total armature leakage inductance and t = time counted from the instant of short circuit. Similarly, for phase B we have $\phi_b \, \epsilon^{\frac{r_a}{\lambda_a} t}$. Now, $\phi_a = M\, I_f \cos \omega\, t_1$ where M = mutual inductance between field and armature. I_f = field current before short circuit. With reference to the field circuit we have:

ϕ_n = normal flux in the field before short circuit.

ϕ_{psh} = flux in the field at the end of short circuit; *i. e.*, flux in the field during permanent or sustained short circuit.

$\phi_{psh} + (\phi_n - \phi_{psh})\, \epsilon^{-\frac{r_f}{\lambda_f} t}$ = field flux at any instant during short circuit.

Now, returning to Mr. Laffoon's paper we can say that

$$\phi_a \, \epsilon^{-\frac{r_a}{\lambda_a} t} = \text{flux in phase } A \text{ during short circuit.}$$
$$= M\, i_f \cos(\omega\, t + \omega\, t_1) + L_a\, i_a$$

$$\phi_{psh} + (\phi_n - \phi_{psh})\, \epsilon^{-\frac{r_f}{\lambda_f} t} = \text{flux in field during short circuit.}$$
$$= M\, i_a \cos \omega\,(t + t_1) + L_f\, i_f + M i_b \sin \omega\,(t + t_1)$$

For phase B we shall have an expression similar to the one given for phase A. These equations are very simple and they are given in a graphical form in the paper, except that the attenuation factors are entirely omitted. To obtain the armature or field current it is necessary to solve the whole set of equations, and that part may be termed mathematical. Let me repeat that the solution of the equations just given may be mathematical but the analysis and physical interpretation of each equation are very simple. In fact, I think simpler and certainly more complete than that given by the author. It is not necessary to give an extended discussion of the simple physical meaning of the equations as that has already been done. See TRANS. A. I. E. E., 1915; *Electrical World* May 18; June 1; June 29, 1918. Mr. Laffoon uses the conception of a circuit without resistance; this was also used by Doherty and Shirley in 1918. Is it necessary to make this assumption, which is not easy to understand? Suppose the flux changes from ϕ_1 to ϕ_2; the e. m. f. generated by this change will be $\frac{(\phi_1 - \phi_2)}{t}$ and this transient e. m. f. will produce a quantity of electricity $q = i\, t$, where i is a decaying direct current. Thus a direct current is produced in phase A of the armature provided that phase A enclosed an amount of flux ϕ_1 at the instant of short circuit. If the position of the phase A is such that it encloses no flux at the instant of short circuit then there will be no direct current produced in it.

In this way all the phenomena can be explained withouf recourse to a *circuit without resistance*. Another advantage ot this is that it involves an old well-known principle, which is used to determine the apparent resistance of a ballistic galvanometer on closed circuit. I would like to ask if Mr. Laffoon has made use of this principle and how and why did he resort to the conception of the circuit without resistance.

In Table I values for the maximum possible armature currents are given. These do not include the attenuation factor of either the armature or the field, and nothing is said about their effect. In all my work I had found that the effect of these was not negligible; I would like to have Mr. Laffoon's opinion on this since he has accumulated a great deal of experimental data on the subject.

It is stated by the author that damper or amortisseur windings have no effect on the armature current. I would like to know if damper windings have any effect on the attenuation factor, that is, on the rate of decay of the armature current. To what extent do test results check with the approximate and more accurate equations given by Boucherot for alternators with and without damper windings? To what extent do the values for $i_{o\,max}$ given in Table I agree with the expressions given by Boucherot?

C. M. Laffoon: In presenting the analysis of the short-circuit currents of alternating current generators, the mathematical derivation of the general relations was not given on account of the fact that this phase of the problem has already been given considerable consideration by other writers. It was thought that the presentation of the physical conception of the phenomena would facilitate the interpretation of the actual results and mathematical relations by an appreciable number of engineers. That is, the physical or graphical analysis was intended to be considered as a supplement to the mathematical treatment rather than as a substitute for it.

Mr. Doherty's criticism in regard to the writer's statement that

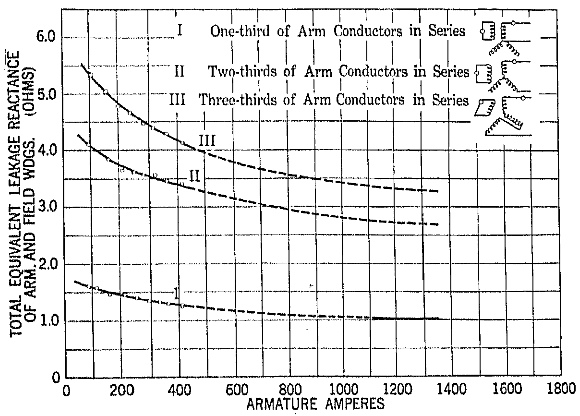

FIG. 1

the constant linkage theorem was based on Lenz's law is well taken. The statement of the constant linkage theorem as given by the writer follows from Lenz's and Kirchhoff's Laws.

It is practically impossible to calculate the effect due to saturation on account of the complexity of the leakage flux paths and the distribution of the leakage fluxes. The effect of saturation is apt to be quite large when the short-circuit occurs at normal voltage, for approximately double the normal amount of flux interlinkages must traverse the leakage flux paths. The following curves show the decrease in value of the total equivalent leakage reactance coefficient of the armature and field windings with armature current for the case of a 6250-kv-a. turbo generator. These test results were obtained by locking the rotor in such position that the axis of the field winding coincided with one phase group of the armature winding, short-circuiting the field winding, and then applying alternating voltage to the armature winding.

The formulas for the maximum peak values of the armature current and the comparison ratios for the different winding combinations, which are shown in Table I of the paper, were determined on the basis that the short-circuit occurs at the instant the axis of the field winding coincides with the axis of the part of the armature winding included between two adjacent leads. All of these cases are treated in considerable detail in the original paper, and it would be necessary to know the assumed short-circuit conditions under which R. F. Franklin obtained his results before attempting to account for the discrepancies. However, at the present time sufficient reliable test data is not available to definitely confirm the relative ratios as given in Table I.

In presenting a quantitative physical conception of the short-circuit phenomena, it seemed advisable to the writer to consider the case of an ideal generator first, and then to show the effect of the different physical constants which are present in the actual generator. The writer is famiiar with the method suggested by N. S. Diamant for determining the value of the resultant flux interlinkages of each circuit at any given time. While this method is sufficiently accurate for most cases, the actual change in flux interlinkages is quite different from that shown by a simple exponential equation. This question is considered by the writer in a second paper on the same subject, which was presented at the Northeastern Regional Meeting, at Worcester, Mass., June, 1924.

A damper winding which is located at quadrature with respect to the field winding has no effect on the magnitude of the peak values of the armature current, but it does modify the wave shape and hence affects the r. m. s. values. If part of the damper winding acts in parallel with the field winding, the maximum peak value of the armature current will be affected to the extent that the total equivalent leakage induction coeffiient of the armature winding is modified. The effect of the damper winding on the rate of decay of the armature current is given in the writer's second paper which was previously referred to.

Dr. P. Boucherot's original paper only considered the case of the single-phase, and two-phase generators; consequently sufficient data was not available for making a comparison with the results given in Table I.

The Economic Development of a Step-by-Step Automatic Telephone Equipment

BY PAUL G. ANDRES

Associate A. I. E. E.

Research Engineer, Automatic Electric Co., Chicago, Ill.

***Review of the Subject.**—Since Campbell published his paper in 1910, modifications have been made on the step-by-step telephone equipment. This paper covers a review of the economic development of this system with particular emphasis on the technical development in general. The material is grouped under development of circuits and trunking, mechanical design, manufacturing methods, maintenance improvements and possible future developments. Saving in equipment and trunks is considered under the switching selector repeater, director and frequency selecting connector while the reduction in maintenance cost is shown by the reduced number of troubles per line per month when comparing the newer developments with equipment installed fifteen years ago.*

TELEPHONY has together with the electric power industry undergone a tremendous development within the last fifteen years. The rapid advances made in electrical materials, the study and analysis of methods and means of manufacture and the contributions of pure science are finding application in the industry.

Since the inception of the telephone in 1876 the subscriber's needs and operating demands have increased constantly and definitely, tending to complicate the apparatus. Particularly is this true in the case of automatic telephony where the subscriber, because of the nature of the system, expects to obtain an answer from a called party in a minimum time and with the least mental and manual effort. On the other hand the manufacturer has by the most approved and latest methods tried to improve the quality of the product and at the same time tried to make it more economical. Briefly stated the situation resolves itself into two main issues: (a) the increasing needs of the subscriber and operating company and (b) the reduction of cost of the equipment.

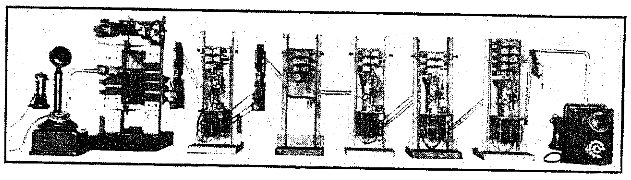

FIG. 1—SIMPLE STEP-BY-STEP SYSTEM

Without regard to the changed economic conditions of the country the subscriber's increasing needs from the start have forced the cost of the equipment up faster than the manufacturer could reduce the cost by redesign and methods. At the present time these needs are still of prime importance and still slightly overbalance the gain made by improvements and developments.

Because of its unit structure the step-by-step telephone system lends itself readily to an analysis of how the needs of the subscriber and operating company are met economically by the use of the latest developments. Each unit performs a definite function practically independently of the other units and consequently may be studied with regard to cost, performance, maintenance, life, and so forth without involving the rest of the equipment.

Inherently the system consists of a series of line switches, selectors, repeaters and connectors operated by a dial at the subscriber's station. Campbell[1] in 1910 outlined the major parts and functions of the elementary step by step system. Fig. 1 shows the parts that constitute this system assigning to each part its proper place in the chain of equipment.

In order to consider the various phases of the development and the result obtained, the subject will be considered with regard to the developments in design of circuits and trunking which represent the ideas to be carried into practise, mechanical design and materials which crystallize these ideas in actual mechanisms, manufacturing methods producing the mechanism in quantities, maintenance improvements or the performance in practise and possible future economic developments.

Developments in Design of Circuits and Trunking

During the past thirty years that the step-by-step system has been in use various developments have been made on the original idea advanced by Strowger. Naturally some of the early work was revolutionary during the time the apparatus was serving its apprenticeship. These changes may well be reviewed as early developments, while the more recent progress is considered under the subject of later developments.

EARLY DEVELOPMENTS

All early exchanges were operated on the three-wire system, which in reality consisted of a two-wire system plus the ground circuit. The change from three-wire to a straight two-wire system, first introduced in 1907,

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

1. A Modern Automatic Telephone Apparatus. W. Lee Campbell, TRANS. A. I. E. E., 1910, Vol. 29, p. 55.

came about largely by the possibilities offered by the two-wire system for purposes of station metering, pay station control, supervision and the like, besides simplifying the telephone wiring with resulting lower maintenance costs. Among other ailments, the three-wire system had the disadvantage of premature release in certain conditions in party line service. It required a good ground connection in the circuit when setting up a call. While in many cases an excellent ground connection is maintained at every subscriber's station at the present time, be it manual or automatic, this is used for purposes of signaling and protection, whereas early automatic stations used such a ground primarily for dialing.

The two-wire system was made possible largely by the adaptation of slow release relays. This type of relay has gradually been developed until it now finds a place on nearly all switches used in the system.

Machine ringing, although first used in manual exchanges, was applied to automatic service because its use resulted in shorter holding time of trunks besides relieving the subscriber from the additional burden of ringing the called subscriber's bell.

Later Developments

Mixed Number Systems. Although mixed number systems had been used in special cases, the Columbus, Ohio installation illustrates the advisability of using such a system resulting in an economy of equipment. As mentioned in the introduction the simple system required a major switch for every digit dialed. In the

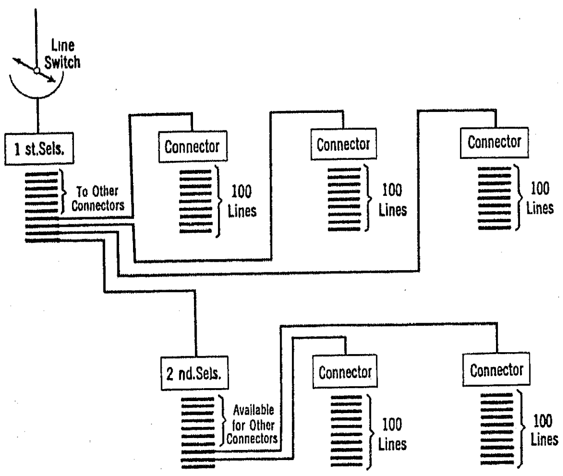

Fig. 2—Mixed Number System

case of the exchange mentioned a four-digit system was used until the growth of the system required additional equipment. By the addition of third selectors, as required, the system was expanded gradually. Fig. 2 indicates how the simple step-by-step system lends itself to future growth by the addition of but small amounts of equipment and no rearrangement of subscriber's numbers. If a proper traffic study has been made and the traffic development can be forecast with a fair measure of certainty, then the installation of the mixed number system is a real economic advantage; if, however, this information cannot be obtained, the possible rearrangement of certain groups in case the system is installed may affect the advantage gained.

Traffic Recorders. The study within recent years of traffic conditions by operating companies, with a view toward the elimination of superfluous equipment, the addition of equipment where needed, the economic distribution of traffic and the economical number and arrangement of trunks, both local and inter-office,

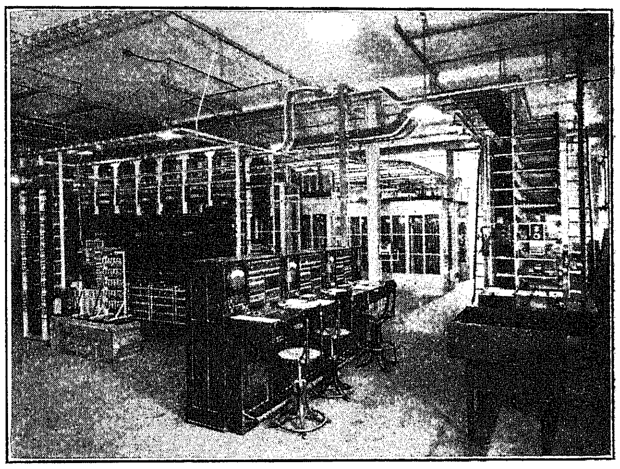

Fig. 3—Traffic Recording Machine in Operation in an Exchange

required that the group equipment be modified to allow the obtaining of this traffic data. Various traffic recording machines have been developed and find increasing application. Fig. 3 shows such a traffic recording machine in operation in an exchange. Numerous theoretical calculations have been made along this line and these machines are being used to obtain the practical substantiation of these formulas.

Line switches. Plunger type line switches on account of their preselecting nature are commonly used for primary line switches. The introduction of secondary line switches invariably effects a saving due to trunk efficiency wherever the traffic is normal. The development of the rotary line switch came about largely through efforts to make a self-contained unit. Because of its unit structure, that is, independence of common mechanism, compactness and reliability, the rotary line switch lends itself admirably for secondary line switch duty.

Switching Selector Repeater. The development of the switching selector repeater was one of the milestones in recent years. This switch as its name implies is a unit combination of a repeater, selector and a discriminating device, intended to repeat impulses to the main office and at the same time to determine whether or not the call is going to or through the main office or whether it is intended for a local number. Eventually the number dialed will indicate to the switch whether or not the call terminates in the local or main office.

Just as soon as the proper combination of digits is dialed, which determines that the call is not intended for the local office, the discriminating feature ceases to function and the switch continues to function simply as an impulse repeater. If, however, the call is intended for a local subscriber, the switch operates as a selector after the last digit of the discriminating part of the number and at the same time releases the trunk to the main office with its attached apparatus and leaves it

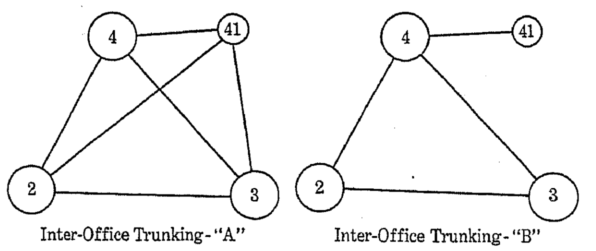

FIG. 4—TRUNKING TO SUB-OFFICE WITHOUT AND WITH SWITCHING SELECTOR REPEATERS

available for other connections. The general method of operation consists in elevating and rotating the shafts of major switches simultaneously in the local and main offices and after the last discriminating digit, releasing the switch or switches in the undesired office.

This device finds its greatest economic application in the case of the sub-office as shown in Fig. 4. In the simple step-by-step system inter-office trunks are required from each office to every other office in the

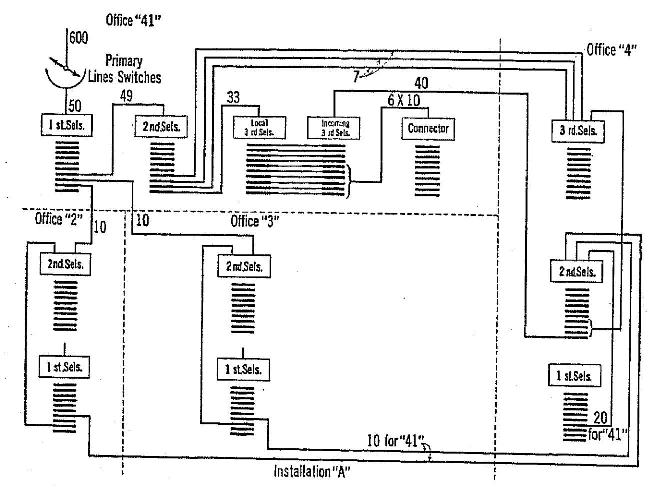

FIG. 5—EQUIPMENT REQUIREMENTS IN SUB-OFFICE WITHOUT SWITCHING SELECTOR REPEATERS

system, but the use of the switching selector repeater requires trunks only to the main office nearest the sub-office.

The economy effected by the use of switching selector repeaters varies with the specific case and depends on the merits of the individual case. The additional inter-office trunks required largely determine and limit the saving. As an illustration of the equipment saving in the sub-office, Fig. 5 and Fig. 6 show the arrangement of the equipment and trunks required in a simple system and a typical installation with switching selector repeaters.

As a basis of calculation let the traffic requirements rest on the following values, where $T\ C$ represent traffic units based on the busy hour traffic.

Office 41 to Office	41	12.84 T C	Office 4 to Office	41	5.92 T C
41	4	5.92	3	41	2.96
41	2	2.96	2	41	2.96
41	3	2.96	41	41	12.84
Total originating		24.68 T C	Total incoming		24.68

The quantities of equipment are as follows:

	Installation A.	Installation B.
1st Selectors	50	0
2nd Selectors	49	0
3rd Selectors Local	33	50
3rd Selectors Incoming	40	40
Connectors	60	60
Outgoing Sec. Line Sw.	0	50

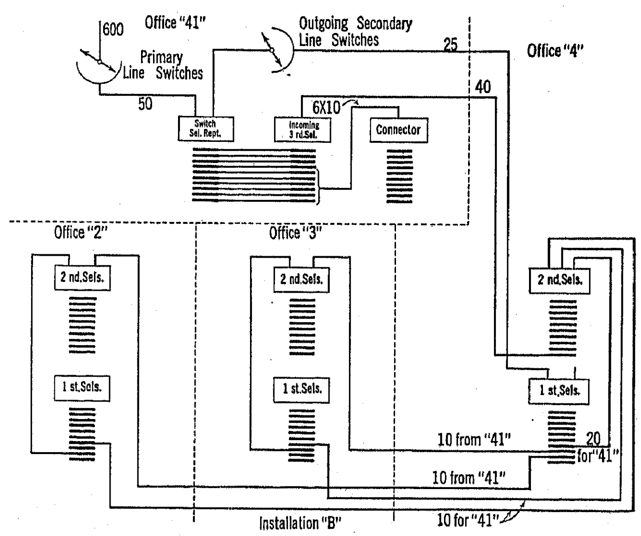

FIG. 6—EQUIPMENT REQUIREMENTS IN SUB-OFFICE WITH SWITCHING SELECTOR REPEATERS

Summed up in brief form installation B replaces 82 selectors with 50 line switches, the relative cost of the two complete being in the ratio of three to one.

Frequency Selecting Connector. Another decided economic advance, particularly in the case of the small community automatic exchange, came about through the development and application of the frequency selecting connector. As shown in Fig. 7 the switch resembles the ordinary connector, except for the addition of two relays and a minor switch, which selects the desired frequency.

Previous to the adoption of this switch party line service depended on a group of party line connectors, the banks of which were multipled together, giving access to one hundred lines for each group. The group was taken from a first selector level and the desired frequency obtained from a level on a second selector. In the case of the frequency selecting connector each

connector selects the proper frequency. Since these connectors can be used indiscriminately for straight, four-party or ten-party line service they can be used on any board resulting in a saving of group equipment. This is very noticeable in the case of mixed service where the exchange is small and party line service predominates.

The Director. A very recent development adapting step-by-step equipment to large metropolitan areas where tandem offices and other complex trunking problems are encountered, is the director. The standard equipment previously described makes it imperative to correlate the office number dialed with a certain and definite level on each of the major switches. Further,

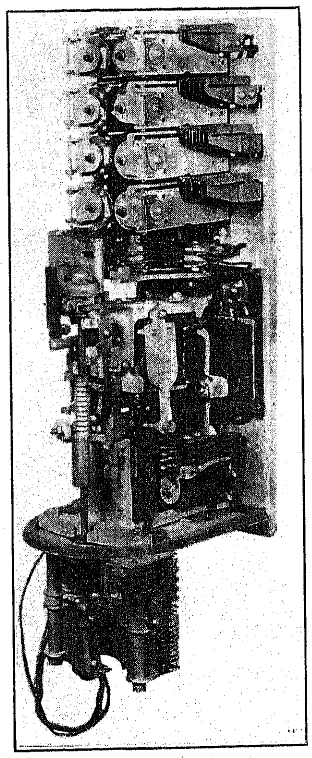

Fig. 7—Frequency Selecting Connector. Minor Switch Just Below Relay Group

in calling an office it may be necessary to pass through tandem offices, each of which would require that the subscriber dial at least one digit. The director is an equipment inserted between the secondary line switch and the first selector to dissociate the numbering from the trunking scheme. It comes into play during the dialing of the number, it rearranges this number and directs the call over the most economical trunk route by any suitable combination of digits and is then disconnected re-establishing the usual through connection.

The actual apparatus as shown in Fig. 8 consists of a director selector, the director, a common impulse machine and a group of relays common to all directors. The director selector in the case of a three-letter office code system is practically identical with a standard selector except for one additional relay, and functions to select one of a number of directors on the first digit called. It releases the director after the completion of the call but remains busy during the duration of the conversation.

The director, Fig. 9, consists of an office code register, four numerical registers, register control, a cross connecting block, sender control switch and a group of relays. By dialing the second and third digits the office

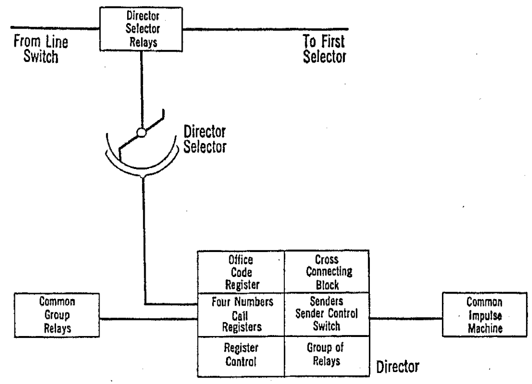

Fig. 8—Director System

code register can connect its four wipers to any one of one hundred sets of four bank contacts making one hundred possible offices available for this director. Since there are ten levels in the director selector this makes a possible one thousand offices available to the subscriber. The numerical register records the successive digits as they are sent in. In the meantime the sender starts to retransmit the number, but due to

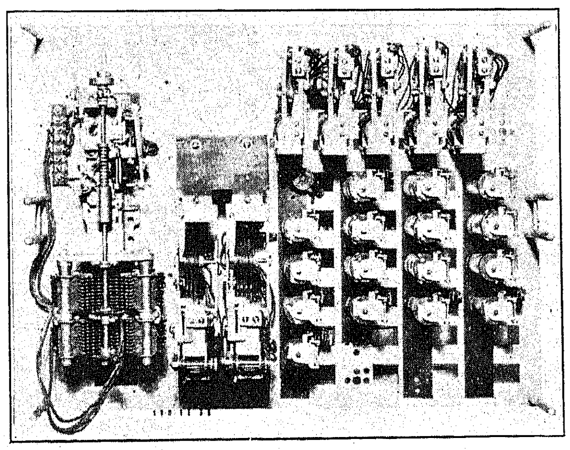

Fig. 9—Director

the arrangement of wiring on the cross connecting block which allows the number dialed in to be converted into any other number of either more or less digits, the call is actually routed over a number combination most favorable to the various offices through which it passes. The common-impulse machine supplies the proper electrical impulse to propagate the call, while the relay equipment consisting of supervisory, and the like, is similar to that customarily in use.

As previously outlined the switching selector repeater, when economically applied to a certain traffic area, effects an economy of switches against a slightly increased number of inter-office trunks. The director, on the other hand, when applied to a large metropolitan area, and in general this is its only economic application, results in a saving of trunks, not only in the number of trunks used, but also in the efficient use of existing trunks.

For a particular case the use of the director reduces the number of second selectors required from 545 to 80 or a saving of 465 selectors. In this particular case the saving in selector equipment approximately counterbalances the additional cost of director equipment. In larger metropolitan areas where the trunking is more complicated and where tandem operation is required, the saving in trunk groups will more than compensate for the cost of director equipment. This is especially true when two or more complete units of 10,000 lines are installed in one building.

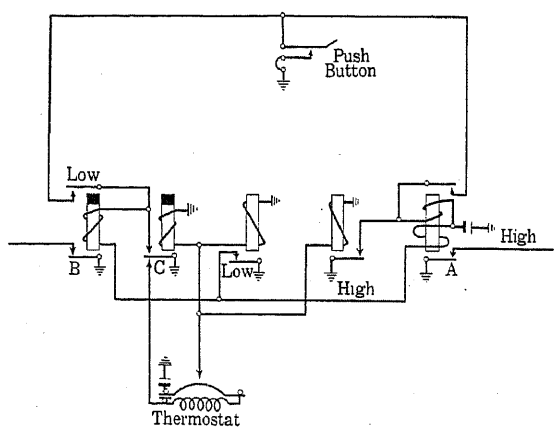

FIG. 10—DIAGRAM OF VOLTAGE LIMITS EQUIPMENT

Voltage Control Apparatus. An interesting power development, resulting incidentally in connection with the development of automatic telephony, is the voltage control apparatus. Since it is desired to keep the battery voltage between 46 to 49 volts the voltage control apparatus must be extremely sensitive and at the same time sturdy enough to stand considerable abuse. The common form of high low-voltage control in the form of a meter element is not reliable, due to the light contact pressure resulting in poor contact particularly after a period of operation when the contacts are slightly pitted or dusty. The most recent device along this line consists of two relays margined to pull up on a voltage in excess of a certain value. Fig. 10 shows the general arrangement of the scheme. A test relay tests the line voltage intermittently, say four or five times per minute. In case the voltage is low no relay pulls up and the circuit condition causes a counter-cell to be cut out; if the voltage is normal one relay only pulls up causing no movement of the counter cell switch; in case the voltage is high the operation of both relays causes a circuit condition to be established which results in the cutting in of a counter cell. The specific application of this scheme is shown on the fifty-line private automatic exchange equipment, Fig. 11A. The two high and low operating relays may be seen in the lower right corner. Fig. 11B gives the front view of the board showing the battery-charging generator

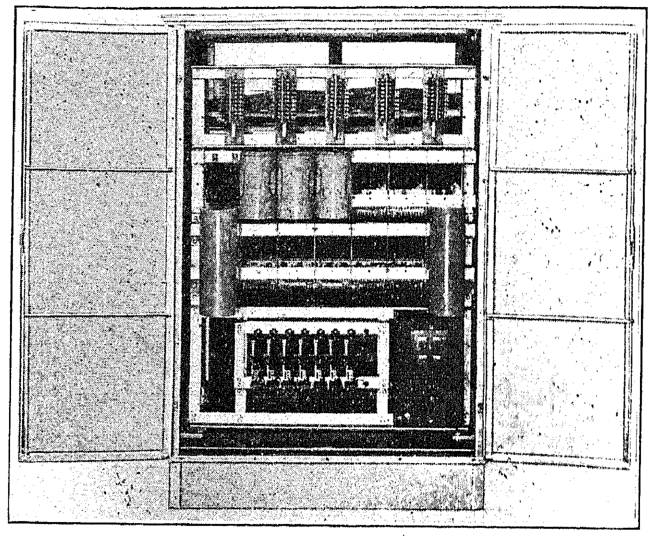

FIG. 11A—FIFTY-LINE PRIVATE AUTOMATIC EXCHANGE. Rear View showing Voltage Control Relays

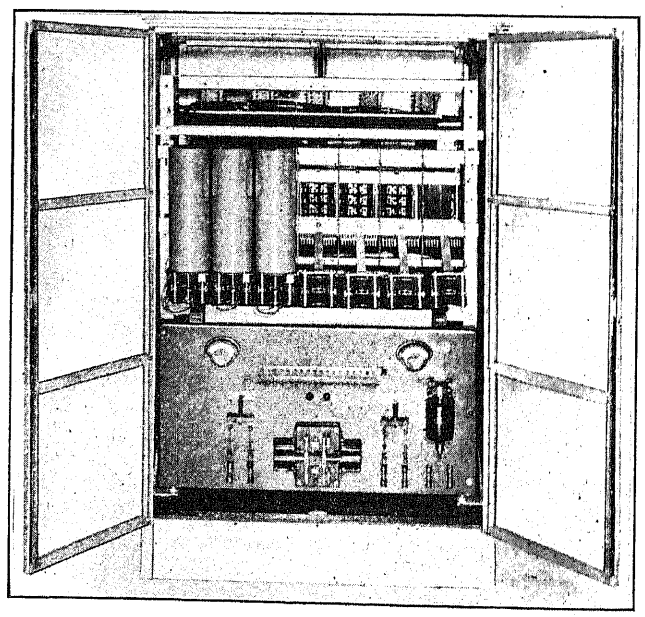

FIG. 11B—FIFTY-LINE PRIVATE AUTOMATIC EXCHANGE. Front View showing Motor Start Switch

start switch and the combination end cell and cut-off switch.

Incidental Developments. Many incidental developments were made during the last five to ten years. The rotary movement on the selector was changed from the common interrupting for a group of selector switches to the self interrupting and later to the relay controlled type.

Although this resulted in a slightly slower speed of hunting an idle trunk this was compensated by a positive stop on the first idle contact and uniformity of operation. Reverting-call switches, code ringing on community automatic exchanges, rotary connectors for private branch exchanges, zone metering, toll switching, measured service and many other parts of the equipment were perfected.

Mechanical Design and Materials

The development of circuits is closely allied with mechanical design and this in turn with materials. A typical case illustrating this point is that of the major switch which was changed in the case of the selector in 1910 and in case of the connector in 1918 from the side switch type to the present type. This change resulted in a switch controlling movement electrically by relay action, instead of mechanically. While the ensuing circuit was made slightly more complex the mechanical structure was materially simplified. The above change was brought about largely by the increasing use of the copper collar or slow acting relay, the time margins of which have been investigated with respect to their performance in step-by-step equipment.

The subsequent change in 1915 of the horizontal for the vertical type relay resulted in a switch which could

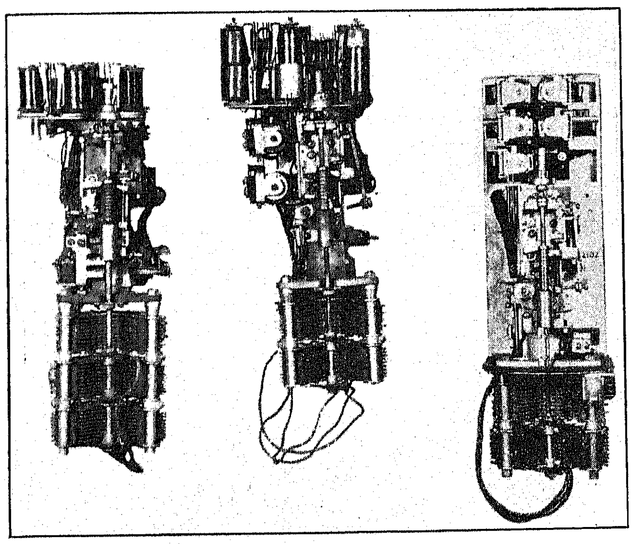

FIG. 12—VERTICAL AND HORIZONTAL RELAY TYPE SELECTORS

be equipped with an individual dust cover. Fig. 12 shows the early styles of vertical relay switches together with the late horizontal relay type switch, and Fig. 13 shows the latter type of switch equipped with the usual dust cover. In both the early and late switches the contacts and springs were mounted in a vertical position allowing any foreign matter as dust and small metal particles to pass through without becoming permanently lodged between the contacts.

Materials used in the construction of the relay and magnets have been improved similar to the changes made in magnetic circuits of the electrical power industry where low retentivity and high permeability are considered advantageous. Extensive tests have been made and are still in progress to find suitable magnetic materials. Various mechanical improvements have been made from time to time on the relay. The substitution of a hinge pin bearing for the pivot point type resulted in a relay with more uniform performance characteristics. This becomes apparent when it is

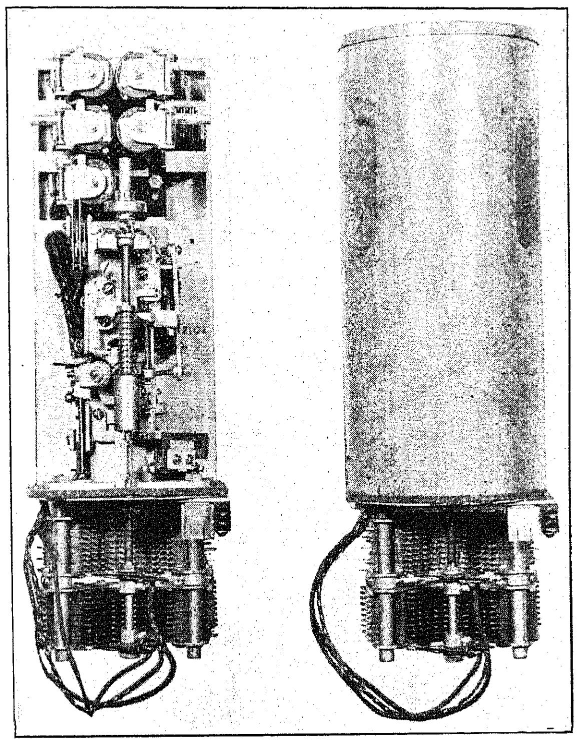

FIG. 13—HORIZONTAL RELAY TYPE SELECTOR WITH DUST COVER

considered that the gap between the armature and the heel piece is on the order of 0.0015 in.

Adaptability of the same type relay for various circuit conditions further led to uniformity of design resulting in a type of relay which may be given any reasonable time characteristics by change in windings. A comparison of the horizontal type of equipment with the vertical type shows this uniformity of design in a striking manner.

The advent and use of high grade modern insulating materials did much toward the production of a higher grade relay and magnet. Formerly coils were made by winding the wire against the fiber heads, using paper insulation next to the core and the leads were brought out through holes in the fiber heads. Notwithstanding the fact that the negative side of the battery is connected to the coil permanently in most cases, electrolysis still occurred between spool heads and the wire. Only by insulating the lead in wires between hard rubber washers, connecting them to termi-

nals on the head and winding the wire on a core insulated with empire cloth could this trouble be eliminated. Phenol fiber, bakelite and micarta are gradually replacing fiber and even though the first cost is higher, the resultant constancy of performance together with long life and freedom from electrolysis result in a more economical equipment.

Enamel-covered wire, particularly in the small sizes of wire, is finding increasing application in the general electrical engineering practise. While enameled wire is commonly used on relays and magnets in order to conserve space and to get the maximum number of ampere turns within a certain space, the protection this wire offers against electrolysis and corrosion is one of its greatest advantages. The adoption in recent years of enamel-covered wire cable has done much toward the reduction of electrolysis and leakage between cable pairs within the office.

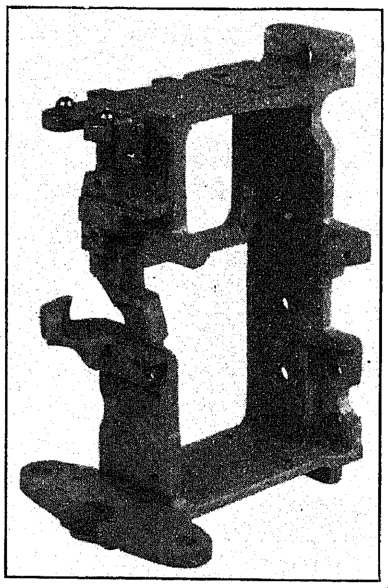

Fig. 14—Cast Iron Switch Frame

The various adjustments require that the switch frame does not change materially during the life of the frame. Numerous die cast metals have been tried, but have been found wanting in permanency. The cast iron frame, Fig. 14, has gradually been developed and has been found extremely constant in retaining its shape. It may be noted at this point that this switch frame is the basis and foundation mechanically of all step-by-step major switches. The use of universal relays (mechanical) mounted on a standard plate together with the magnets mounted on the frame did much toward the standardization of this type of equipment. Major and minor parts are designed to be interchangeable allowing various special circuits to be used on standard equipment in case of some particular individual necessity.

Manufacturing Methods

Mechanical design as a rule must be closely allied with manufacturing methods. Although methods do not change frequently the universal use of the automobile did much toward the change in methods by the evolution of complex machinery for the finishing of small parts. Fig. 15 shows a multiple

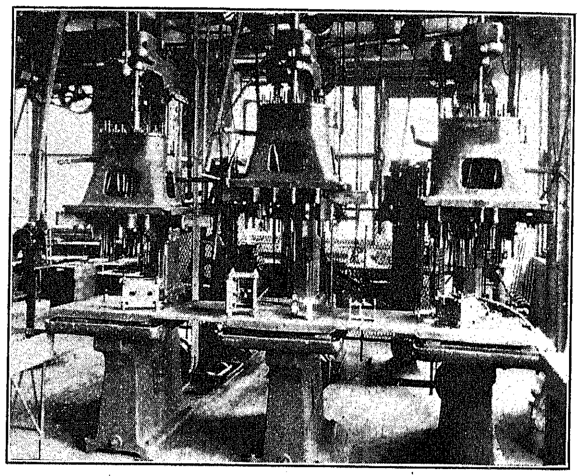

Fig. 15—Multiple Drill Press for Drilling Switch Frame

drill, such as is in common use in the drilling and tapping of holes in the switch frame mentioned above. By means of these multiple drills the frames are drilled quickly and accurately. Many other automatic and semi-automatic machines are used in the manufacture of a step-by-step equipment which are different from machines in customary use, such as contact welders,

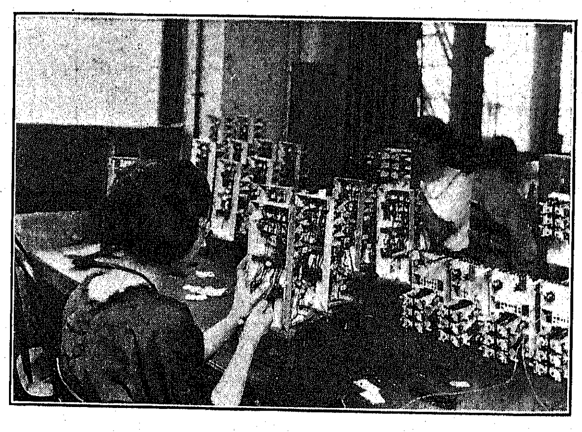

Fig. 16—Connector and Selector Wiring

either single or double contact, special wire braiding machines, and the like.

With regard to manual operations girls have been found to be excellent workers. In the wiring of major switches, Fig. 16, one girl wires the switch completely using two tools. No single tool has been found which will perform as well or obtain as good results as the two

which are in use. The average time of wiring a selector complete is one half hour. This involves the skinning and attaching of 95 connections. In the standard connector there are 215 connections with approximately one hour and fifteen minutes required for wiring. Soldering these connections requires five minutes for a selector and twelve minutes for a connector. After wiring three or four switches from blue prints the prints are found unnecessary and all future wiring is done from memory. Squeezing and alining fixtures, Fig. 17, assure that the spring assemblies are in their correct positions horizontally and vertically and contribute materially toward the manufacture and assembly of these parts which, in order to function uniformly, must be very accurate.

An inspection and engineering inspection department maintain the product at a uniform standard and determine and set all standard adjustments. These

Fig. 17—Spring Alining Fixture

standard adjustments make the performance of the switches commercially uniform. The economic development of the step-by-step system is in a large measure due to the most approved methods of manufacture which allow the full use of circuit development and mechanical design.

Maintenance Improvements

The standard parts with their definite tolerances and standard adjustments resulted in a decided uniformity of service while the proper routining keeps the equipment in first class condition. The change from three wire to two wire, from vertical to horizontal relay equipment and the introduction of dust covers gradually reduced the cost of maintenance per line per month. Fig. 18 gives some interesting comparative data regarding the number of these troubles. The main advantage, however, results in the use of less technical help in maintenance work due to the uniform construction and adjustment of the apparatus as mentioned above. By the use of a jack arrangement of mounting, the switches may be removed for repair in case of necessity and easily replaced by similar reserve switches.

Routining, that is, the periodic testing of all switches and equipment, results in keeping the equipment in first class working order by discovering possible future troubles before they develop into factors which impair telephone service. This service together with the obtaining of service observation data provides an index

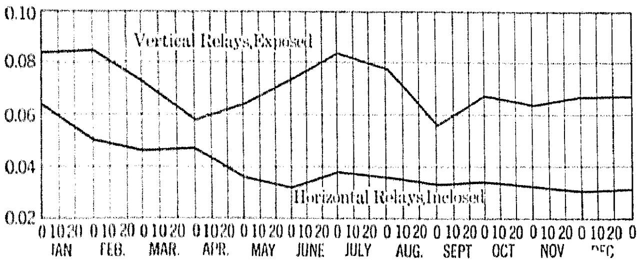

Fig. 18—Comparison of Two Specific Cases of Vertical and Horizontal Relay Equipment from Maintenance Standpoint.

Note Irregularity of Vertical Relay Equipment Curve while Horizontal Relay Equipment Curve Gradually Flattens out.

of the kind of service the equipment renders. Table I gives the tabulated results of service observations in various exchanges together with a final average obtained over a number of years. It is interesting to note that in the final average approximately 22.11 per cent of all lost calls are due to the subscribers whereas only 2.19 per cent are due to total plant trouble. Fig. 19 shows the seasonal variation between the various causes contributing to lost calls.

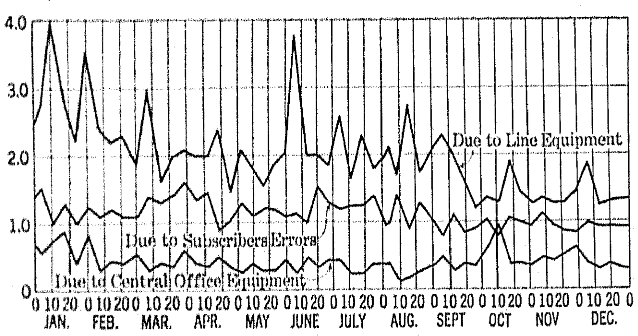

Fig. 19—Seasonal Variation of Per cent of Calls Lost due to Different Causes

In general it may be stated that all development in a measure reflects the maintenance viewpoint. The advances above mentioned on insulating materials, economy of equipment, economy of trunks, etc. invariably result in a lower maintenance cost.

Possible Future Economic Developments

The introduction of better materials, as in the case of the relay, has shifted the proportion of that much of the over-all cost as pertains to first cost and maintenance cost

from the latter to the former, at the same time reducing the sum of the two. By means of intensive circuit study and design coupled with mechanical simplicity the first cost may perhaps be lowered, while keeping the maintenance cost the same or even less.

Special materials are constantly developed. The selection of the proper materials with a knowledge of their capabilities and limitations offers unlimited possibilities in improving the performance and a possible reduction in over-all cost.

A definite value must be placed on lost calls, their significance in a trunking area and their evaluation against a definite amount of equipment and trunks, before equipment and inter-office trunks can be reduced to an economic balance in general. For instance, the calculation of equipment on a lost call of one to one hundred leads to a materially reduced quantity of equipment over that calculated from a lost call of one to one thousand. The service on the other hand is not lowered in the same proportion. The cost of installation and maintenance vary very materially in different localities, and in the same trunking area, therefore, the problem must be viewed in the light of the local situation. The study of local traffic conditions in any particular area by means of traffic recording apparatus to obtain definite and exact data is highly desirable.

The vacuum tube used as an amplifier offers possibilities in that a smaller current may be used and then amplified to the present values. Numerous advantages may accrue from such an arrangement as:

(a) High-resistance subscribers' loops of from 2000 to 3000 ohms.

(b) Replacement of 19 gage and smaller by gages in the neighborhood of 26 to 28 gage cables.

(c) Centralized office equipment in low value real estate areas.

(d) Use of high-resistance transmitters and receivers with possible gains of efficiency and clearer articulation.

Items (b) and (c) particularly indicate possibilities of effecting a saving, but as in the cases mentioned, these changes must depend on the merits of the individual case.

Conclusion

The step-by-step automatic telephone equipment has been developed largely along the lines of filling definite subscribers' and operating companies' needs. The system has undergone but minor changes but the equipment has been improved resulting in a lower maintenance cost and a longer life. Like the locomotive, the automobile and kindred pieces of mechanism, the step-by-step system has been standardized and its operation over a large number of years has been made uniform and reliable. No revolutionary future changes on the system appear imminent but the minor individual parts constituting that system will no doubt be modified to accomplish their specific circuit or mechanical function most economically.

SERVICE OBSERVATION TABLE

	Per cent of Originating Calls		Analysis of Uncompleted Originating Calls			Analysis of Failures		
Exchange	Completed	Uncompleted	Busy	Don't Answer	Failures	Subscribers Errors	Total Plant Trouble	Central Office Equipment Failures

Discussion

G. K. Haspel (by letter): In general, only one connector group is required per 100 lines when these lines serve individual or P. B. X. subscribers, but for party-line service it has been the practise to provide as many groups of connectors per 100 lines as there are parties on the party line, that is, for two-party service, two connector groups per 100 lines are required and for four-party service, four groups.

The comparatively recently developed frequency-selecting connector which selects the ringing frequency (or other party-line station selecting feature), as well as connects to the called line, requires only one connector group per 100 lines, regardless of whether the line gives two-party, four-party or ten-party service.

It is obvious, with the regular connector method, that more connector groups will be required than line switch groups, or, in other words, the number of line switch groups will correspond to the number of hundreds of lines while the number of connector groups will correspond to the number of hundreds of possible stations.

In reducing the number of connector groups so that it corresponds to the number of groups of 100 line switches, the use of frequency-selecting connectors not only reduces the total number of connectors but in many cases also reduces the number of selectors. This saving in equipment is illustrated in the attached sketches showing trunking schemes for an exchange of 800 lines of mixed individual and party-line service.

Fig. 1 herewith shows the switching scheme for 800 lines using frequency-selecting connectors and provides for individual and party-line service up to ten parties per line. Fig. 2 shows a scheme for the same number of lines but for individual and four party service with four connector groups for each 100 lines. In the latter scheme, 32 connector groups are required, making necessary the use of second selectors between the first selectors

and the connectors, which is not necessary in the frequency selecting connector scheme, since the latter has only 8 connector groups.

In Fig. 1, eight levels of the first selectors are used (the "1" and "0" levels are usually reserved for special services) but when more than eight groups of connectors are required, the introduction of intermediate selectors, with access to ten groups each becomes necessary. Thus in Fig. 2, with 32 connector groups, four groups of second selectors are required.

In the two schemes illustrated, the same number of first selectors is required in each case; 137 second selectors are required in Fig. 2, while none are required in Fig. 1; and the number of connectors is greater in Fig. 2 because 32 smaller groups are required as against ten large groups in Fig. 1.

Not only is more equipment required for Fig. 2 but there is also an increase in the battery drain per call, of about 7%, due

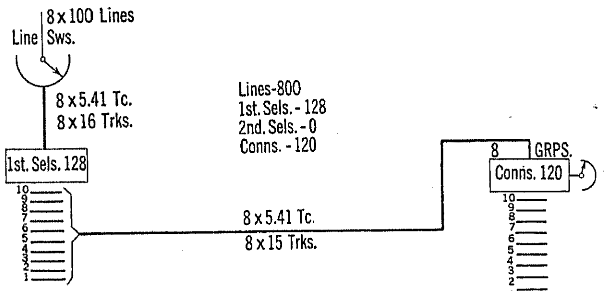

Fig. 1

to the necessity of the second selector in the train of each call. The greater number of switches and associated equipment involved would also increase the maintenance costs.

Further advantages for the frequency-selecting connector scheme, when used for all services (excepting P. B. X. or trunk-hunting service), are:—the use of any line for either individual or party-line service, and by mixing these on each unit a more equal distribution of traffic may be obtained; selective ringing of extension telephones; and the possibility of changing individual to party lines without changing the directory numbers.

The principal objection to the frequency-selecting connector scheme is the difficulty of providing intercepting service for "dead" and changed numbers. This is accomplished by the use of frequency relays bridged across the lines on which calls are to be intercepted and, if the number of calls to be intercepted is large, the cost of the relay equipment is considerable. However, in many exchanges, this intercepting service is not considered necessary, so in such cases the objection does not apply.

With frequency-selecting connectors, each line has a possible ten directory or station numbers and, when less than ten stations are assigned to a particular line, the remaining numbers are useless. This has been called a "waste of numbers," but, since no waste of equipment is involved, the loss is not a material loss, and the objection is not considered valid. Moreover, whether all the

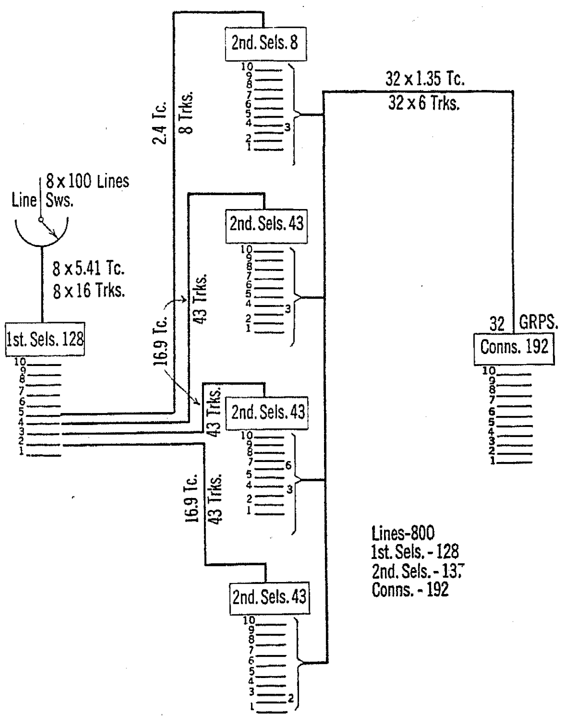

Fig. 2

numbers are used or not, they are available for use, which gives them an actual economical value.

The frequency-selecting connectors are somewhat more expensive per switch than the regular type connectors, but this is often counter-balanced by the decrease in the amount of selectors and connectors required for the entire office or exchange, or, even if the total cost is greater, it is quite possible that the service advantages will justify the extra expense.

High Quality Transmission and Reproduction of Speech and Music

Review of the Subject.—*Radio broadcasting has drawn attention to the problems involved in obtaining high quality in systems for the electrical transmission and reproduction of sound. This paper gives the general requirements for such systems, discusses briefly the factors to be considered in design and operation and indicates to what extent the desired results can be obtained with the means now available.*

* * * * *

THE primary function of telephone circuits, as normally used in commercial service, is the electrical transmission and reproduction of speech sounds. In considering the operation of such a system, the reproduced sounds are referred to as having two properties, intelligibility and naturalness. While these two properties are not by any means unrelated and are both of importance in all sound reproducing systems, the first is naturally the more important in a commercial communication system. In broadcasting and public address systems, the communication function is supplemented by the function of entertainment and the property of naturalness, therefore, increases in importance in the reproduced speech. Furthermore, the use of music with such systems imposes, in general, more severe requirements upon them because of the wide range of frequencies and intensities required for proper appreciation.

In this paper the fundamental requirements for a system for faithfully transmitting and reproducing sound are outlined, and their applications considered, particularly in connection with broadcasting and the use of loud speakers.

In any system for the electrical transmission and reproduction of sound there are three essential elements: A means for converting sound into electrical energy, usually called the telephone transmitter or microphone; a means for converting electrical energy into sound, usually called the telephone receiver; and means for transmitting the electrical energy from the transmitter to the receiver.

In the operation of such a system, there are three general requirements which it is desirable that the reproduced sounds should meet: First, that they be at about the same loudness as people are accustomed to hearing the original sounds; second, that they be free from appreciable distortion, that is, that the character of the reproduced sounds be so close to that of the original sounds that the ear cannot distinguish between them; and third, that they be free from extraneous sounds. The degree to which these requirements of loudness, freedom from distortion and noise are met is the measure of the quality of the system.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

The discussion in this paper will be directed primarily to the second of the above requirements, that is, the matter of obtaining accurate transmission and reproduction of the original sounds, and the requirements of loudness and noise will be considered only in so far as they have a bearing on the principal discussion. In this connection, it may be noted that with the development of practically distortionless amplifiers, it is possible to compensate for the losses in volume incurred in transmission and in the conversions between sound and electrical energy and thus obtain any degree of loudness desired. The problems of eliminating noise, however, are in many cases difficult, but are too extensive to be within the scope of this paper.

DISTORTION

The sounds which comprise speech and music involve, as is well known, complicated pressure variations. For any small interval, of time, these pressure variations may be resolved into a series of component sinusoidal waves. As the speech or music proceeds, however, the amplitude, the frequency and the phase of these components change. The transmission and reproduction of such sounds may be conveniently considered as a matter of transmitting and reproducing the several component waves.

For a system to be ideal from a quality standpoint, these components must be reproduced unchanged, and no new components introduced. Experience has shown that changes in phase, such as are usually obtained, produce no effects which are noticeable by the ear. Also, as discussed later, all the amplitudes may be diminished or increased uniformly through an appreciable range before the quality is affected.

The requirements then for no noticeable distortion in a sound-reproducing system may be stated as follows:

1. The reproduced sounds shall have the relative intensities of the component frequencies the same as the original sound.

2. The reproduced sounds shall not contain any components of frequencies not present in the original sound.

Failure to meet the requirement set up in (1) is referred to as "frequency distortion." This results

when a system has different transmission efficiencies for the different frequencies.

Failure to meet the requirement set up in (2) is referred to as "non-linear distortion." This results when the relation between the output and input powers is not independent of the magnitude of the input power. Distortion of this type may be obtained from the iron cores of transformers or other coils, from vacuum tubes, from carbon transmitters and from diaphragms or other vibrating mechanical parts. All of these have a load characteristic which generally has a practically linear relation between output and input when operated below certain energy limits, but which shows a non-linear relation between output and input when the input power exceeds these limits. Operation over the non-linear part of such a characteristic results, in addition to changing the intensity relations of the components of the original sounds, in the setting up of components of frequencies which may be different from those of the components in the impressed wave.

Another important factor in the reproduction of sounds which is not generally appreciated is that apparent distortion is obtained if the loudness of the reproduced sounds is materially outside of the range in which the listeners are accustomed to hearing the original sounds. Recent work[1] in hearing has shown that the transmission mechanism of the ear is non-linear in its response even at loudness levels commonly used in speech and music. From this it is seen that the interpretation of complex sounds by the ear is partly accomplished by the "subjective" frequencies introduced by the ear itself. Due to this non-linear characteristic of the ear, when the intensities of reproduced sounds are materially different from those of the original sounds, there is an apparent distortion.

With these requirements in mind, consideration will now be given to the extent to which they can be met with the means and methods now available. In this connection, three electrical transmitting and reproducing systems will be discussed, a high quality telephone circuit, the public address system and the broadcasting system. The first two and the elements used in them have been previously described in some detail. A brief description of them will be given here, however, to show their similarity with the third, which will be discussed more comprehensively, and also to indicate to some extent the evolution of high quality reproducing means. It will be noted that the successful design, maintenance and operation of any high quality system depends upon the development of methods of measuring its operational characteristics, such as the relation between input and output energies over a range of frequencies and intensities.

1. Physical Measurements of Audition and Their Bearing on the Theory of Hearing, H. Fletcher, *Jour.* Franklin Inst., September 1923.

High Quality Telephone Reference System

A number of years ago a telephone circuit was set up in the Bell System Laboratories in which use was made of the various available means to eliminate distortion as much as possible. This was used as a reference circuit in a comprehensive investigation of the effects on the intelligibility of reproduced speech sounds, of variations in the volume of the reproduced sounds, of various types and amounts of distortion and of various amounts and kinds of extraneous noise.[2] This system and the variation of its efficiency with frequency are shown in Figs. 1 and 2.[3] It has also negligible noise and non-linear distortion for the sound powers that it is designed to handle, that is, those corresponding to talking in the normal way over a telephone circuit.

With this system, the fundamental vowel and consonant sounds used in speech are reproduced so well that when a series of such sounds are impressed upon

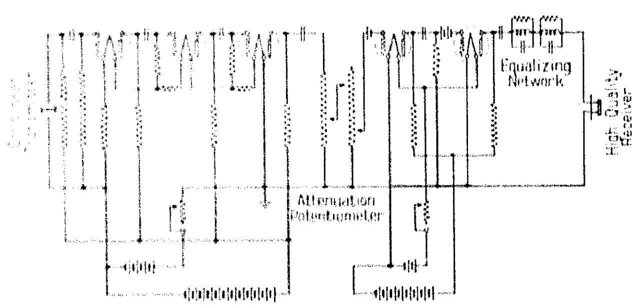

Fig. 1—Circuit of High Quality Telephone Reference System

the system, 99 per cent are correctly understood. This recognition is for the condition when these sounds are combined into meaningless monosyllables, which makes the test much more severe than for these sounds as ordinarily used in conversation where the context aids in the recognition. The degree of recognition obtained with this system is within a few tenths per cent, as good as that obtained by direct hearing. This circuit, therefore, from the standpoint of intelligibility of speech is practically perfect.

This high quality circuit made use of several important developments. First is the condenser transmitter which gives a practically distortionless conversion from sound to electrical energy. This transmitter, which has been previously described,[4] uses a thin metal diaphragm, tightly stretched and placed close to a heavy metal plate. The diaphragm and the heavy plate form an electric condenser and the air film

2. The Nature of Speech and its Interpretation, H. Fletcher, *Jour.* Franklin Inst., June 1922.

3. The "transmission units" used in Fig. 2 and elsewhere in this paper are a logarithmic function of power ratio. The number of transmission units, N, corresponding to the ratio of two amounts of power P_1 and P_2, is given by the relation $N = 10 \log_{10} P_1/P_2$. The power ratio corresponding to N units is therefore $10^{N(.1)}$.

4. Wente, *Phys. Rev.*, June 1917 and May 1922. Crandall, *Phys. Rev.*, June 1918.

between the two serves to damp the vibration of the diaphragm.

Second is the design of vacuum tube amplifiers which are distortionless over a wide range of frequencies and loads. The design of such amplifiers will be discussed in a future paper, so will not be described here, other than to show later some amplifier frequency characteristics which have been obtained.

Third is a telephone receiver having small distortion. For this a permanent magnet type of receiver was used in which the principle of damping the diaphragm by an air film was employed in a manner similar to that described above for the condenser transmitter.

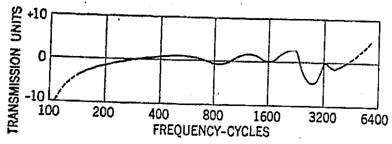

Fig. 2—Frequency Response Characteristic of High Quality Telephone Reference System

Fourth is the use of a network of impedances designed to introduce into the circuit the distortion which compensated for any distortion in the system which it was not practicable to eliminate in the several parts. In this circuit this compensation was needed primarily to take care of residual distortion in the receiver.

Public Address System

The public address system and its applications were described in two papers presented before this Institute in February 1923,[5] and as already noted will be referred to only briefly here. In the public address system which was used at the presidential inauguration in March 1921, the condenser transmitter and high quality amplifiers were used to obtain good quality. In November 1921, this public address system was used with the toll lines to transmit the Armistice Day Service at Arlington, Va., to New York and to San Francisco. At this time use was made of a new design of high quality transmitter, the double carbon button transmitter employing the stretched damped diaphragm of the condenser type. At this time, also, corrective distortion networks were employed to compensate for the distortion of the non-loaded cable circuits which were used to connect to the toll lines. The "volume indicator" for showing the power carried by the amplifiers was also used on this occasion in order to keep them from being overloaded and causing non-linear distortion. This volume indicator, as described in the papers referred to, consists of a vacuum tube amplifier-rectifier operating a quick acting ammeter. In both these loud speaker applications, extensive use was made of single-frequency measuring apparatus for determining the efficiency of the various parts of the system over a wide range of frequencies.

Use of Public Address Systems with Telephone Lines, Martin and Clark, Journal of A. I. E. E., April 1923.

Broadcasting System

When radio broadcasting started its phenomenal development, this high quality apparatus and the associated testing methods found new applications. It will be noted that the public address and the broadcasting systems are very similar, the main difference being the use of radio in the latter as a convenient means of reaching a large number of receiving stations from one transmitting station.

In Fig. 3 are indicated the essential elements of a radio broadcasting system. In this system, M is the microphone or means for converting from sound to electrical energy, A_1 is the amplifier used to increase the output of the microphone before transmitting it over the wire connection L_1 to the broadcasting station. The amplifier A_2 and the radio transmitter $R\ T$ increase and transform the energy into that which is put upon the antenna. At each of the receiving stations there are required, in general, a radio receiver $R\ R$ for converting the received radio frequency currents into audio frequency currents, an amplifier, and a telephone receiver, either of the type held to the ear or of the loud speaker type.

In regard to the wire line L_1 to the broadcasting station, it should be noted that while much of the material to be broadcast is at present specially produced in a studio closely associated with the broadcasting station, a large and probably increasing proportion of the broadcasting material is produced at points at some distance from the station. In this latter class come (1) material which is not given primarily for broadcasting, such as concerts and speeches for some local audience, (2) material given in a studio located at a point convenient to the artists or speakers, but remote from the broadcasting station and (3) announcements of the progress of athletic games or other sporting events which are made from the place where the games are held.

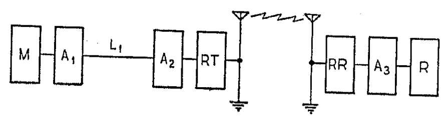

Fig. 3—Schematic Diagram of Radio Broadcasting System

Broadcasting Material

The material used for broadcasting consists in general of speech or music. Speech sounds are extremely complex in their nature and involve frequencies from about one hundred cycles to above six thousand. The first two charts in Fig. 4 show the sound spectra for the sung vowels "ah" and "ā". When these and the other vowels are spoken they are modulated both in pitch and volume from this steady state, the particular manner of starting or stopping them determin-

ing the so-called stop consonants[6]. The unvoiced fricative consonants, "s", "f" and "th", have their sound spectra in the upper frequency regions between 4000 and 10,000. In general most of the energy is carried by the vowel sounds and at frequencies below 1000 cycles, but the fine modulations of the vowels which produce the stop consonants and also the production of the fricative consonants involve frequencies mostly above 1000 cycles. For this reason it is well to bear in mind that the importance of any frequency region for carrying the energy in speech is quite different from that for carrying the intelligibility. On Fig. 5 are shown two curves which contrast this difference.[7] The curve for intelligibility does not directly take into account the naturalness of the sounds. It is found, for example, that while a system, which transmits only the frequency range from 500 to 2000 cycles, reproduces speech which can be easily understood, it leaves much

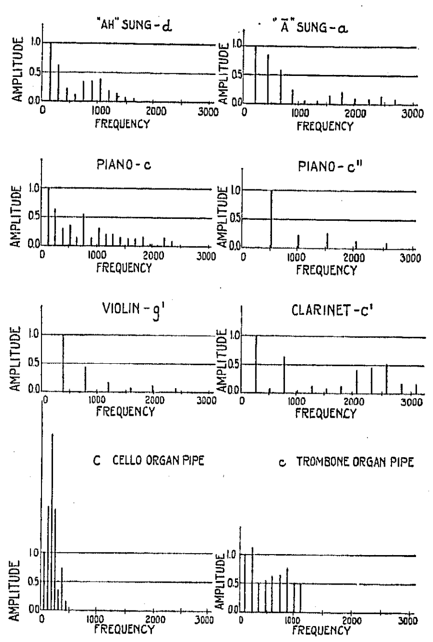

FIG. 4—SOUND SPECTRA OF TYPICAL MUSICAL TONES

to be desired from the standpoint of naturalness. In broadcasting, a broader frequency range is desirable because of the importance of naturalness. Results can be obtained for speech which are good for intelligibility and fairly good for naturalness with a frequency range from about 100 to 3000 cycles, although appreciable improvement is obtained by the extension of the upper end of the range.

The various types of vocal and instrumental music, solo, choral and orchestral, have widely varying characteristics, with fundamental tones as low as 16 cycles and harmonics above 10,000 cycles. The breadth of this range makes its proper handling in a reproducing system extremely difficult, particularly when the large energy of some of the low notes such as used in the pipe organ are taken into account. Fig. 4 gives also charts showing the sound spectra for some typical musical instruments when they are sounded at the pitches indicated. It is very difficult to obtain any quantitative measurements of the importance of the various frequency regions for properly transmitting music, but it has been found that with a frequency range of from about 50 to 5000 cycles good reproduction can be given for most kinds of music. In this connection it may be pointed out that the pitch of musical tones of very low pitch is carried to the ear mainly by the harmonics rather than by the fundamental.[8] For example, with a system not reproducing any frequencies below 100 cycles, the pitch is preserved for notes even as low as 30 cycles. The musical quality is marred, however, when the lower frequencies are not present.

Another important characteristic of speech and music is the intensity range. For speech the range of the average power is of the order of 1000 to 1. In music, such as that given by a symphony orchestra, the corresponding range may be as great as 100,000 to 1. These ranges have an important bearing on the load capacity required for the parts of the broadcasting system as will be brought out later.

PICK-UP OF MATERIAL

In picking up material for broadcasting, that is, in getting the sound energy into electrical energy, the general requirement would seem to be to get to the high quality microphone the sounds in the form in which a skilled listener would wish to hear them if he were free to choose his location with respect to the source of these sounds. In this respect, the skilled listener would be largely governed by hearing the sounds under the accustomed conditions with all undesirable noises, echoes and abnormal reverberations removed. In considering the pick-up of material for broadcasting it should be noted, however, that it corresponds to listening with one ear, that is, the binaural sense of direction which is normally obtained in hearing the sounds directly is lacking. With binaural audition, it is possible to concentrate on one sound source and to disregard somewhat the effect of other sounds coming from different directions or distances. Because of the monaural character of broadcasting it is necessary, therefore, to go even further in reducing noises and reverberation at the transmitter than would be the case for an observer using two ears at the same location.

In picking up sounds, undesirable effects which may be classed as distortion, may be obtained by having either too much or too little reverberation or, where the sounds come from several sources, such as in the case of a quartet or an orchestra, by not having the proper

7. Curve for energy distribution given in Analysis of the Energy Distribution of Speech, Crandall and MacKenzie, *Phys. Rev.*, XIX, No. 3. Curve for Intelligibility derived from data given in paper mentioned in Note 6.

8. Physical Criteria for Determining the Pitch of a Musical Tone, H. Fletcher, *Physical Review*, September 1923.

relation between the intensities of the sounds which reach the transmitter from the several sources. Since most speeches and musical selections are given indoors, a certain amount of reverberation is generally present. Because of this customary condition, music particularly, without reverberation, such as is obtained in a heavily padded room, sounds "dead." Too much reverberation, on the other hand, causes one tone to drag over into a succeeding one and tends to blur the sounds. In some tests carried out by Prof. W. C. Sabine with rooms in which the reverberation was varied it was found that a group of musicians consistently selected a particular reverberation condition as being most desirable for the piano.[9]

Much of the material that is broadcast is given in a special studio where it is possible to control the conditions. The studio can be placed in a quiet location, it can be treated with absorbing material to give the proper amount of reverberation and the speaker, singers, or musicians can be placed with respect to the microphone so as to obtain the desired balance between the direct sounds and the reverberation and also between the sounds from the several sources where more than one source is used. With the large number of variables involved, it is not as yet possible, however, to give general rules governing all of them.

In regard to the matter of equipping such a room with sound absorbing material, it is seemingly a common mistake to cover as completely as possible the ceiling, walls and floor of a studio with such material. Such a room, in addition to making the music sound "dead," makes it difficult and in some cases impossible for a singer or violinist to keep on the key because they are accustomed to get the pitch of one note from the reverberation of the preceding note. In one studio of about 20 by 30 feet, in which a large amount of experimental work was done to get a suitable reverberation for music, the final arrangement is a hardwood floor with a few rugs, the walls hung with monks cloth and about two-thirds of the ceiling covered with one inch hair felt. The reverberation can be increased when desired by taking up rugs or pulling back some of the wall hangings. In such a room for speaking, however, undesirable reverberation is obtained if the speaker is more than about four feet from the microphone. In connection with the statement regarding the effect of the monaural character of broadcasting on the requirement for the placing of the microphone, it is of interest to note that the reverberation time for this studio, using Sabine's method and coefficients, was somewhat less than that found to be desirable in his tests which were referred to.

There is an increasing demand in broadcasting for the use of material which is not being given specifically for broadcasting, such as a speech by some well-known person or a concert by a symphony orchestra. In such cases it is not usually possible to change the acoustics, so that the problem becomes one of getting the best location for the microphones.

For a speech, the problem is generally not difficult as the microphone can usually be located within about three feet of the speaker so as not to restrict unduly his usual movements. For a symphony orchestra of 75 to 100 pieces the problem presents some difficulties. It is desirable to get the transmitter far enough away from the orchestra so that the paths from it to all the pieces of the orchestra are about equal, in order to get proper balance between the parts, and at the same time, not to be so far away from the orchestra that the incidental noises of the audience are loud compared to the music. Good results have been obtained under these conditions by suspending the transmitter from the ceiling of the concert hall over a point on the floor about thirty to fifty feet from the orchestra and about ten to twenty feet from the ceiling. This brings it over the audience, but far enough away so that noises from it are not bothersome and far enough away from the orchestra to get a good balance between the parts. Also this permits the sound striking the transmitter through reverberation to be sufficiently appreciable as compared to the direct sound. This reverberation gives the impression of the orchestra playing in a concert hall, which, of course, is the natural condition. The scheme of using several transmitters distributed throughout the orchestra, in order to pick up the different parts, is in general undesirable because of the lack of reverberation and the difficulty of getting proper balance between the parts.

Curve B—Relative importance for intelligibility

Transmitters

Two transmitters or microphones of the air-damped, stretched-diaphragm type have been extensively used for broadcasting, the condenser type and the carbon button type.

The frequency response characteristics of present models of these two types of transmitters are shown in Fig. 6, that designated A being for the carbon and that designated B for the condenser type. Both of these have already been described elsewhere and will not need further consideration here. It should be noted that the condenser type can be designed to have a

9. Collected Papers on Acoustics, Harvard Univ. Press, page 75.

frequency characteristic of almost any degree of flatness desired. Material improvements have been made recently on the carbon type. One of these is the use of a light metal diaphragm by means of which the electrical output for a given sound input has been increased about ten times. A second important improvement in the carbon type has been a change in the acoustic spaces associated with diaphragm to reduce the distortion. The advantage of the carbon type of transmitter is that it requires two stages of amplification less than the condenser type and approaches it closely from the standpoint of freedom from distortion. As a result of the small diaphragm motions used in this transmitter the carbon button is worked far below the saturation point.

Transmission to Broadcasting Station

When material is picked up at a point remote from the broadcasting station, care must be used to avoid distortion in getting it to the station. When, as is usually the case, the point where the material is given and the broadcasting station are in the same city, it is generally possible to get non-loaded telephone cable circuits between the two points. By the use of corrective distortion networks or "attenuation equalizers" with such circuits, uniform transmission efficiency

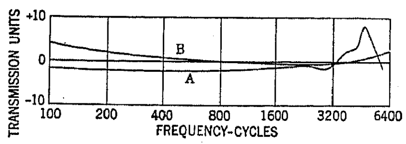

Fig. 6—Frequency Response Characteristics of High Quality Transmitters
Curve *A*—Stretched diaphragm double carbon button transmitter
Curve *B*—Stretched diaphragm condenser transmitter

over the desired frequency range can be obtained, even though the circuits themselves may have considerable distortion.[10] With these equalizers it is possible to equalize such circuits so that the variations of efficiency over the frequency range from the average value are less than one transmission unit.

The high quality transmitters which are used to pick up the material to be broadcast have energy outputs which are so low as to require amplification before they are transmitted to the broadcasting station in order to over-ride extraneous noises which may be encountered. Such amplifiers, in addition to having uniform efficiency for a broad frequency range, must also be capable of giving a large range of amplification and of handling without distortion a wide range of power in order to take account of the variations in the volume of sounds which are impressed upon the transmitter. In picking up speeches, for example, different amplifications may be required for the different loudness of the voices of the speakers. In making a speech, an orator often intentionally changes the loudness of his voice for emphasis. The amplification must be such as to permit low parts to be heard satisfactorily and also the amplifier must be capable of handling the loud parts without overloading. The amplification can be reduced for the loud parts to reduce the power handled, but the power output cannot be kept constant without spoiling entirely the emphasis effects desired by the speaker. In music, the volume of sound varies frequently and over a large range.

Considering this matter from the standpoint of the operator of a radio receiving set, it is desired first, that when the volume of the original sound is at its low point the reproduced sound should be loud enough to override static and other radio frequency interference, incidental noises in his set and room noise at his set. With this condition satisfactorily met, it is desired that the receiving set be capable of handling the maximum volumes of sound without overloading. The sets now available are capable of handling in the order of about a hundredth of this range and to make them handle this larger range would at present be practically prohibitive from a cost standpoint. The same requirement imposed upon the radio transmitter at the broadcasting station would also increase its cost by a large factor. The circuits used between the point where the material is picked up and the broadcasting stations also impose restrictions on this volume range. The lower limit to the power placed upon such circuits is set by the extraneous noise which may exist upon them due to induction from other circuits. The upper limit to the power on the circuit is determined by two factors, one, the capacity of the amplifiers which may be used and the other, the interference which this circuit would cause in other telephone circuits which are in the same cables with it. These circuit requirements, in general, limit the power range which can be satisfactorily handled to a range of about 1000 to 1. From the standpoint of the circuits alone, this range could be increased by special measures which, however, it might not always be practicable to apply.

These conditions, therefore, make it highly desirable to control the volume range given out by the amplifier associated with the transmitter. Some of this control could be exercised at other points in the system, but it is obviously desirable to have it all take place at one point and keep the rest of the system fixed. For this purpose the amplifier associated with the transmitter is equipped with a means for giving a quickly adjustable amplification. To make these adjustments correctly, it is necessary for the operator of the amplifier to know what power is being delivered by it. Use is made here of the "volume indicator," which is bridged across the output of the transmitter amplifier and the amplification of the volume indicator varied by means of a calibrated potentiometer until a standard deflection is obtained. The amplification required to get this deflection is then a measure of the output of the transmitter amplifier. This is supplemented by a monitoring loud-speaking receiver bridged across the circuit

10. Use of Public Address System with Telephone Lines, Martin and Clark. Jour. A. I. E. E., April 1923, page 361.

at the same point. By the aid of these, the operator can check the operation of the transmitter and its associated amplifier and keep the volume of electrical power delivered to the broadcasting station between certain prescribed limits which are far enough apart to give suitable expression to the music or speech. When the sounds striking the transmitter become too loud, the gain of the transmitter amplifier is reduced and when these sounds become too low, the amplification is increased, these changes being made gradually in order to avoid noticeable abrupt shifts in volume. The limits between which the electrical power is kept, are those which have been found experimentally to avoid overloading any part of the broadcasting system and to keep above any extraneous noises in the system.

This adjustment of the gain of the transmitter amplifier to keep the power delivered to the broadcasting set within certain prescribed limits is required also when the pick-up of the broadcasting material is in a studio at the broadcasting station.

Broadcasting Station

In the radio broadcasting transmitter the incoming electrical power is generally amplified before being used to modulate the radio frequency carrier. In this transmitter, the frequency and volume range requirements, discussed for amplifiers, also apply. The amplification obtained in this part of the system should generally be fixed and all necessary adjustments during operation made in the amplifier associated with the microphone. The following discussion of the broadcasting station is from the standpoint of operation, as the apparatus itself is described in another paper.[11]

Operating Requirements. With a fixed setting of the radio transmitter, it is important to determine the maximum power which can be introduced into it without causing noticeable overloading. To do this, there are required a means for indicating power such as a volume indicator, a high quality radio receiving set, a high quality loud speaker and high quality amplifier for operating it and some skilled observers. With the loud speaker, first determine for speech and several kinds of music, the maximum power which can be delivered by the microphone amplifier before overloading is detected. Then with the amplifier connected to the radio transmitter and with the radio receiving set, high quality amplifier and loud speaker, determine what power input into the radio transmitter causes overloading. If this is less than has been previously determined as the overloading point of the microphone amplifier, the overloading is in the radio transmitter. The station should then be operated so that the power delivered to the radio transmitter never exceeds this amount.

As a check on the operation of the station, a monitoring system such as the following should be used constantly. In this system a loud speaker and associated amplifier are connected either directly to the output of the microphone amplifier or to the output of a high quality radio receiving set. In these two connections the reproduced speech or music should sound the same and neither should show any signs of overloading.

This matter of guarding against overloading has been stressed so much because it is a common source of poor quality in broadcasting. Furthermore, it is often a defect in operation rather than in apparatus and as such, constant care is required to avoid it.

Another important factor in good broadcasting is insuring that the system and all its parts maintain their good quality. For this purpose, periodic tests should be made of the complete system with single-frequency currents over the range to be transmitted. For these tests the microphone can be replaced by a source of known amount of current and a measurement made of the electrical output of the high quality monitoring radio receiver. For such tests, use can be made of a "dummy" antenna, if it is not possible or desirable to go out "on the air."

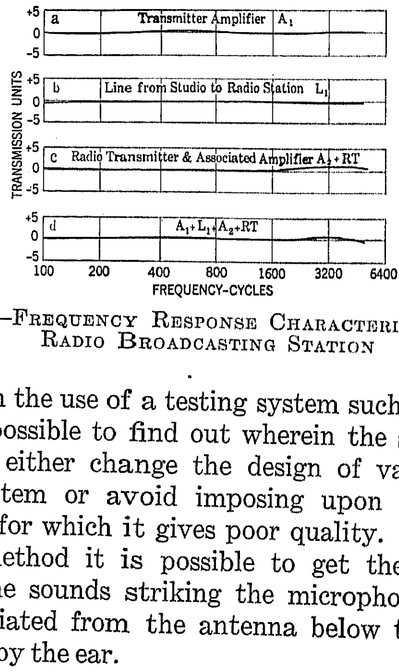

Fig. 7—Frequency Response Characteristics of Radio Broadcasting Station

It is with the use of a testing system such as outlined that it is possible to find out wherein the system falls down and either change the design of various parts of the system or avoid imposing upon the system conditions for which it gives poor quality. By following this method it is possible to get the distortion between the sounds striking the microphone and the energy radiated from the antenna below the amount detectable by the ear.

Frequency Characteristics. The curves of Fig. 7 indicate what can be done in obtaining good quality in broadcasting. These curves are for station WEAF in New York City where the studio and the broadcasting station are in different buildings, the two being connected by a cable circuit about a mile and a half long. Curve a is for the microphone amplifier (A_1 in Fig. 3), curve b for the equalized line between the studio and station (L_1, in Fig. 3) and curve c for the radio transmitter and associated amplifier ($R\,T$ and A_2 in Fig. 3). Curve d is for the system from electrical power of audio frequency leaving the microphone to power from the antenna at radio frequencies. The curve for complete operation of the broadcasting system

11. Transmitting Equipment for Radio Telephone Broadcasting, E. L. Nelson. Presented I. R. E. Jan. 16, 1924.

from sound in the studio to radio frequency power in the air can be obtained by combining curve *d* with the microphone curve from Fig. 5. Curve *d* shows the station as it is now operated. The small variations from the horizontal line can, of course, be eliminated, if worth while, by the use of an attenuation equalizer.

Receiving Station

The apparatus at the receiving station of a radio broadcasting system is required to perform three and preferably four functions. The three are selectivity, conversion of electrical energy from radio to audio frequency and conversion from electrical energy to sound. The fourth is amplification. The first two, selectivity and detection, are the essential functions of a radio receiving set. While it is not within the scope or purpose of this paper to discuss in detail various types of radio receiving sets, some general discussion will be given of the functions of the set in so far as they affect quality. Similar consideration will also be given to the other functions of the receiving station apparatus.

Amplification. The function of amplification is desirable and often necessary in order to bring the energy received by the antenna up to a point where it can produce sounds loud enough to be easily heard. This is particularly the case where loud speaking telephones are used to perform the third function. While it is a relatively simple matter to provide amplification without distortion, it is in performing this function that serious distortion is now introduced at many receiving stations, particularly when the amplification is in the audio frequency range or when it is obtained by regeneration. The provision of amplification without distortion is largely a matter of proper design, based on a knowledge of the characteristics of the tubes used and means for coupling stages together. A common offender in audio frequency amplifiers is the transformer, although with proper design it can be made to function satisfactorily.[12]

Selectivity. In performing the function of selecting the radio wave which it is desired to receive and discarding others, there is a conflict between the degree of selectivity, or sharpness of tuning, and width of the frequency band for the reproduced sounds. If this band width for the reproduced sounds is to be 5000 cycles and both side bands of the radio carrier are to be received, obviously all other waves within a band width of 10,000 cycles will also be received. Further, because it is not possible with the resonant type of selective means to let through without distortion this 10,000 cycle band and at the same time cut off absolutely all other waves near the edges of this band, the set will respond to a wider range of frequencies.
